How do you know what size of capacitor to use? Well, a rule of thumb is to have a capacitor whose reactance to the signal that you want to *keep* is greater than the resistance coming in to the capacitor (we want a larger resistance because we don't want that signal coming through the capacitor).

Therefore, we can modify Equation 22.1 to say

$$f = \frac{1}{2\pi \cdot R \cdot C} \tag{22.8}$$

or

$$C = \frac{1}{2\pi \cdot R \cdot f} \tag{22.9}$$

If you know the incoming resistance, you can use that last equation to just solve for the size of capacitor you will need (if you don't have any incoming resistance, then you can simply add a resistor of your choosing and calculate for C).

22.7 Converting a PWM Signal into a Voltage

In Chapter 15, we talked about how the Arduino microcontroller can't emit an analog voltage, but can mimic it with a PWM signal, where it turns its 5 V signal on and off to mimic in-between voltages. We can use a low-pass filter to transform a PWM signal into a voltage.

The circuit to do so is fairly straightforward and is given in Figure 22-2. The resistor and capacitor serve to tune the lower end of the frequency of the signal that gets removed.

According to the specs, the PWM frequency is about 490 Hz. In theory, we could find the reactance of the capacitor using Equation 22.1. However, in practice, because the PWM is a square wave (it has very sharp edges), it requires a larger capacitor. In any case, this filter removes the AC component of the PWM and just leaves the residual voltage that it represents.

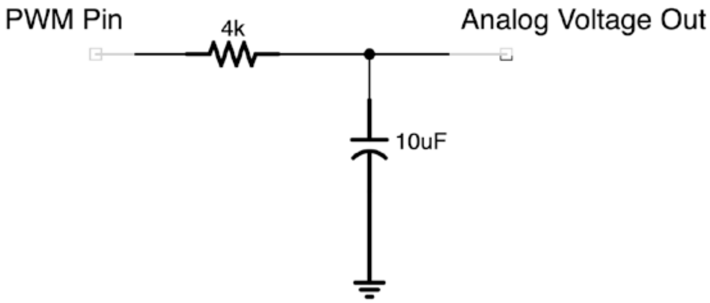

Figure 22-2. *Converting PWM to Analog with a Capacitor*

Review

In this chapter, we learned the following:

1. Reactance (X) is a property of some electronic components that is similar to resistance, but it *prevents* the flow of current instead of *dissipating* the flow (i.e., converting it to heat).
2. Reactance, like resistance, is measured in ohms. A j is placed in front of the reactance to specify that it is a reactance value.
3. Reactance is frequency dependent—the amount of reactance depends on the frequency of the signal.
4. Capacitors and inductors each have formulas that can be used to calculate the reactance of the components.

5. Capacitors yield negative reactance and inductors yield positive reactance. This means that their reactances will oppose and cancel each other out to some degree.
6. Impedance (Z) is the total inhibition of the flow of current, combining both resistive and reactive elements.
7. Reactance and resistance are combined into impedance in the same way that walking two different directions can be combined into a total distance from your originating point—using the Pythagorean theorem.
8. RMS voltage (V_{RMS}) is the average voltage of an AC circuit, regardless of the direction (positive or negative) of the voltage. This can be used to summarize the effects of an AC voltage.
9. RMS current (I_{RMS}) is the average current of an AC circuit, regardless of the direction (positive or negative) of the voltage. This can be used to summarize the effects of an AC current.
10. Ohm's law for AC circuits yields the summary relationship between RMS voltage, RMS current, and impedance in an AC circuit. It is identical to the previous Ohm's law, but uses the summary values for the circuit at a particular frequency, rather than the values at a particular point in time.
11. The resonant frequency of a circuit is the frequency at which inductive reactance and capacitative reactance cancel each other out.

12. Resonant frequencies can be used in any application where isolating a frequency is important, because the resonant frequency will be the only frequency not encountering resistance.
13. Low-pass filters remove AC signals and allow lower-frequency signals to pass.
14. A low-pass filter can be used to convert an Arduino PWM signal into a voltage.

Exercises

1. As the frequency of a signal goes up, how does that affect the reactance from a capacitor? What about with an inductor?
2. As the frequency of a signal goes down, how does that affect the reactance from a capacitor? What about with an inductor?
3. What is true about the relationship between the capacitative reactance and the inductive reactance at the resonant frequency?
4. Why is power not used up with reactance?
5. How are reactance and resistance combined to yield impedance?
6. Calculate the capacitative reactance of a 3 F capacitor at 5 Hz.
7. Calculate the capacitative reactance of a 20 μF capacitor at 200 Hz.

8. Calculate the inductive reactance of a 7 H inductor at 10 Hz.
9. Calculate the inductive reactance of a 8 mH inductor at 152 Hz.
10. Calculate the impedance of a circuit with a 200 Ω resistor in series with a 75 μF capacitor with a signal of 345 Hz.
11. Calculate the impedance of a circuit with a 310 Ω resistor in series with a 90 nF capacitor with a signal of 800 Hz.
12. Calculate the impedance of a circuit with no resistor and a 60 mH inductor with a signal of 89 Hz.
13. Calculate the impedance of a circuit with a 50 Ω resistor in series with a 75 μH inductor with a signal of 255 Hz.
14. If I have an AC circuit with an RMS voltage of 6 V and an impedance of 1 kΩ, what is the average (RMS) current of this circuit?
15. If I have an AC circuit and I measure the AC voltage as 10 V RMS and I measure the AC at 2 mA RMS, what is the impedance of this circuit?
16. If I have an 80 Hz AC circuit that has an 8 V RMS voltage source in series with a 500 Ω resistor, a 5 H inductor, and a 200 nF capacitor, what is the RMS current flowing in this circuit?
17. Calculate the impedance of a circuit with a 250 Ω resistor in series with a 87 μH inductor and a 104 μF capacitor with a signal of 745 Hz.

18. What is the resonant frequency of the circuit in the previous question?

19. What is the reactance of a circuit at its resonant frequency?

20. If I have a 10 μF capacitor, what size inductor do I need to have a resonant frequency of 250 Hz?

CHAPTER 23

DC Motors

A **DC motor** is a device that converts DC electrical power into mechanical power. It operates by rotating a shaft using electromagnetism. DC motors are fairly simple to use, though they require slightly different reasoning from the way we have been examining circuits so far.

23.1 Theory of Operation

While there are more than one kind of motor, the "typical" DC motor is known as a **brushed electric motor**. This motor has a fixed outside container (called a **stator** because it is stationary) that contains magnets with opposite poles. Within the stator is an armature with electromagnets that is connected to the **shaft** (the shaft is the thing that turns). The electromagnets on the shaft's armature are then energized to be the same pole of the current magnetic orientation.

If you have ever tried to push two magnets together that have the same pole, you know that the magnetic fields exhibit a lot of physical force to try to prevent this from happening. Therefore, the fixed magnets' magnetic fields push on the temporarily created electromagnets' fields on the shaft's armature. When the shaft turns to align itself with the fixed magnets, it also turns the connector that connects the shaft to the electricity. When it is turned, the connectors on the shaft are now connected to the *opposite* polarity than they were, so their fields are no longer aligned again! Thus, the shaft continues rotating on.

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_23

A certain type of motor, called a **brushless motor**, has a similar operation, except that instead of having the rotating shaft change the polarity of the current, it uses fixed magnets on the shaft and uses electromagnets for fixed magnets. Then, by pushing AC through the electromagnets, it changes the polarity of the fixed magnets back and forth, moving the shaft through the magnetic field. Brushless motors tend to be more expensive, but can rotate faster and have fewer parts which can wear out.

Even though brushless motors use AC internally, they are operated just like DC motors from the outside. Brushless motors have internal circuitry that converts the DC into an AC waveform for energizing the electromagnets appropriately.

23.2 Important Facts About Motors

Motors require a lot of current, especially to start up. Starting up, they require even more current (often ten times their normal current). This is also the amount of current they require if they ever stop rotating (known as stalling).

Motors are rated according to their most efficient operating voltage. If a motor is rated at 5 V, then it's not that you can't operate it at a different voltage, but that operating it at different voltages will change some of its characteristics and probably won't be as efficient.

Motors generate a negative voltage called *back EMF* that is in opposition to the voltage provided to them. Motors generate more back EMF the faster that they spin. At the point at which the back EMF is equal to the voltage provided, the motor will no longer spin faster. There is also some voltage drop by the internal resistance of the motor's coils, but it is relatively minor compared to the back EMF drop.

If there is nothing attached to the shaft, the amount of current the motor operates with is known as the **no load current**, and the speed at which the motor spins is known as the **no load RPM** (**RPM** means "revolutions per minute").

However, the most difficult thing that a motor does is to *start* rotating. When the motor isn't moving and is exhibiting its maximum rotational power (known as **torque**) to try to move, this is known as a **stall** condition. This is the most strenuous thing a motor can do, and many motors can't survive more than a few seconds in stall conditions. The amount of torque that a motor supplies in stall conditions is known as the **stall torque**, and the amount of current that the motor uses in these conditions is known as the **stall current**. Oftentimes, if you think you have a circuit that is properly sized for a motor, but it won't start spinning, this is because it isn't getting enough current for stall conditions. You can sometimes even check this by spinning the shaft by hand and seeing if the motor then springs to life.

Note that when a motor first turns on, it is always in stall conditions.

23.3 Using a Motor in a Circuit

DC motors are nice because they basically self-regulate. They spin fast enough to match whatever voltage is given to them and draw enough current to manage the proper torque for the load. If you want to know the details and calculations behind these things, see Appendix D, Section D.3, "Motor Calculations." However, if you stick with the voltage listed in the specs, the RPM of the motor generally gets fairly close to the specifications. In general, lower voltages lead to lower RPMs, and higher voltages lead to higher RPMs.

It is pretty rare to add series resistance to a motor circuit. There are several reasons for this. The first is that, as mentioned, motors basically self-regulate. This means that

1. They will draw the amount of power they need to draw for the given torque and no more. Thus, a current-limiting resistor is not needed. Additionally, if you calculate the current-limiting resistor for steady-state conditions, it will provide too little current for stall conditions.

2. They will utilize the given voltage to achieve the RPM that balances it out. Therefore, there will not be any excess voltage to consume.

Additionally, series resistance can actually cause problems. The amount of current a motor can draw can vary very widely. As mentioned, the stall current can sometimes be ten times the steady-state current. With series resistance, the voltage drop across the resistor will then vary up to ten times as well, which will affect the voltage available to the motor and thus alter the performance specifications of the motor. Under stall conditions, it will decrease the performance of the motor at precisely the wrong moment.

Therefore, while you might want to down-step voltage for a motor to get the proper RPM, you want to do so in an essentially non-resistive way, using diodes, transistors, or other components that are not likely to add significant series resistance to the motor.

However, you may want to prevent problematic conditions as well. You don't want a short circuit in your motor to fry your whole circuit. Because of this, you may want to add a fuse (instead of a current-limiting resistor) that will trip if it experiences excessively high current to protect the rest of your circuit.

Additionally, since motors contain electromagnets, they utilize induction. As mentioned in Chapter 20, when current to an inductor stops, it creates a voltage spike due to the collapsing of the electromagnetic fields. Therefore, we have to provide a snubber diode to prevent that current from blowing out our sensitive equipment. You can refer back to Figure 20-2 to see how this is wired.

Because motors are operated through induction, they are often represented with the same symbol as an inductor.

23.4 Attaching Things to Motors

Motors just spin a shaft. What happens after the shaft starts spinning is, technically, outside the scope of this book and entirely up to you. Nonetheless, I thought I would take just a moment to talk about attaching things to motors.

The first thing that comes up is, *how* do you attach something to a motor's shaft? There are several common options:

1. Some items are built to have a **mechanical fit** onto a shaft. That is, you can push them onto the shaft with some force, but they are unlikely to just fall off on their own.
2. Some items are attached with a **set screw**. This is similar to the previous method, except that what keeps the attachment in place is not the pure fit, but an extra screw that applies the force after your attachment is in position. This allows for a little wider range of variance in size, so if the sizes are off slightly, the set screw will make up for the lack of mechanical force.
3. Finally, some items need to be glued, welded, or in some other way permanently affixed to the shaft. The problem with this method is that, once attached, you can't really use your motor for anything else.

So what are we attaching to our motor?

Well, you *can* directly attach things such as wheels to the shaft of the motor. For free-spinning things such as propellers, this is exactly what you do. It works for wheels too, kind of. The problem is that small DC motors often can't generate the kind of torque you need for typical usages. Therefore, you need gears to translate the low torque/high RPM of the motor into a high-torque/low-RPM output to the wheels.

Many places sell gearboxes which handle all of this for you. In fact, you can even buy motors with the gearboxes inside the motor packages as well. Then, you connect your gearbox to the axle of the wheels using a gear or a belt, and the wheel is what performs the final actions.

I find it interesting that all of these are just a series of conversions. We first convert electrical power into mechanical power. We then convert low-torque/high-RPM power into high-torque/low-RPM power. This is actually very similar to the operation of a transformer in electronics, which converts low current/high voltage into high current/low voltage and vice versa. Then, the wheels convert rotational power into linear power, by driving your project along the ground or driving a belt around and so on. We have a source of power (the battery) and the thing we want to do (moving things), and what we have to figure out is the best way to convert the kind of power we have into the kind of power that we need.

23.5 Bidirectional Motors

Oftentimes we want motors to spin both forward and backward. Most motors can spin backward just by reversing the positive and negative leads to the motor. However, we need to be able to do that electrically instead of forcing someone to go and reverse wires on our circuit board whenever they want to back up instead of go forward.

Creating a circuit that can have current go either direction is hard enough, but added to that is the problem of positioning the snubber diodes—they will be needed in *both* directions! However, if we just attached snubber diodes in each direction, we would wind up with a short circuit no matter what (the current would prefer to just go through the diode pointing our way rather than through the motor).

A type of circuit to manage these considerations has been developed, known as an **H-Bridge**. We will not delve into the details of how H-Bridges work or how to use one, but I thought I should mention them.

If you are interested in H-Bridges, a popular chip is the L293.

23.6 Servo Motors

A **servo motor** (usually just called a servo) is a motor that, instead of spinning, creates an angle. Think about a remote-controlled car. To turn the car, the wheels have to be at an angle. A regular DC motor is what spins the wheels, but a servo motor is what causes the wheels to turn to a specific angle.

Servos are operated by sending an oscillating signal, much like the output of a 555 timer (see Chapter 18). Servos expect a signal every 20 milliseconds, and the length of the signal will determine the angle of the servo:

- If the signal is 1.5 milliseconds, the servo will be in the middle (neutral) position.
- If the signal is 1.0 millisecond, the servo will rotate 90 degrees counterclockwise.
- If the signal is 2.0 milliseconds, the servo will rotate 90 degrees clockwise.
- Between these positions, the servo will rotate in a proportional way.

As you can see, the servo can swing through 180 degrees of rotation. The servo expects to continually receive signals while it is on in order to maintain its position, but that position can be changed at any time with a change in the length of the signal. The behavior of a servo when no signal is applied depends on the particular servo you are using.

Servo motors have separate inputs for their voltage supply and their signal. The signal does not have to power the motor—it is powered through its supply voltage. Instead, the servo motor just needs to receive a small signal to know its rotation, and the actual power is supplied through its voltage input.

23.7 Stepper Motors

Stepper motors are motors that rotate in very precise increments. If you need something that can freely rotate, but need an *exact* number of revolutions or even half-revolutions, quarter-revolutions, and so on, a stepper motor supplies this capability. Stepper motors are often used in 3D printers, where the print head needs to move a precise distance. The integrity of the generated structure depends on the print head being in the exact correct location. Therefore, the rotation of the shaft must be precisely controlled.

The control of stepper motors is far outside the scope of this book and usually requires additional hardware (known as a stepper motor driver circuit), but I wanted to be sure you are aware of what they are and why they are important.

Review

In this chapter, we learned the following:

1. A DC motor converts electrical power into mechanical rotational power by either changing the magnetization of the shaft (in brushed motors) or of the fixed magnets (in brushless motors).
2. Rotational mechanical power is known as torque.
3. Motors tend to require a lot of current, especially at startup.
4. The rated voltage of a motor is related to the motor's RPM—decreasing the voltage decreases the RPM and increasing the voltage increases the RPM. This is due to the negative voltage (back EMF) generated by the movement of the motor.

5. The current flowing through a motor is related to the torque needed to spin the motor—more required torque draws more current.
6. When a motor is not spinning (either because it is just starting or because its load is too high), it is in a stall condition.
7. Stall current is the amount of current the motor draws in stall conditions (usually about ten times more than in a steady state).
8. Stall torque is the amount of torque generated in stall conditions.
9. Loading a motor so that it stays in stall conditions for any significant amount of time can damage the motor.
10. Series resistance is almost never added to a motor circuit.
11. Snubber diodes are used to mitigate against inductive spikes that happen when the electromagnetic field of the motor shuts off.
12. Gears can convert the low torque/high RPM of a motor into a high-torque/low-RPM output.
13. Motors can be used bidirectionally using an H-Bridge.
14. A servo motor is a motor that, instead of spinning, creates a fixed angle based on the length of a signal that is sent to it every 20 milliseconds.
15. A stepper motor is a motor that provides precise control over the amount of rotation of the shaft.

Apply What You Have Learned

1. If you wanted to prevent too much current from going through a motor, what should you use for this?
2. What happens to the RPM of a motor when I reduce the voltage to my motor?
3. What should be attached to a motor to protect the other parts of the circuit when a motor is shut off?
4. List one reason why a series resistor should not be used with a motor.
5. If I was building a robot and wanted to control the angle of a robot's arm, what type of motor could I use?
6. If I was building a machine to place components into a precise position onto a board, what type of motor should I pick to achieve that?

PART IV

Amplification Circuits

CHAPTER 24

Amplifying Power with Transistors

Amplification is the conversion of a low-power signal to a higher-power signal. Normally when we think of amplification, we think of sound amplifiers for musical instruments. Indeed those are amplifiers, and we will build a sound amplifier later in this book. However, *anytime* you convert a low-power input to a higher-power output, you have amplified the signal, whether that was a DC signal or an AC signal. In this chapter, we will focus on amplifying DC signals.

Many devices have limits to the amount of power they can output or even the amount of power we want them to output. Microcontrollers, for instance, are generally very sensitive with the amount of power they can source. The ATmega328/P (used in the Arduino Uno), for instance, has a maximum current rating of 40 mA, which is actually quite generous for a microcontroller. Other types of microcontrollers, such as many PIC microcontrollers, are rated for current outputs of 25 mA or less. Additionally, the voltage is more or less fixed at the operating voltage of the chip, which is usually 3–5 V.

However, numerous applications require more output (whether current, voltage, or power) than these can provide. A typical toy DC motor, for instance, needs about 250 mA for operation. So, if you want to control the motor with a microcontroller, then you have to have some way to convert your small output current into a larger output current to drive your motor.

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_24

Another scenario to consider is a situation where we want to control a high-power motor or another device from a button or switch. Sometimes it can be problematic to have a switch for a device to have high power run through it. It could be dangerous, or it could cost money. Let's say that we had a switch that we wanted to control a high-power device that was 1,000 feet away. If we had the full power running through the switch, that means that we have to run larger cables and will have to account for the large resistance in the wires. Running power across that distance will result in power loss because of the resistance in the wires, which will increase the cost for running the unit! However, if we instead use a low-power circuit to run the switch, we don't get nearly as much power loss. We just need to *amplify* the power output of the switch to control our device once the signal reaches it. The amount of amplification that occurs is known as the **gain** of an amplifier.

24.1 An Amplification Parable

As we noted in Chapter 10, physics tells us that we can't actually increase the power of something. What we can do, though, is use a smaller power signal to control a larger power source, and that is what we refer to as amplification.

Let's say that we have a dam on a river. The river wants to go downstream, but it is blocked by the dam. Let's say that we have a giant named Andre, which is able to lift the dam using his strength. If Andre lifts the dam a little bit, a little bit of water flows. If Andre lifts the dam a lot, all of the water can flow. The power of the water itself is actually more than Andre's power. Therefore, Andre can "amplify" his power by raising and lowering the dam.

Let's say that at the end of the riverbed was a structure that Andre wanted to destroy, but Andre himself isn't strong enough to do it. However, the river is strong enough to do it. Therefore, rather than try to destroy the structure on his own, Andre decides to raise the dam and let the river's power do it.

Note that Andre didn't actually increase the amount of power in the river. Instead, he (a being with lesser power) *controlled* the operation of the river (a higher-powered entity) by adjusting the dam (the physical resistance against the water). Thus, he *amplified* the effects of his actions by controlling the resistance on the higher-powered current.

24.2 Amplifying with Transistors

A very common method of amplifying power output in projects is with **transistors**. The term "transistor" is short for "transconductance varistor," which means that it is an electrically controlled variable resistor. In other words, it helps you amplify a signal in your project the same way that the dam allowed Andre to amplify his power. The transistor operates as a controllable electric dam, allowing a smaller-powered electric signal to control a higher-powered electric signal by adjusting resistance.

Another way you can think of it is like an outdoor faucet—the water going through the faucet is controlled by the wheel knob on the top, which provides a variable amount of resistance to the flow. The faucet can be fully on, fully off, or somewhere in between, all based on where the knob is set. The knob setting is like the input current—a specific level of input current will control the amount of flow that comes out.

There are many different types of transistors, with a wide variety of ways in which they work. What they all have in common is that they have three (sometimes four) terminals, and one of the terminals acts as a control valve for the flow of electricity between the other two.

The main way that the types of transistors differ is in whether the knob on the faucet is controlled by voltage or by current. The transistors operated by current are known as **bipolar junction transistors** (BJTs), and the ones operated by voltage are known as **field effect transistors** (FETs).

As a gross overgeneralization, FETs are most useful for lower-power switching applications, while BJTs are most useful for power amplification. This chapter will cover BJTs.

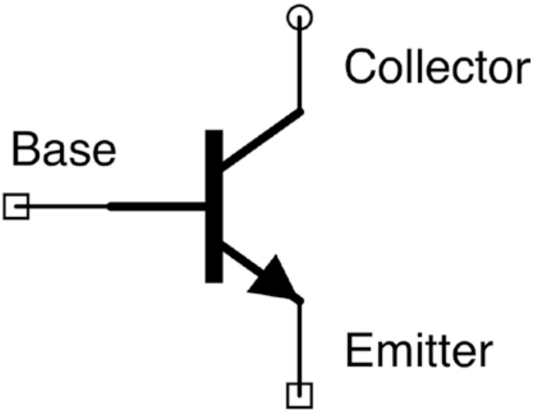

Figure 24-1. *The Schematic Symbol for a Transistor*

BJTs come in two basic forms based on whether the knob is normally closed but turned on by positive current (an NPN transistor) or whether the knob is normally open but closed off by positive current (a PNP transistor). Here we will focus on NPN transistors.

24.3 Parts of the BJT

A BJT has three terminals—the collector, the base, and the emitter. In BJT NPN transistors, a small positive current comes in at the base (which you can think of as the knob of a faucet), and it controls the current moving from the collector to the emitter. The more current that comes through the base, the more current is allowed to flow between the collector and the emitter.

Figure 24-1 shows what an NPN BJT looks like in a schematic. The collector is at the top right of this diagram. The emitter is the line with the arrow pointing out. The current being controlled is the current between the collector and the emitter. The base is the horizontal line coming into the middle of the transistor. The base acts as a knob which can limit the flow of current between the collector and emitter.

Figure 24-2 shows a conceptual picture of how the transistor operates. The connection from the base to the emitter operates as a diode, and the connection from the collector to the emitter operates as a variable resistor, offering resistances from zero (completely open dam) to infinity (completely closed dam). The resistance of the variable resistor is based on the current flowing through the base. The variable resistor is adjusted so that, under certain conditions, the *current* flowing from the collector to emitter is a certain multiple of the current flowing from the base to the emitter.

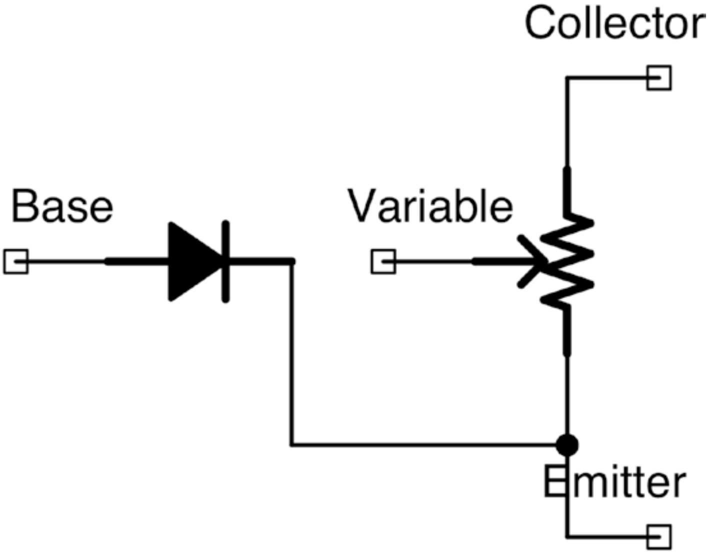

Figure 24-2. *A Conceptual View of Transistor Operation*

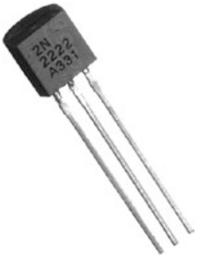

Figure 24-3. *A 2N2222A Transistor in a TO-92 Package*

When we talk about the voltages and currents flowing through the resistor, there are special names you need to remember and keep in mind. Each of the legs of the transistor is named by the first letter of its role. The collector is C, the emitter is E, and the base is B. Then, each of the voltages/currents is labeled based on which leg it is going from and to. Therefore, V_{BE} is the voltage difference between the base and the emitter, V_{CE} is the voltage difference between the collector and the emitter, and V_{CB} is the voltage difference between the collector and the base. I_{BE} is the current flowing between the base and the emitter, and I_{CE} is the current flowing between the collector and the emitter. The total current coming out of the emitter is $I_{BE} + I_{CE}$. Take time to think about these designations as we are going to be using them extensively when we talk about transistors and their usage in a circuit.

A photo of a transistor can be seen in Figure 24-3. This is the transistor we will focus on in this chapter—the 2N2222A (sometimes called the PN2222A). It is important to read the datasheet to find out information about your transistor—especially to know which transistor leg is which! For the picture in Figure 24-3, the collector is on the right, the base is in the middle, and the emitter is on the left. Note that some other transistors have *different* pin configurations, which is why it is so important to check the datasheets. For instance, the P2N2222A (very similar name!) has the collector and emitter pins reversed!

Transistors can also come in a variety of shapes and sizes, known as **packages**. The package depicted in Figure 24-3 is known as a TO-92 package. Other packages you might see are a TO-18 package (which looks like a tiny metal cylinder) or a package similar to an integrated circuit.

24.4 NPN Transistor Operation Basics

To fully understand NPN transistor operation requires a lot of complicated mathematics. However, you can get a "good enough" understanding of it just by remembering a few simple rules.

Rule 1: The Transistor Is Off by Default

By default, if there is no current flowing in the base, there will be no current flowing from the collector to the emitter. NPN transistors default to an "off" state.

Rule 2: V_{BE} Needs to Be 0.6 V to Turn the Transistor On

Remember that there is essentially a diode connecting the base to the emitter. Diodes have a voltage drop of about 0.6 V. Therefore, once the base voltage rises to 0.6 V *above* the emitter voltage, the transistor will turn on, and current will start to flow.

Rule 3: V_{BE} Will Always Be Exactly 0.6 V When the Transistor Is On

This is a corollary of the previous rule. Remember from Chapter 8 that we used diodes to give us fixed voltage differences between points on a circuit. This is the same in a transistor. Because the BE junction acts as a diode, the base will always be 0.6 V above the emitter while the transistor is turned on.

Rule 4: The Collector Should Always Be More Positive Than the Emitter

While technically you can have the collector go below the voltage of the base or the emitter, it is generally a bad idea with NPN transistors. It makes the circuit much harder to analyze. This book will assume that the circuit is set up in this manner.

Rule 5: When the Transistor Is On, I_{CE} Is a Linear Amplification of I_{BE}

So, when the transistor is on, the transistor amplifies the *current* flowing from the base to the emitter by adjusting the floodgates between the collector and the emitter. The multiplier that the transistor amplifies by is known as the transistor's **beta**—this is the current gain that an NPN transistor provides. The symbol for this value can be either β or h_{FE}. The problem with a transistor's beta is that it isn't very exact or very constant. A batch of "identical" transistors can have betas that vary quite a bit. And, while they are operating, their temperature and other environmental factors will affect the beta as well. There are things you can do to compensate for this, but for now just realize that it happens. While there are transistors with a wide variety of ranges of their betas, the most common NPN transistors have a beta of around 100.

The exceptions to this are in Rules 6 and 7.

Rule 6: The Transistor Cannot Amplify More Than the Collector Can Supply

This is mostly a reminder that the amplification comes *from* the collector current. If the collector can't supply the amplification, it won't happen. Basically, we need to think of the transistor as controlling a resistor from the collector to the emitter which will adjust itself to maintain the ratio (beta) between the base-emitter current and the collector-emitter current. Thus, it can't provide less resistance than no resistance.

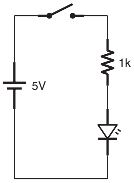

***Figure 24-4.** Using a Switch at the Start of a Circuit*

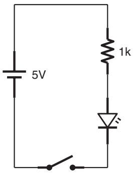

***Figure 24-5.** Using a Switch at the End of a Circuit*

Rule 7: If the Base Voltage Is Greater Than the Collector Voltage, the Transistor Is Saturated

If the base voltage rises above the collector voltage, this causes the transistor to behave as if there was no resistance going from the collector to the emitter. This is known as **saturation mode**.

Using these rules, thinking about transistor action is fairly straightforward. In the next section, we are going to put these rules into practice.

24.5 The Transistor as a Switch

One of the issues with transistors is that it takes a while before using a transistor becomes intuitive. Transistors, as we will see in the forthcoming chapters, wind up needing a lot of special considerations. Because of this, many people don't use transistors directly and instead choose to only use integrated circuits (see Chapter 11). Integrated circuits, since they are based on the needs of a circuit instead of simple physical properties, tend to be much easier to work with. Most of the guess work has been taken out, and the chips are built so that they can be inserted into a circuit in a straightforward way. Even though some people opt to use integrated circuits instead of using transistors directly, it is worthwhile to understand their operation. It is always better to choose an option because you understand your available alternatives instead of choosing an option because that choice is the only one you understand.

Now, when we think of buttons and switches, most people naturally put the switch at the *beginning* of the circuit that is being turned on or off. Figure 24-4 shows what this looks like. However, it is just as valid to place the switch at the end, as shown in Figure 24-5.

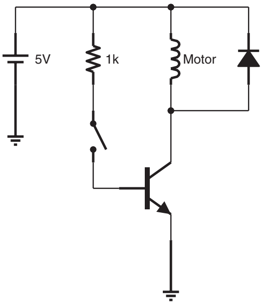

Figure 24-6. *Using a Transistor as a Switch for a Motor*

When using transistors as a switch, we almost always place them at the *end* of a circuit. The reason for this should become clear as we examine circuits.

The first circuit we will look at is Figure 24-6. In this circuit, there is no real *need* for a transistor—we could just as easily have put the switch where the transistor is. However, understanding how this setup works will help us understand other transistor circuits. In this circuit, the base is controlled by a small signal (the size of the signal is set by the size of the resistor). When the base turns on, it switches on the connection from the collector to the emitter, which controls current to the motor (the diode is simply a snubber diode as described in Chapter 20).

VISUALIZING INDUCTIVE KICK

If you wanted to see inductive kick in action, you can replace the snubber in the circuit in Figure 24-6 with an LED. Every time you turn of the switch, the LED will light up for a moment.

If the emitter of a transistor is simply connected directly to ground as it is in this example, the easiest way to analyze the circuit is by looking at the flow of current through the base. When the switch is closed, current will flow from the voltage source, through the resistor, across the transistor to ground. How much current? Well, this is actually a simple question. Remember that the junction from the base to the emitter can be treated as a simple diode (Rules 2 and 3). Therefore, we have a very simple circuit to analyze—voltage source to resistor to diode to ground. The voltage source is 5 V, and we have a diode (0.6 V) in the circuit path, so the voltage going through the resistor will be 4.4 V. Since the resistor is a 1 kΩ resistor, then, using Ohm's law, the current will be $I = \frac{V}{R} = \frac{4.4}{1000} = 0.0044\text{A}$, or 4.4 mA.

Since the current going through the base (I_{BE}) is 4.4 mA, how much current is flowing from the collector to the emitter? We will assume for our exercises that the beta of transistors is exactly 100. According to Rule 5, that means that the current going from the collector to the emitter is 100 times the base current. Therefore, the current going from the collector to the emitter can be determined by $I_{CE} = \beta \cdot I_{BE} = 100 \cdot 4.4 = 440\text{mA}$. Therefore, the current going from the collector to the emitter is 440 mA. Because the current at the collector is 440 mA, that means that the current going through the motor is also 440 mA.

Depending on the current we *wanted* flowing through the motor, we could choose other resistor values to set the current to the appropriate level. However, because of Rule 6, the collector current will be limited by the motor's characteristics as well.

So why did we put the transistor at the end of the circuit? Let's imagine that we added one component to the circuit—a resistor after the emitter before the ground. All of a sudden, the circuit is a lot harder to analyze. Why? Well, we can no longer determine the base current by simply looking at the current path through the base. The voltage across that final resistor will *not* be based on the base current, but based on the *combined* current from both the base and the collector. Thus, when there are components after the emitter, in order to analyze the base current, you have to analyze how the components after the base respond to the *combined* current of the base and collector, but we won't know that until *after* you calculate the base current. It is *possible* to do this, but the math isn't fun. Instead, by connecting the emitter *directly* to ground, we simplify our calculations because we *know* the voltage after the emitter—since it is connected to ground, it will be zero.

Thus, by connecting the emitter directly to ground, we can analyze the current flow from the base *independently* of the current flow from the collector. Additionally, connecting the emitter to ground will automatically make sure our DC circuits follow Rule 4 and make it easy to analyze when the transistor turns on and off by Rule 2.

Just as we have looked at several common resistor circuit patterns, there are also several common transistor circuit patterns. The transistor pattern we are looking at in this chapter is known as a **common emitter** circuit. This is because the "interesting" parts of the circuit are at the base (which provides the current to be amplified) and the collector (where the preceding circuit enjoyed the amplified current) and the emitter is connected to a common reference point (the ground in this case).

24.6 Connecting a Transistor to an Arduino Output

To understand *why* we would use a transistor for a switch in the first place, let's imagine that we have a motor just like in Figure 24-6, but in this case we want it to be controlled by an output pin from an Arduino running on an ATmega328/P.

Now, on this chip, output pins put out 5 V, but their current rating maxes out at 40 mA. However, motors usually require much more current than that. If we wanted our motor to use as much current as in Figure 24-6, it would blow out the chip if we tried to connect it directly to the output.

However, we can instead wire the output of the Arduino to the base of a transistor. Then, the current coming out of the Arduino will be *much smaller* than the current used by the motor.

Figure 24-7 shows how this is configured. The schematic for this setup is almost identical to that of Figure 24-6. The only difference is that the electrical output of the Arduino is being used to control the base current instead of a mechanical switch. We can even calculate exactly how much current will be used. Since there is a diode (in the transistor), the resistor will be using 4.4 V. Therefore, since $I = \frac{V}{R}$, then $I = \frac{4.4}{1000} = 4.4\text{mA}$. With a beta of 100, that means that our motor can source 440 mA.

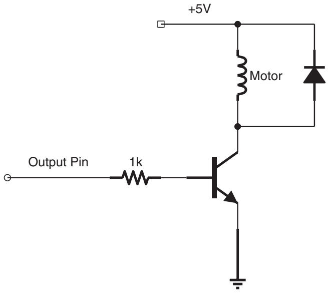

Figure 24-7. *Using a Transistor to Control a Motor with a Microcontroller*

24.7 Stabilizing Transistor Beta With a Feedback Resistor

As we mentioned earlier, the transistor's beta is not a very stable parameter. If we mass-produced something with a transistor, each device would wind up having a transistor with a different beta. Additionally, as the device was used, the beta would *drift*, meaning that things such as the temperature of the transistor would affect the beta, so it wouldn't even have the same value the entire time it was turned on!

In order to get around this, engineers have developed ways of stabilizing the *actual* gain of a circuit even when the transistor's beta shifts. The way that this is achieved depends greatly on the type of circuit used. In a common emitter circuit like the one we have been looking at in this chapter, we can add a resistor to the emitter to stabilize the transistor's gain. I know that I *just said* not to do this because it is hard to analyze the effects. However, if you add a single resistor to the emitter, other people have worked out the math for you in order to make this work easily.

Now, to imagine *why* adding a resistor to the output stabilizes the transistor beta, we have to think about what happens when you do this. Without the resistor, when the transistor beta increases, it simply increases the current flow at the collector. Since the emitter is connected to ground, there aren't any more real effects. However, if I add a resistor to the emitter, then increasing the current flow at the collector will *also* increase the voltage at the emitter. Now, since the voltage between the base and the emitter (V_{BE}) *must* be at 0.6 V, this will actually *reduce* the current in the base.

This is known as **feedback**—where the *output* of the circuit comes back in some way to affect the input. Sometimes, feedback occurs because the output is wired back to the input, but in this case, the resistor simply increases the voltage at the emitter, causing the base to pull back.

What the final effect of adding a resistor to the base will do is to *limit* the gain of the transistor to a *fixed* value that won't change either due to manufacturing issues or due to changes during operation as the transistor beta changes due to temperature. Additionally, the computation for this is very simple. If your transistor beta varies between 50 and 200, you can add a resistor to the emitter which will limit the actual transistor gain below 50, and it will keep this value very stable even as the transistor's beta drifts. In such a configuration, the most stable gain you can get for a given transistor beta is about $\frac{1}{4}$ of the transistor's lowest beta.

The equation for the effect that a feedback resistor has on a transistor circuit depends on the circuit design itself—there isn't a one-size-fits-all rule. However, feedback resistors are usually fairly small compared to the rest of the circuit.

For most circuits, simply start with a small feedback resistor (10–100 Ω). The feedback resistor will usually improve the stability of your design, even if you can't calculate exactly how that affects the beta of the transistor. It means that your design will likely continue to work even with different transistors and operating at different temperatures. Just know that while you add stability, this will also limit the gain (which is sometimes problematic with motors).

24.8 A Word of Caution

One thing to keep in mind with transistors is that they can get very hot! Transistors have a maximum current rating, and that often is based on the amount of heat that they are able to dissipate. Transistors that are able to handle large currents are called **power transistors**, and usually have an attachment for a **heatsink**, which helps them dissipate heat to the air more efficiently.

If you build a circuit similar to the one in this chapter, be sure to keep in mind both the specs of the motor (how much voltage and current is required for it to operate) and the specs of the transistor (how much current the transistor can handle). If the motor doesn't have enough voltage or current, it might not turn on, and if the transistor can't handle the current, it could easily burn out.

Review

In this chapter, we learned the following:

1. It is often beneficial to be able to control a high-power signal using a low-power signal.
2. The two major types of transistors are bipolar junction transistors (BJTs) and field effect transistors (FETs).
3. BJTs are current-controlled devices and FETs are voltage-controlled devices.
4. The terminals of a BJT are the base (B), the collector (C), and the emitter (E).

5. Voltages and currents going through a transistor are labeled using the terminals that the current is passing through. For instance, I_{BE} refers to the current flowing between the base (B) and the emitter (E), and V_{CE} refers to the voltage difference between the collector (C) and the emitter (E).

6. BJTs come in two main configurations—NPN and PNP.

7. With NPN transistors, a small positive current at the base causes a larger current to flow from the collector to the emitter.

8. With PNP transistors, current at the base reduces the current flow from collector to the emitter.

9. NPN transistors can be analyzed using these seven rules:

    - The transistor is off by default.
    - V_{BE} needs to be 0.6 V to turn the transistor on.
    - V_{BE} will always be *exactly* 0.6 V while the transistor is turned on.
    - The collector should always be more positive than the emitter.
    - When the transistor is on, I_{CE} is a linear amplification of I_{BE}.
    - The transistor cannot amplify more than the collector can supply.
    - If the base voltage is greater than the collector voltage, the transistor is saturated (it will offer no resistance from the collector to the emitter).

10. The amount of current amplification a transistor provides is known as the transistor's beta (also known as β or h_{FE}).
11. The actual beta of a transistor is not very stable and fluctuates quite a bit both because of manufacturing differences between transistors and even within a single transistor due to environmental changes such as temperature.
12. When used as a switch, transistors are usually placed at the *end* of a circuit in order to make the circuit analysis easier.
13. Transistors are often used to couple the outputs of devices with low current limits (such as a microcontroller) with devices that require higher output currents (such as motors).
14. To stabilize a transistor circuit's gain so that it doesn't vary with the transistor's beta, you can add in a small emitter resistor.

Apply What You Have Learned

Unless otherwise specified, assume that the transistor is a BJT NPN transistor and that the beta is stable:

1. If the base of a transistor is at 3 V and the transistor is on, what will be the emitter voltage?
2. If the base of a transistor is at 45 V and the emitter is on, what will be the emitter voltage?

3. If the base of a transistor is at 5 V and the emitter, if conducting, would have to be at 4.5 V, is the transistor on or off?

4. If the base of a transistor is at 0.6 V and the emitter is at ground, is the transistor on or off?

5. If the base of a transistor is at 0.4 V and the emitter is at ground, is the transistor on or off?

6. If a transistor has a base current (I_{BE}) of 2 mA and the transistor has a beta of 55, how much current is going through the collector (I_{CE})?

7. In the previous problem, how much total current is coming out of the emitter?

8. If a transistor has a base current of 3 mA and the transistor has a beta of 200, how much current is going through the collector?

9. If the base voltage is greater than the collector voltage, what does this mean for our transistor operation?

10. The output of your microcontroller is 3.3 V and supports a maximum output current of 10 mA. Using Figure 24-7 as a guide, design a circuit to control a motor that requires 80 mA to operate. Assume that the transistor beta is 100.

11. Redesign the previous circuit so that it utilizes a stabilizing resistor on the emitter to prevent variations in the transistor beta.

CHAPTER 25

Transistor Voltage Amplifiers

In Chapter 24, we started our study of the BJT NPN transistor. We noted that what the transistor actually amplified was *current*, so that the current coming into the collector was a multiple (known as β) of the current coming into the base.

Even though what a transistor does is provide *current* amplification, in this chapter, we will learn how to transform that into voltage amplification.

25.1 Converting Current into Voltage with Ohm's Law

If the transistor provides us with current amplification, how might we translate an amplification in the amount of current into an amplification in the amount of voltage? The answer is simple—Ohm's law describes the relationship between current and voltage: $V = I \cdot R$. Therefore, a current amplification can be transformed into a voltage amplification if we use a resistor! The larger the resistor, the larger the change in voltage drop that a given change in current will induce for that resistor.

To see that happening, take a look at the circuit in Figure 25-1. Note that this circuit on its own is rather useless, but it is helpful for illustrating how the calculations work. In this circuit, the current at the

© Jonathan Bartlett 2020

J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_25

base is controlled by the resistor R_B. This current will be amplified into an increased current from the collector. However, the current at the collector is driven through a resistor, R_C. Because this is through a resistor, that means that Ohm's law will take effect, and the size of the voltage drop across R_C will depend on the current running through it.

Remember Ohm's law states that $V = I \cdot R$, so any increase in current will increase the voltage drop across R_C, at least until the voltage at the collector is equal to the base voltage (which, in this circuit, is 0.6 V). If that happens, there is nothing more the transistor can do—it will just treat the collector-emitter junction as a short circuit.

Let's calculate what our circuit is actually doing. The voltage across the base is 5 V – 0.6 V = 4.4 V (remember we have to account for the diode-like voltage drop in the transistor from the base to the emitter). Therefore, using Ohm's law, we can calculate the base current at I = V/R = 4.4/10000 = 0.0004 A.

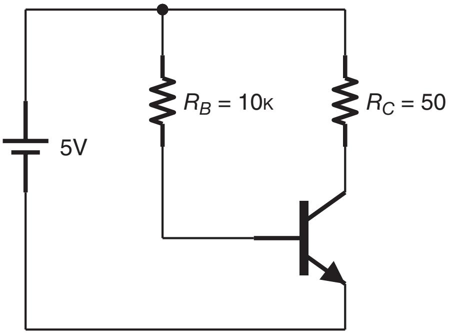

Figure 25-1. *A Simple Current-to-Voltage Amplifier*

Let's assume the transistor beta is 100. Therefore, the current flowing at the collector will be 0.0004·100 = 0.040 A. So the voltage drop across the resistor can be calculated using Ohm's law. $V = I{\cdot}R$ = 0.040·50 = 2 V.

Now, let's say that we change R_B so that we have more current running in the transistor. Let's decrease R_B from 10 kΩ to 6 kΩ. Now the base current will be $I = V/R = 4.4/6000 = 0.000733$ A. Now the current flowing at the collector will be $100 \cdot 0.000733 = 0.0733$ A. So the voltage drop across the resistor is now $V = I \cdot R = 0.0733 \cdot 50 \approx 3.67$ V.

When we increase the current, we increase the voltage drop across the resistor. You may be wondering what happens to the extra voltage. That is, since the emitter of the resistor is at ground and the voltage across R_C keeps changing, where is the remainder of the voltage? The transistor essentially swallows it up.

Remember, in our model of the transistor in Figure 24-2, the transistor acts as a variable resistor for the collector current. Therefore, the rest of the voltage drop happens *within* the transistor.

So, in effect, what we are doing is to translate changes in current at the base into changes in the voltage drop across R_C (and likewise the V_{CE} of the transistor).

As you might have noticed, when dealing with transistors, the place where the "action" occurs is not always right where you might expect it. In this circuit, the location where the voltage amplification *actually occurs* is at a resistor (R_C) connected to the *collector*. So the transistor, acting as an amplifier, is not sending the amplified signal to the emitter. Instead, you can think of it as sending the amplified signal to the collector, where the resistor at the collector converts the amplified current into a corresponding voltage drop.

> **Example 25.28** In the circuit given in Figure 25-1, what is the voltage across the resistor R_C if the base resistor R_B goes up to 20 kΩ?

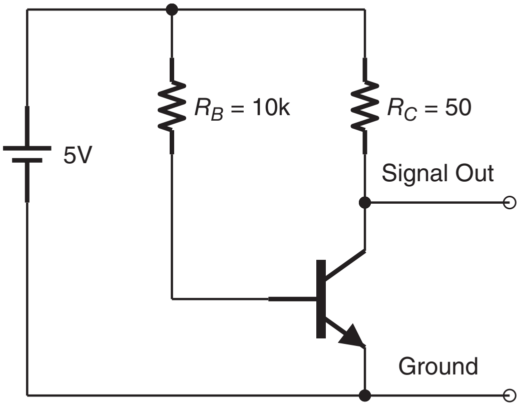

Figure 25-2. *Reading the Amplified Signal from a Voltage Amplifier*

$$I_B = 4.4 / 20000 = 0.00022\text{A}$$
$$I_C = 100 \cdot I_B = 100 \cdot 0.00022 = 0.022\text{A}$$
$$V_{RB} = I_C \cdot R_B = 0.022 \cdot 50 \approx 1.1\text{V}$$

Just to see where we are going, eventually we will use small voltage changes in the base to trigger current changes in the base which will then be amplified into a larger change in the voltage across R_C.

25.2 Reading the Amplified Signal

So we have managed to create a voltage drop which changes in response to changes in current at the base. But how do we read this voltage drop? It is rather difficult to read it directly, but we can read its *inverse* directly.

Take a look at Figure 25-2. In this figure, we added some output signal line to show where we would read the output of the amplifier (i.e., where we would connect the rest of the circuit that receives the amplification). We put the output line *between* the collector resistor R_C and the transistor. What this will do is give us the voltage of the source voltage (5 V) *minus* the voltage across R_C. So, when we have a large voltage across R_C, that will be reflected in a low voltage in our output. Likewise, when there is a low voltage across R_C, that will be reflected in a high voltage in our output.

This sort of an output is known as an **inverted output**, because the output voltage is essentially reverse-amplified. That actually works just fine for audio signals, as it does not matter to the listener if the signal is inverted or not. However, if we needed to get it back to the non-inverted form, we could just add another amplification stage onto the end (we will see how to do this in Section 25.4, "Adding a Second Stage").

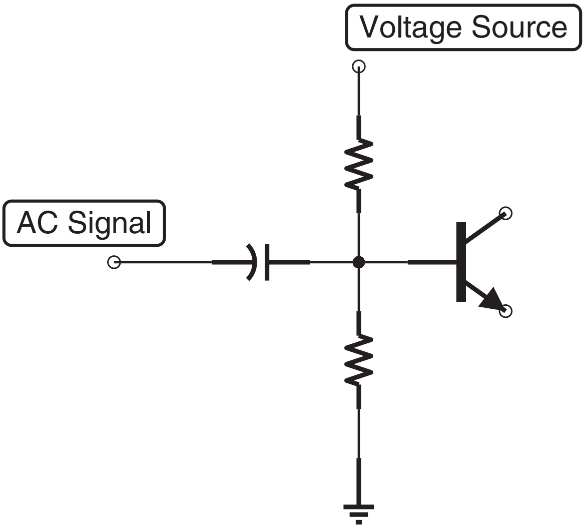

Figure 25-3. *Components of a Transistor Biasing Circuit*

Having said all that, I should point out that we still don't know how to amplify an audio signal—yet. That is coming in the next section.

25.3 Amplifying an Audio Signal

What we really want to do is to amplify an audio signal. Imagine that someone is singing into a microphone, and we want to amplify the signal we get so that we can send it to a speaker. How would we do that?

There are a number of problems that you have to solve in order to get this done. You might imagine that you could just connect a microphone to the base of the transistor and just amplify directly. That's a good idea, but sadly life is not always that easy. To understand why, remember that audio signals are basically alternating current. That means that the signal will swing both positive *and* negative. Also remember that the base voltage has to remain *above* the emitter voltage and the emitter is tied to ground. Therefore, if we tried to do this, we would lose the bottom (negative) half of the signal. In fact, if it was a small signal, we might lose the *entire* signal if it never reached the required 0.6 V above ground.

Therefore, the signal coming into the transistor needs to be **biased**. We basically need to bring the voltage of the incoming signal up so that it keeps the transistor on, but doesn't overwhelm the signal coming in.

If you remember in Chapter 19 when we built the tone generator, we had to unbias the signal. We did that by taking the signal and coupling it through a capacitor. That allowed the two sides to exist at different base voltages, but transmit the *changes* in the voltage through the capacitor. This will be the same idea, but where the input is unbiased and the output is biased.

Figure 25-3 shows what this looks like in general terms. A simplistic way to think about this is to think of it as a voltage divider. The resistors are basically setting a bias voltage, and that voltage is varied based on the current that comes in through the capacitor.

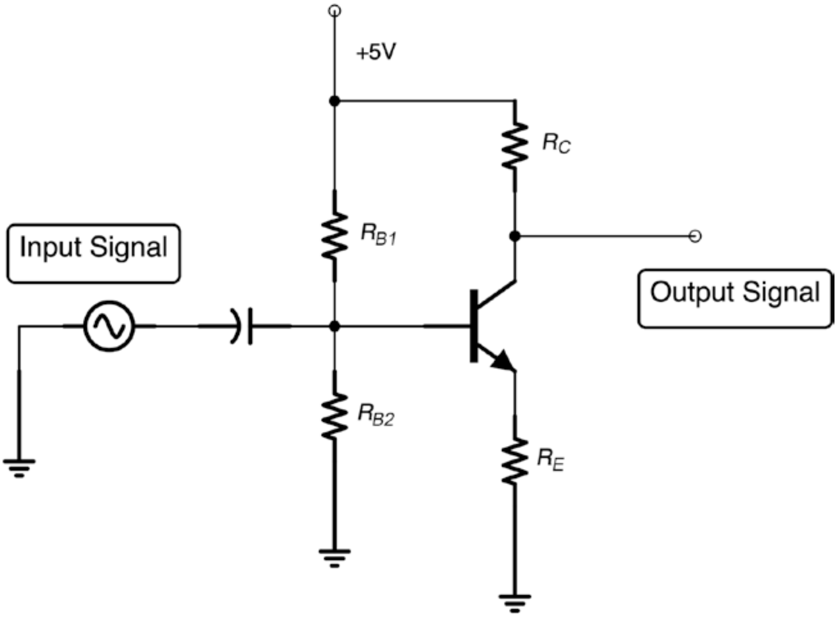

Figure 25-4. *A Single-Stage Transistor Voltage Amplifier*

While that is somewhat true, the details get more complicated as we add more components, especially the transistor. The emitter of the transistor will be connected to ground though through a resistor, R_E. This means that, for the transistor to be on, the actual voltage coming in to the base of the transistor must always be 0.6 V (or above, based on R_E). That means that the voltage divider itself must always be 0.6 V (or slightly above, due to R_E) as well.

Figure 25-4 shows all of the parts of our simple transistor amplifier. The main question is, what do we set the values of each of these resistors to? There are many considerations, and they affect both the amount of gain you will get in your amplifier and whether or not the signal is clipped.

Clipping will happen if the base voltage goes below 0.6 V because the transistor will simply stop conducting (and actually a little above that because of R_E). Clipping will also happen if the R_C resistor is too large, because if the current going through R_C causes the voltage at the collector to get too low, the transistor will have reached its saturation point and therefore will stop amplifying. Since R_C is converting the current into voltage, it also needs to be large enough to yield a wide voltage swing with the amount of current expected.

For the base resistors (R_{B1} and R_{B2}), you need to keep in mind how much current you expect the input source to have. Remember that this current is going to be going to be alternating between the positive and negative directions. Therefore, when the input source swings negative, there has to be enough current coming through R_{B1} to keep the voltage positive and keep the transistor on. When the input source swings fully positive, R_{B2} can prevent clipping as well, as it provides an alternate path for incoming current that isn't through the transistor.

You may be wondering what the resistor at R_E is doing. R_E is a feedback resistor. The gain (β) of a transistor varies both within manufacturing and based on temperature. A feedback resistor, by raising the voltage at the emitter of the transistor, will limit the amount of gain that the transistor can deliver based on its source input.

Feedback means that the output of a circuit is affecting the input in some way. Sometimes, feedback occurs because the output is wired back to the input. However, in this case, the resistor simply increases the voltage at the emitter, causing less current to flow in through the base and more current to flow through R_{B2}.

Limiting the gain of the resistor stabilizes the gain over a variety of operating parameters, so that your circuit will continue to work as the transistor heats up. Additionally, were you to manufacture the circuit, limiting the gain would make it less susceptible to manufacturing differences between individual parts.

In any case, if the output of the circuit has a resistance R_O, then the current gain from the input through the output can be calculated as

$$\text{gain} = \frac{R_{B2} R_C}{R_E R_O} \qquad (25.1)$$

To understand why this formula works, see Appendix D, Section D.5, "Output Gain Calculations in BJT Common Emitter Applications."[1] The formula just gives you a starting point, though you normally have to play around with resistor values a little to get it to work.[2] Also note that the formula only works when $R_O > R_C$.

When you think about your circuit, you will want to analyze it at two points—when the source current coming in at the input is at its highest and at its lowest (which in this case will be negative). If you have developed your circuit correctly, this should give a good swing in the voltage across R_C, but without ever clipping (the transistor turning off or going into saturation).

The best place to start is to recognize that your voltage divider must always provide enough current to keep the transistor on even when the source current swings negative. Therefore, the current coming in to the base through the voltage divider should be a little larger than the signal's current. This is known as the **quiescent current**.

In our case, we are going to develop our circuit to handle passive microphones, so the source signal current will only be on the order of about 10 microamps (0.01 mA). Therefore, we will set our quiescent current to be 0.1 mA. The means that R_{B1} should be a little less than 50 kΩ. We will use a standard 47 kΩ resistor here. R_{B2} can tolerate a wide range of values—basically anything that is at least a quarter the size of R_{B1} (we can't let the voltage drop below the emitter voltage, or the transistor will stop conducting). We'll make it 20 kΩ here.

---

[1] I will warn you that the calculations are pretty ugly (which is why they are in the appendix). Also, to fully understand what is happening, you need to read the rest of this chapter through Chapter 26.

[2] The reason for this is that the formula itself was made by making a *lot* of assumptions and simplifications. Those don't always hold in the real world, so you have to make adjustments.

We want a value for R_C that will swing the voltage about half as far as we can go (we have to save headroom for both the 0.6 V drop on the transistor and the actual output to the rest of the system). If we want a 25x gain, then, if our max base current will be 0.11 mA (quiescent current plus source current), that will put our max collector current at 2.75 mA (25 ∗ 0.11). We want R_C to be dropping about 1.5 V at this level (we need to save some headroom for a number of purposes, including staying above the voltage drop at R_E, the additional diode drop to stay above the base voltage, and some additional which will be used for the current going out of this stage of the amp). Therefore, the resistance for a 1.5 V voltage drop at 2.75 mA is $R = \frac{V}{I} = \frac{1}{0.00275} \approx 545\Omega$. Anything near that value should work fine, so we will go with a 510 Ω resistor.

Then, we mentioned earlier that the total gain will be given by $\frac{R_{B2}RC}{R_E R_O}$. So far, we have $\frac{20{,}000 \cdot 510}{R_E R_O}$. We can estimate the next stage of the amplifier as having a resistance of 2,000 Ω (this is the base resistor of the next stage of the amplifier—see Appendix D, Section D.5, "Output Gain Calculations in BJT Common Emitter Applications," for why this works as an estimate). Therefore, to get a 25x gain, we can do

$$\begin{aligned}
\text{gain} &= \frac{R_{B2}R_C}{R_E R_O} \\
25 &= \frac{20{,}000 \cdot 510}{R_E 2{,}000} \\
R_E &= \frac{20{,}000 \cdot 510}{2{,}000 \cdot 25} \\
R_E &= 204
\end{aligned}$$

In testing, I found that a smaller resistor worked better for R_E, so I used a 47 Ω resistor. Again, the equations are greatly simplified and only give a starting point for experimentation.

25.4 Adding a Second Stage

A single amplification stage is not always enough. If your signal source is weak enough, sometimes you need more power just to hear it. This can be accomplished in a number of ways. The simplest, conceptually, is to add another output stage to your amplifier.

In order to do this, we need to design the next stage to take into account the output of our first stage. We will need to use a coupling capacitor to handle the change in voltage from the output of the first stage into our bias circuit for the second stage. Without the coupling capacitor, the voltage characteristics of the transistor would severely alter the way that our previous stage works. Therefore, the coupling capacitor helps us to isolate the different parts of the circuit.

Now, the current coming in to this stage will be significantly larger than the previous stage. Our previous stage had about 0.01 mA coming in. While not exact, with an actual 25x gain, the current coming in will probably be about 0.25 mA. Therefore, we have to plan this stage differently (i.e., using a different quiescent current).

Using the same procedure as we used for the previous stage, we can use 0.75 mA as the quiescent current and utilize a 5.1 kΩ resistor (to choose a standard value) for R_{B1} and a 2 kΩ resistor for R_{B2}. Our largest swing forward will now be 1 mA, and therefore, the amplified current will be $25 * 1 = 25$ mA. To get the 1.5 V drop, we will need a resistor for R_C of $\frac{1.5}{0.0025} = 60\Omega$. We will approximate to a 100 Ω resistor.

The output resistance will be our headphones, which we can estimate at 16 Ω. Doing the calculation gives

$$\text{gain} = \frac{R_{B2}R_C}{R_E R_O}$$

$$25 = \frac{2{,}000 \cdot 100}{16 \cdot R_E}$$

$$R_E = \frac{2{,}000 \cdot 100}{25 \cdot 16}$$

$$R_E = 100\Omega$$

Again, I had to modify the R_E to get better performance. This is unsurprising because the equation is only even moderately reliable when $R_O > R_C$. Lowering R_E of this stage to 10 Ω seemed to work well.

The output of the second stage will again be coupled through a coupling capacitor to your headphone output and can be attenuated by another resistor (or a variable resistor for volume control) if needed.

Figure 25-5 shows the complete two-stage amplifier. With this circuit, you can use most microphones and most headphones to get enough output power to hear yourself in your headphones (in fact, if you don't have a microphone, headphones can actually work as a microphone in a pinch). Figure 25-6 shows the two-stage amplifier built into a breadboard.

All of the capacitors can be pretty much any standard capacity above around 100 nF. The ones that couple the DC bias signal, if they are polarized, should have their negative side toward the unbiased signal. The coupling capacitor between the two stages should ideally be non-polarized, though with these power levels it doesn't matter too much. If you do need to use a polarized capacitor here, it is best to have the negative side facing the second stage, since that should be right around 0.6 V, while the positive side should be swinging in the positive range.

One thing in this circuit we haven't discussed is the bleed-off resistors connected right next to the coupling capacitors for the input and output circuit. These are very large (1,000,000 Ω) resistors. They are large so that they do not have any effect on the calculations in the circuit itself, but they do provide a place for the negative side of the capacitor to drain out when nothing is connected. Otherwise, any residual charge on the capacitor has no place to go and will remain even when the circuit is turned off and the devices are unplugged.

25.5 Using an Oscilloscope

Designing transistor amplifiers can be tricky because there are a lot of things that can go wrong. Although there is some leeway, using the wrong resistors can result in distortion or a loss of gain. Misconnecting a single component can render the entirety of the circuit inaudible.

Because of the variety of things that can go wrong when building audio circuits, it is best to use an oscilloscope. An oscilloscope can help you visually see what the voltages look like at each point in your circuit. Oscilloscopes can cost as little or as much as you want them to. There are pocket oscilloscopes that you can purchase for less than a nice dinner out, and there are bench oscilloscopes that you would need several months' salary to purchase. Any of those are helpful in analyzing your circuit, so you can see what is happening to your voltages at every point in the circuit.

Review

In this chapter, we learned the following:

1. Although transistors provide current amplification, current changes can be transformed into voltage changes using Ohm's law.
2. Using a resistor at the collector allows us to "read" a voltage change based on the changes in the currents going through the transistor.
3. Using a resistor in this way *inverts* the waveform—it will show low voltage when there is a lot of current and high voltage when there isn't much current.

4. Adding in an emitter resistor limits the amount of voltage gain in the circuit in order to compensate for variable/drifting transistor betas.
5. In order to amplify an audio signal, we have to add a DC bias to the signal so that the transistor stays in its operating range (positive voltage).
6. The simplest way to use a transistor to amplify a signal is to add a voltage divider to the base of the transistor, with a coupling capacitor feeding the signal into the voltage divider.
7. The neutral, “no signal” design point is known as the quiescent point of a circuit. The quiescent point is the state of the circuit when the AC signal coming in is neutral (0 V).
8. The AC signal is coupled into the voltage divider through a coupling capacitor in order to manage the difference between the pure AC signal and the DC biased signal.
9. The circuit should be analyzed both at the highest and lowest swings around the quiescent point from the input signal.
10. The collector resistor should be chosen in order to maximize voltage swing while preventing overdrive.
11. Weak AC signals often need multiple amplification stages to provide sufficient output power for driving outputs.
12. The output of one amplifier can be coupled through a capacitor into the input of a second amplifier.

13. If the signal sources and outputs are not permanently connected, adding a bleed-off resistor will enable the coupling capacitors to drain out after the jacks are disconnected.
14. There are numerous things that can go wrong in a transistor amplifier, including clipping the audio signal, having a bad quiescent current, or accidentally losing your gain through bad resistor choices, not to mention just simply building the circuit wrong.
15. Because of the number of things that can go wrong, it is easiest to diagnose problems in an amplifier using an oscilloscope, which allows you to visualize what is happening at each point in the circuit.

Apply What You Have Learned

1. What is the purpose of the resistor in the collector of a transistor amplifier?
2. What is the purpose of the resistor in the emitter of a transistor amplifier?
3. Why is there a bias voltage on the base of the transistor? Why can't the signal just be connected in directly to the base?
4. Why is the signal coupled in through a capacitor?
5. Why does the single stage voltage amplifier discussed in this chapter invert its output?
6. If the output of the two-stage amplifier is coupled into a third stage, the signal current would swing 1.85 mA in either direction. Design a third amplification stage which can handle this amount of current.

CHAPTER 26

Examining Partial Circuits

We will end our discussion of amplification by discussing partial circuits. Oftentimes you will need to design a circuit which connects to another circuit, either powering it or receiving power from it. For instance, in the amplification circuits from Chapter 25, the outputs were connected to a speaker. They could also be connected to another amplifier or to a stomp box (a device to modulate the incoming signal in some way) or to a recording circuit.

26.1 The Need for a Model

In order to connect circuits together, we need to be able to describe, in general terms, the ways that circuits fit together. When dealing with transistors and other power amplification devices, we often need to come up with a simplified model for how the input to a circuit or the output from a circuit behaves. Early on (in Chapter 7), we learned how to take multiple resistors in series and parallel and combine them into an equivalent single resistor.

When dealing with a power amplification circuit, it is often necessary to look at various parts of the circuit by themselves and figure out how they *look* to other parts of the circuit. The way that a partial circuit looks to other parts of the circuit is called the circuit's **Thévenin equivalent** circuit.

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_26

A Thévenin equivalent circuit takes a partial circuit and reduces it to

- A single voltage source (AC, DC, or DC-biased AC, expressed in RMS voltage)
- A single impedance (i.e., resistance) in series with the voltage source

Note that the single voltage source may be *different* than the voltage source that is actually connected. What you are doing is seeing what the circuit looks like to another circuit. For instance, a voltage divider circuit makes the output of the voltage divider *look like* it is coming from a lower voltage source.

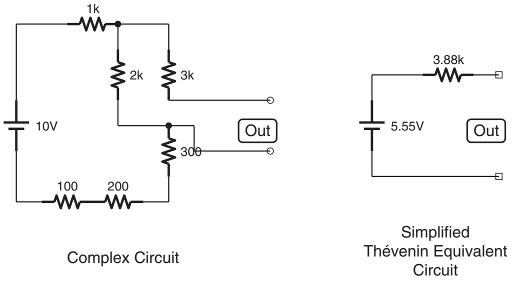

Figure 26-1. *A Complicated Circuit and Its Thévenin Equivalent Circuit*

Figure 26-1 shows a circuit and its Thévenin equivalent circuit. For purposes of thinking about and understanding the relationship between the circuit and things attached to the circuit, we can view the circuit as being the same as its Thévenin equivalent. Thus, having a Thévenin equivalent circuit greatly simplifies our modeling, calculating, and understanding of how circuits work together.

Any network of power sources and resistances can be converted into a Thévenin equivalent circuit. You can also get a Thévenin equivalent circuit for a circuit that includes capacitors and inductors, but the calculations become more difficult and the results are only valid for a specific frequency (each frequency will have a different Thévenin equivalent circuit). For simplicity, we will just focus on resistive circuits.

26.2 Calculating Thévenin Equivalent Values

To see how to calculate the voltage and resistance for a Thévenin equivalent circuit, this section will take a classic voltage divider circuit and analyze how it "looks" to other attached circuits. Figure 26-2 shows an example of a partial circuit. Like most partial circuits, this circuit has two output points—A and B. What we are wanting to know is this—if we attach another circuit up to A and B, is there a model that we can use to understand how the other circuit "sees" our circuit? The goal of making a Thévenin equivalent circuit is to understand what our circuit will look like to other attached circuits.

So, since our Thévenin equivalent circuit will have a voltage source and a single resistor, we need to calculate what the voltage and resistance of this circuit will be. To calculate the voltage, find out what the voltage of the circuit at the output is when there is *nothing connected*. That is, if we were to leave A and B disconnected and I were to connect my multimeter to A and B, what would the voltage be? This is your Thévenin voltage. Since this is a voltage divider, you can just use normal voltage divider calculations to find this out. In this case, we have a 12 V source, and the voltage divider divides it exactly in half (1 kΩ for each half). Therefore, the output voltage is 6 V. Therefore, our Thévenin equivalent circuit will have a 6 V source.

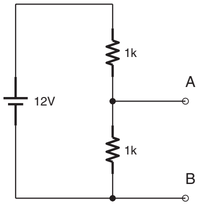

Figure 26-2. *A Voltage Divider Partial Circuit*

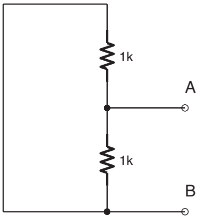

Figure 26-3. *Calculating the Thévenin Resistance of the Circuit*

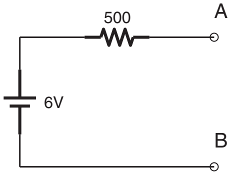

Figure 26-4. *The Thévenin Equivalent of the Voltage Divider*

Now we need to find our Thévenin resistance. There are multiple tricks to do this, but the simplest one is to replace all voltage sources in your circuit with a wire (i.e., a short circuit) and simply compute the total resistance between A and B.[1]

Figure 26-3 shows what this looks like. Therefore, to calculate the Thévenin resistance of this circuit, simply calculate the total resistance from A to B. In this case, there are two parallel paths from A to B—one through the first resistor and one through the second. Therefore, we add up the resistors as parallel resistances. As a result, our Thévenin resistance will be

---

[1] We haven't talked about *current* sources much in this book. However, for completeness, I should note that if you have a current source, you should replace it with an open circuit (i.e., a gap in the wire) when calculating Thévenin resistance.

$$\begin{aligned} R_T &= \frac{1}{\frac{1}{R_1}+\frac{1}{R_2}} \\ &= \frac{1}{\frac{1}{1000}+\frac{1}{1000}} \\ &= \frac{1}{0.001+0.001} \\ &= \frac{1}{0.002} \\ &= 500\Omega \end{aligned}$$

Therefore, we would say that this partial circuit has a Thévenin voltage of 6 V and a Thévenin resistance of 500 Ω. Whenever we attach a circuit to this circuit, what that other circuit will “see” is a circuit like the one in Figure 26-4.

If you wanted to prove this to yourself, you can imagine a variety of different circuits attached to both our original circuit and to the Thévenin equivalent circuit. You will find that, in all cases, the amount of voltage and current the Thévenin equivalent circuit provides to the other circuit is the exact same as what the original circuit will provide.

That isn’t to say that the circuits themselves are exactly equivalent. Our original voltage divider uses up a lot of current stepping down the voltage of the voltage source. Not only does that waste energy from our battery but it probably also causes a lot of heat. However, *any subcircuit that gets attached to A and B* will see both our original circuit and the Thévenin equivalent circuit as providing the same output.

26.3 Another Way of Calculating Thévenin Resistance

There is another way of calculating Thévenin resistance. In this method, we first calculate what the current would be if you shorted A to B directly with a wire. This is known as the short-circuit current, or I_{SHORT}. Then, after calculating this, you can divide the Thévenin voltage by I_{SHORT} to obtain the Thévenin resistance.

When doing this, you have to remember that anything in parallel with our short will be essentially ignored—the current will always want to go through our short circuit.

Figure 26-5 shows what this looks like. What we want to do is to calculate the current going from A to B. Since A to B is a short circuit in parallel with our second resistor, we know that *all* of the current will prefer the short circuit. This means that the current going through A and B will simply be the current that is limited by the first resistor.

So, since we have a 12 V source and a 1 kΩ resistor, the short-circuit current will be

$$\begin{aligned} I_{\text{SHORT}} &= \frac{V}{R} \\ &= \frac{12}{1000} \\ &= 0.012\,\text{A} \end{aligned}$$

Now, to determine the Thévenin resistance, we divide the Thévenin voltage by this number:

$$\begin{aligned} R_{\text{Thevenin}} &= \frac{V_{\text{Thevenin}}}{I_{\text{SHORT}}} \\ &= \frac{6}{0.012} \\ &= 500\Omega \end{aligned}$$

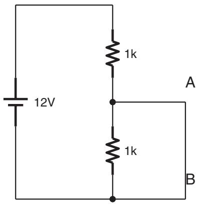

Figure 26-5. *Finding the Short Circuit Voltage*

As you can see, this is the same value that we got from the previous method.

26.4 Finding the Thévenin Equivalent of an AC Circuit with Reactive Elements

If a circuit has reactive elements (inductors and capacitors), we have to do a little more work to find the Thévenin equivalent circuit.

For DC circuits, this is relatively simple. Since capacitors block DCs and inductors are a short circuit for DCs, we can simply treat the capacitors as open circuits (i.e., unconnected) and treat the inductors as short circuits (simple wires). For AC circuits, you can get a feel for what this will be by assuming the opposite—that capacitors will be short circuits and inductors will be open circuits.

However, if you were to try to solve it explicitly, the problem is a little more difficult. The problem is that a full analysis of such circuits requires math involving complex numbers (i.e., numbers involving the imaginary unit *i*). While the technique is roughly equivalent to adding resistances in series and parallel as we have done before, it is much more difficult to do the math with complex numbers.

For the purposes of this book, the previous statements about DC and AC should suffice for a general understanding of how your circuit works.

26.5 Using Thévenin Equivalent Descriptions

Many circuits are described to their users using Thévenin equivalent descriptions. For instance, many circuits are described by their input or output impedance. This gives you a rough guide to imagine what will happen if you connect your own circuit to such circuits.

Imagine that you have a circuit that has a Thévenin equivalent output impedance of 500 Ω. If you connect an output circuit that only has 250 Ω of resistance, what do you think that will do to the signal? Well, since the output of the circuit is equivalent to going through a 500 Ω resistor (that's what Thévenin equivalence means), then if I connect a 250 Ω resistor, then I will have created a voltage divider in which two-thirds of the voltage will be dropped by the circuit I am connecting to and I will only get one-third of the output voltage.

On the other hand, if the impedance of my circuit is 50, 000 Ω, then the voltage drop coming out of the circuit in question is negligible compared to the voltage drop within my circuit. This means that my circuit will essentially receive the full Thévenin equivalent voltage.

We can also use this to calculate the amount of current that our circuit will draw. Let's say that a circuit yields a Thévenin equivalent output of 4 V with an 800 Ω impedance. If I connect a 3,000 Ω output circuit, how much current will flow? The total resistance will be 3,800 Ω, so the current will be $V/R = 4/3800 \approx 1.05$ mA.

The same is true for connecting an input circuit that you make to an output circuit someone else made. For instance, speakers and headphones are normally rated as an impedance—8 Ω, 16 Ω, and so on. They aren't, strictly speaking, resistors, but at normal audio frequencies, they behave essentially like one—they have a Thévenin equivalent impedance (their Thévenin equivalent voltage is zero).

Example 26.29 If I have an output circuit which is a Thévenin equivalent to 3 V RMS and 200 Ω and I connect it to a set of 16 Ω headphones, what will the power of the headphones be in watts?

We can understand this circuit as simply being a voltage source followed by two resistors in series. The voltage source will be 3 V, and the resistances will be 200 Ω and 16 Ω, totaling 216 Ω. The current will therefore be $V/R = 3/216 \approx 0.0139$ A. The voltage drop in the headphones will be $I \cdot R = 0.0139 \cdot 16 \approx 0.222$ V. Therefore the power delivered to the headphones will be $V \cdot I = 0.222 \cdot 0.0139 \approx 0.00309$ W, or 3.09 mW.

26.6 Finding Thévenin Equivalent Circuits Experimentally

In addition to using circuit schematics to determine Thévenin equivalent circuits, it is also possible to determine them experimentally. This way, if you are unsure of the input or output characteristics of your device, you can measure it yourself. The problem with measuring it yourself is that it requires attaching a load to the circuit. Some circuits will fry if a wrongly sized load is attached. You have been warned.

The easiest way to determine Thévenin equivalency experimentally is rather unsafe, but it will help us understand better why the method works. Imagine a voltage divider where the bottom resistor has an extremely large resistance—say, 100 MΩ. In such a voltage divider, the bottom resistor will have almost the entirety of the voltage drop, right? In fact, if the bottom resistor was infinite, it would in fact have all of the voltage drop.

Because of this, we can determine the Thévenin equivalent voltage by measuring the output voltage when there is nothing connected, because no connection means that there is infinite resistance between the output and ground. Measuring this value will give us the Thévenin equivalent voltage.

To determine the Thévenin equivalent current, we can short-circuit the output. This is physical equivalent to the conceptual method we used in Section 26.3, "Another Way of Calculating Thévenin Resistance." When doing this, the *only* impedances to the current will be within the device itself. Therefore, using Ohm's law, the amount of current this draws will tell us how large of a resistance the output is yielding.

> **Example 26.30** If I measure the open-circuit (i.e., disconnected) voltage of the output of an unknown circuit as 8 V and the short-circuit current of the output as 10 mA, what is the Thévenin equivalent circuit?
>
> To find this out, we simply use Ohm's law. What resistance would cause an 8 V source have 10 mA of current?
>
> $$\begin{aligned} R &= V / I \\ &= 8 / 0.010 \\ &= 800 \end{aligned}$$

Therefore, our Thévenin equivalent circuit is 8 V with an impedance of 800 Ω.

The problem with this method is that you don't normally want to short-circuit your output. Additionally, some circuits require some sort of a load to work properly. In order to adjust to such scenarios, there is a set of equations that allow us to measure the voltage drop across a large and small resistance (instead of infinite and no resistance) and come up with a Thévenin equivalent circuit.

The equations are a little complex, but you can actually derive them directly from Ohm's law if you work at it (see Appendix D, Section D.6, "The Thévenin Formula," to see it derived). The first one calculates the Thévenin equivalent voltage (V_T) from the voltage with a high resistance (V_H), the high resistance value (R_H), the voltage with a low resistance (V_L), and the low resistance value (R_L):

$$V_{\mathrm{T}} = \frac{\frac{V_{\mathrm{H}}}{R_{\mathrm{H}}}\left(R_{\mathrm{H}} - R_{\mathrm{L}}\right)}{1 - \frac{V_{\mathrm{H}}R_{\mathrm{L}}}{R_{\mathrm{H}}V_{\mathrm{L}}}} \tag{26.1}$$

Then, we can calculate the Thévenin equivalent resistance:

$$R_{\mathrm{T}} = \frac{V_{\mathrm{T}}R_{\mathrm{L}}}{V_{\mathrm{L}}} - R_{\mathrm{L}} \tag{26.2}$$

For a fairly safe and basic starting point, you can use 1 MΩ for the high resistance value and 1 kΩ for the low resistance value.

> **Example 26.31** I have a circuit that generates an output for which I need to know its Thévenin equivalent properties. I tested the circuit with a 200 Ω resistance for my low resistance and a 1000 Ω resistance for my high resistance. With the 200 Ω resistance, there was a 2 V drop across the resistance. With the 1000 Ω resistance, there was a 5 V drop across the resistance. What is the Thévenin equivalent circuit for this circuit?

First, we find the Thévenin equivalent voltage using Equation 26.1:

$$
\begin{aligned}
V_{\mathrm{T}} &= \frac{\frac{\mathrm{V_H}}{\mathrm{R_H}}\left(R_{\mathrm{H}} - R_{\mathrm{L}}\right)}{1 - \frac{\mathrm{V_H R_L}}{\mathrm{R_H V_L}}} \\
&= \frac{\frac{5}{1000}\left(1000 - 200\right)}{1 - \frac{5 \cdot 200}{1000 \cdot 2}} \\
&= \frac{0.005 \cdot 800}{1 - \frac{1000}{2000}} \\
&= \frac{4}{0.5} \\
&= 8\mathrm{V}
\end{aligned}
$$

Next we can find the Thévenin equivalent resistance using Equation 26.2:

$$
\begin{aligned}
R_T &= \frac{V_T R_L}{V_L} - R_L \\
&= \frac{8 \cdot 200}{2} - 200 \\
&= 800 - 200 \\
&= 600\Omega
\end{aligned}
$$

Therefore, our unknown circuit has a Thévenin equivalent voltage of 8 V and a Thévenin equivalent impedance of 600 Ω.

What makes this method valuable is that it allows a way to *experimentally* determine the Thévenin equivalent of a partial circuit that you don't have a schematic for or for which determining the Thévenin equivalent circuit might be difficult due to nonlinear components such as transistors.

Review

In this chapter, we learned the following:

1. In order to be able to connect circuits together without knowing all of the details of how they are implemented, we need a simplified model of how those circuits work with other circuits they are connected to.
2. A Thévenin equivalent circuit is a combination of a single voltage source and a single series impedance which models the way that the given circuit will respond to other attached circuits.
3. To calculate Thévenin equivalent voltage, calculate the voltage drop for an open circuit between the two terminals. This is the Thévenin equivalent voltage.
4. To calculate Thévenin equivalent impedance, calculate the impedance from one terminal to another (or to ground if there is only one terminal), replacing any voltage sources with short circuits.
5. Alternatively, to calculate Thévenin equivalent impedance, calculate the current flowing from one terminal to another if there was a short circuit between them. Then use Ohm's law to calculate the resistance.
6. Thévenin equivalent circuits can be used to understand how the resistances of attached circuits will affect the signal coming out of or into a circuit.
7. Thévenin equivalent circuits can also be found experimentally.

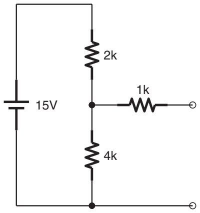
8. Although not recommended, the Thévenin equivalent voltage and resistance can be found easily by simply measuring the voltage drop of an open circuit across the terminals and the current flowing through a short circuit between the terminals.
9. A better option for experimentally measuring Thévenin equivalencies is by measuring the voltage with two different load resistances across the terminals. Then the Thévenin equivalencies can be found using Equations 26.1 and 26.2.

Apply What You Have Learned

1. Why would we want to know what a circuit's Thévenin equivalent circuit is?
2. What are the two components of a Thévenin equivalent circuit?
3. Think about the two-stage amplifier that you built in Chapter 25. How would you go about finding the Thévenin equivalent circuit as it is seen by the headphones?
4. Suppose I have a circuit where the output terminals have a 2 V drop when it is an open circuit and have 2 mA of current flowing through it when it is a short circuit. Draw the Thévenin equivalent circuit.
5. If I have a Thévenin equivalent circuit of 4 V with an impedance of 400 Ω, what will be the voltage drop of the load if I attach a 2000 Ω resistor across the output?

6. If I have a Thévenin equivalent circuit of 3 V with an impedance of 100 Ω, what will be the voltage drop, the current, and the power of the load if I attach headphones rated at 32 Ω?

7. Calculate and draw the Thévenin equivalent circuit of the following circuit:



8. Suppose I have a circuit where when I add a load of 350 Ω, I get a 7 V drop and when I add a load of 2000 Ω, I get an 8 V drop. Calculate and draw the Thévenin equivalent circuit.

CHAPTER 27

Using Field Effect Transistors for Switching and Logic Applications

In Chapter 24, we discussed two kinds of transistors—bipolar junction transistors (BJTs) and field effect transistors (FETs). The previous chapters have focused primarily on BJTs because they are, in fact, great at various tasks that are commonly considered "amplification."

However, there are two amplification tasks for which BJTs are terribly suited—switching and logic circuits. Many people don't think of amplification when they think of logic circuits, but, indeed, they do require amplification. Think about the memory of a computer (which is a type of logic circuit). The memory of the computer has to continue to last after it has been written to. If there was no amplification, the signal would fade over time.[1] Therefore, in order to just "hold on" to the signal, amplification is required.

---

[1] Note that there are indeed some types of memory that can last significant amounts of time without amplification. I'm simplifying to help make the point.

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_27

While this can be done with BJTs, since BJTs are *current* amplifiers, they tend to utilize a lot of current to get this done. Field effect transistors (FETs) operate instead on voltage and require very little current to operate. Therefore, they are very efficient for logic-type applications.

27.1 Operation of a FET

A FET has a very similar set of parts to a BJT. There are three parts—a **gate**, a **source**, and a **drain**.[2]

The basic operation of the FET is that a *voltage* at the gate controls the *current* conduction between the drain and the source. The gate controls the conduction between the drain and the source. Like BJTs, FETs have fully off, fully on, and partially on states. However, unlike BJTs, even when "fully on," FETs still offer a resistance between the drain and the source. This is why, for current-focused applications, BJTs are often used—in their fully on state, they don't limit the current from the collector to the emitter.

Unlike the BJT, the FET is operated by voltages rather than current. Because of this, the gate essentially consumes almost no current whatsoever (it can have a Thévenin equivalence of hundreds of megaohms of resistance). So, while BJTs consume current to perform their operation, FETs consume almost none.

FETs can be built to perform in one of two operating modes:

- A **depletion mode** FET is normally "on" (allowing current to flow between the drain and the source), but turns off when a sufficient voltage (compared to the source) is applied at the gate. The voltage works to "deplete" the transistor of its conducting ability.

---

[2] Some FETs also have a **substrate** (also called a **body**), but that is beyond the scope of this book.

- An **enhancement mode** FET is normally "off" (blocking current flow between the drain and the source), but turns on when a sufficient voltage (compared to the source) is applied at the gate. The voltage works to "enhance" the transistor's ability to conduct.

FETs are distinguished as **N-channel** or **P-channel** based on their orientation. In an N-channel FET, the current flows from the drain to the source (i.e., the drain acts like the collector, and the source acts like the emitter). In a P-channel FET, the current flows from the source to the drain (i.e., the source acts like the collector, and the drain acts like the emitter). For an enhancement mode FET, the gate activates the channel when the gate voltage (compared to the source) is sufficiently positive if it is an N-channel and sufficiently negative if it is a P-channel. For a depletion mode FET, the gate closes the channel when the gate voltage (compared to the source) is sufficiently negative if it is an N-channel and sufficiently positive if it is a P-channel.[3]

So, for instance, in a P-channel depletion mode FET, the source will be positive, the drain will be negative, and the channel will close as the gate voltage becomes more and more negative compared to the source.

Additionally, most FETs have a "threshold voltage" that the gate must achieve before it switches on.

In addition to the channel and the mode, FETs are made in a variety of different ways, which leads to numerous different types of FETs—MOSFETs, JFETs, QFETs, MNOSs, and others. Each of these has its own distinct operating characteristics (threshold voltage, channel resistance, etc.). We will focus on one particular FET to make life easier—the N-channel enhancement mode MOSFET. This is the most commonly used FET by hobbyists.

---

[3] I know this is a lot of information, but there are so many terms that you are likely to encounter that I want to be sure you are familiar with what they mean on a practical basis. As you will see in the following, we are only going to actually use one kind of FET here.

27.2 The N-Channel Enhancement Mode MOSFET

The most popular general FET is probably the N-channel enhancement mode MOSFET. Because it is N-channel, the drain operates as the collector, and the source operates as the emitter (if we think of it in terms of our BJT terminology). That is backward from the way we normally think of things, but that is the reality of the naming scheme. Because it is an enhancement mode device, the bridge between the drain and the source is closed, unless a positive voltage (compared to the source) is applied at the gate.

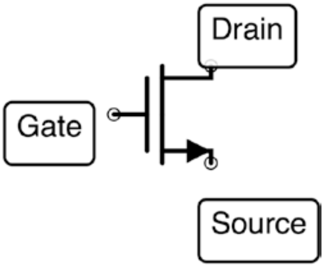


Figure 27-1. *The Schematic Symbol for an N-Channel MOSFET Transistor*

Figure 27-1 shows the schematic symbol for the N-channel MOSFET. Notice that the arrow is pointing out from the *source*. Again, that is because in this transistor, the source performs the same function as the emitter on a BJT.

27.3 Using a MOSFET

Figure 27-2 shows a schematic of a simplistic usage of a MOSFET. In this figure, the gate of the MOSFET is controlled by a switch. When the switch is on, the MOSFET conducts. However, the important thing to note is that the pathway into the gate of the MOSFET consumes basically no current whatsoever!

This is especially important when dealing with small microcontrollers. Some of them have extremely low tolerances for what currents they can deliver. By putting a MOSFET on the output pin, you can make the actual current output from the microcontroller effectively zero and simply have the current delivered through the MOSFET. Figure 27-3 shows this configuration. This is basically the same circuit as Figure 27-2 except that (a) a microcontroller is controlling the gate and (b) we added a pull-down resistor at the gate (note—Figure 27-2 also needs a pull-down resistor, but we left it off for simplicity). The pull-down resistor will make sure that even when the pin is not actively sending a signal, the gate is tied to a known voltage. This is especially important with MOSFETs since they do not consume very much current at all, so charge can stay on the circuit after disconnection.

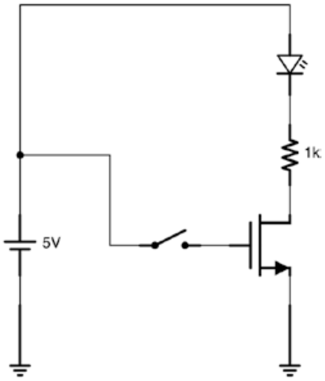

Figure 27-2. *A Simple MOSFET Circuit*

***Figure 27-4.** Combining a MOSFET with a BJT to Power a Motor*

One issue, however, is that, as we mentioned, MOSFETs always have resistance between the drain and source, limiting the amount of current that a MOSFET can source. If we wanted to power a motor, for instance, we would need to increase the current. We can do this by adding a BJT to the output of our MOSFET. Figure 27-4 shows this configuration. Notice that both transistors have a pull-down resistor attached. This prevents any accidental conduction of our devices.

In this configuration, when the gate to the MOSFET is pulled high, it will open up the connection from the drain to the source. Current will flow into the base of the BJT, which will allow current to flow from the collector to the emitter. The amount that it allows is based on the β of the transistor. This current is used by the motor.

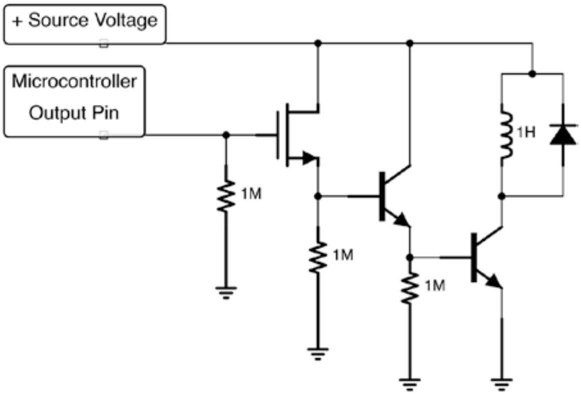

Figure 27-5. *A MOSFET with Two BJTs for Higher Current*

However, even this configuration may not provide enough current. The transistor can only amplify what it gets from the MOSFET, and the current output from the MOSFET is sometimes just not high enough for a single-stage amplification. Therefore, we can use the output from the first BJT as an input to the base of a second BJT to open up the power even more. Figure 27-5 shows this configuration. Note that each transistor has a pull-down resistor to make sure that it gets shut off when the pin goes low.

This configuration provides practically unlimited current through the collector of the transistor and doesn't utilize any current output from the microcontroller.

27.4 MOSFETs in Logic Circuits

MOSFETs are also great to use in logic circuits, again, because they use practically no current at all. While the pathway from the drain to the source can draw current, if the output coming from the source goes to *another* MOSFET, then it won't utilize any current either. As we mentioned earlier, we can think of the gate of a MOSFET as having a resistance on the order of a hundred megaohms. Therefore, Ohm's law will prevent any significant amount of current running into them.

In Chapter 12, we learned about integrated circuits that could perform logic functions such as AND, OR, and NOT. We can mimic these same logic functions with MOSFET transistors (we can also mimic them with BJTs, but we would waste a lot of current doing it).

Figures 27-6, 27-7, and 27-8 show how these gates could be wired using MOSFETs. Note that each transistor requires a pull-down resistor as well, which is not pictured for simplicity of understanding.

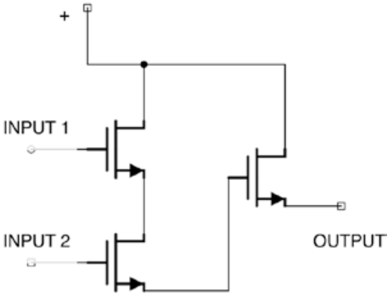

Figure 27-6. *An AND Gate Using MOSFETs*

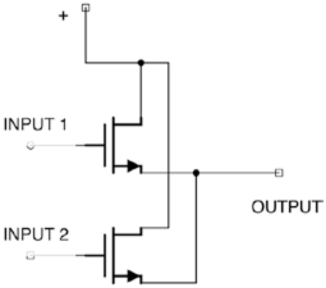

Figure 27-7. *An OR Gate Using MOSFETs*

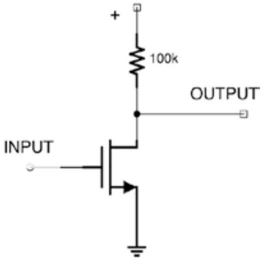

Figure 27-8. *A NOT Gate Using MOSFETs*

Review

In this chapter, we learned the following:

1. Field effect transistors (FETs) are similar to BJTs, but they are controlled by voltage instead of current.
2. The parts of the FET transistor are the gate, the source, and the drain, though whether the source or the drain is on the positive side depends on the type of transistor.

3. The N-channel depletion mode MOSFET is wired (somewhat confusingly) so that the drain is on the positive side and the source is on the negative side. Applying a positive voltage at the gate allows current to flow from the drain to the source.
4. Because FETs operate using voltage, the gate consumes almost no current, making it ideal for controlling devices from microcontrollers.
5. When a device is truly power-hungry, a FET can be used in combination with one or two BJTs to provide additional current output to the device.
6. FETs can also be used in combination with each other to produce logic circuits that utilize very little current.

Apply What You Have Learned

1. Why is it especially important to include pull-down resistors with FET transistors?
2. Which types of FETs are normally conducting between the drain and the source? Which ones are normally not conducting?
3. Create a circuit that combines an AND gate and an OR gate using N-channel MOSFETs. It should turn on an LED if buttons 1 and 2 are pressed or if button 3 is pressed.
4. Why is a BJT needed to power an electric motor in addition to the MOSFET?

CHAPTER 28

Going Further

Congratulations! You have reached the end of this book! Hopefully, though, this is just the beginning of your electronics journey. From here, there are many directions you can go.

If you are mostly into digital electronics (programming and using microcontrollers), then this book probably has all of the electronics knowledge you need. From here, you should learn more about programming and more about the devices you want to use for your projects. Additionally, there are a ton of add-on devices that can be controlled with these sorts of microcontrollers. Learning about how to program and what devices are available would be your best next step. A good start to this would be Michael McRobert's book *Beginning Arduino*, Brian Evans's book *Beginning Arduino Programming*, or Bob Dukish's *Coding the Arduino*.

If you were more interested in the sound and amplification sections, the next steps would be to either learn how to do this with microcontrollers or learn to do it directly with capacitors, inductors, and other electronic components. For the microcontroller path, try out Mike Cook's *Arduino Music and Audio Projects* or Alexandros Drymonitis's *Digital Electronics for Musicians*. For direct work in electronics, check out Craig Anderton's classic, *Electronic Projects for Musicians*, or, if you can find a copy, Nicholas Boscorelli's *The Stomp Box Cookbook*. Ray Wilson's *Make: Analog Synthesizers* is also good.

© Jonathan Bartlett 2020

J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_28

If you want to learn more about electric motors and devices that move, there are a lot of options as well. David Cook's *Robot Building for Beginners* is a great place to start, as well as the follow-up book *Intermediate Robot Building*. Jeff Cicolani also has a book, *Beginning Robotics with Raspberry Pi and Arduino*, that is worth looking into. The book *Arduino Robotics* has a lot of more advanced ideas as well, including a DIY Segway clone.

If you want to know more about the operation of the components themselves, the best in-depth guidebook (though very expensive!) is Paul Horowitz's *The Art of Electronics*. If electronics is going to be your profession, it's worth every penny. Otherwise, it is probably a little too advanced (and expensive) for the casual hobbyist.

If you enjoyed the math and wanted to know more, I suggest that you start by learning calculus, as much of the math of electronics is based in some way on calculus. The book I would suggest for that is my own *Calculus from the Ground Up*.

Anyway, I wish you well on your electronics journey. You are well prepared to begin!

APPENDIX A

Glossary

AC See *alternating current.*

AC mains This is the type of current that is supplied to your house by the public utility companies. This is usually 120 volts AC and cycles back and forth 50–60 times per second.

AC signal This is the type of current usually picked up by a microphone or antenna. It has very low current and usually must be amplified before processing.

alternating current Current where the flow of current continually changes direction. This can also refer to a continual stream of fluctuations of voltage.

amp A shorthand way of saying ampere. See *ampere.*

ampere An ampere is a measurement of the movement of charge. It is equivalent to 1 coulomb of charge per second moving past a given point in a circuit.

amplification Taking a low-power signal and converting it to a high-power signal. This is usually done by using the low-power signal to control a high-power source and manipulate it to mimic the low-power signal.

AND function A logic function which yields a true value when all of its inputs are true.

AND gate A logic gate which implements the AND function.

anode An anode is the "positive side" of a polarized device. Note that, in batteries, the anode is actually the negative terminal (because the positive charge *enters* here).

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5

Arduino A popular environment for programming microcontrollers, including a standard set of development boards for a variety of microcontrollers.

Arduino IDE A software program used to write and upload programs for Arduino-based microcontrollers.

atomic number The number of protons that a given element has.

auto-ranging multimeter A multimeter which does not require that you know the likely value of the measured value ahead of time.

baud A way of expressing rates of communication. Means “bits per second.”

beta The amount of gain that a BJT can generate.

bit Binary digit. A true or false (or 1 or 0) value.

BJT Bipolar junction transistor. In this type of transistor, current at the base of the transistor controls the conduction between the collector and the emitter.

boost converter See *DC-DC power converter*.

breadboard A device which makes it easier to attach components together. See also *solderless breadboard*.

breakdown voltage The voltage drop that occurs when a diode is blocking current, but the voltage goes beyond the capacity of the diode itself and “breaks down” the blockade. This is problematic in normal diodes, but an expected part of operation of Zener diodes.

bridge A space in the middle of a breadboard separating terminal strips.

brushed electric motor A motor that operates by changing its interior magnetic configuration based on wires that are rotating in the shaft.

brushless electric motor A motor that operates by changing its exterior magnetic configuration based on generating an alternating current inside the motor. Brushless motors are less prone to fail because of fewer parts that wear down.

capacitance Capacitance is the ability to hold an electric charge.

capacitative reactance The reactance that comes from capacitor-like components.

carrier frequency A frequency on which another signal is laid.

cathode A cathode is the “negative side” of a polarized device. Note that, in batteries, the cathode is actually the positive terminal (because the positive charge *leaves* here).

charge Charge is a fundamental quantity in physics. A particle can be positively charged (like a proton), negatively charged (like an electron), or neutrally charged (like a neutron). Charge is measured in coulombs.

chip See *integrated circuit.*

circuit diagram The drawing of a circuit using special symbols to show how the components are connected without worrying about how the circuit will be physically laid out on the breadboard.

circuit pattern A circuit pattern is a common way of building (and understanding) certain types of circuits or subcircuits.

closed circuit A circuit is closed if there is a complete pathway from the positive to the negative.

CMOS CMOS is a technology for building integrated circuits (especially MOSFETs) and stands for “Complementary Metal Oxide Semiconductor.” It is also a standard for true/false voltage levels used by logic chips made using CMOS technology.

coil See *inductor*.

comment In computer programming, a comment is a line of code that the computer ignores and is meant to communicate information to the person reading the code.

common point See *ground*.

common emitter A transistor circuit pattern where the emitter is tied to a known, fixed voltage.

connection point A place on a breadboard where a wire or component can be attached.

conserved quantity A quantity is conserved if, in the normal course of action, it cannot be created or destroyed. Energy is a conserved quantity—it cannot be created or destroyed but only transferred.

conventional current flow Conventional current flow traces the flow of positive charge in a circuit from a positive source (often a battery) to either ground or a negative terminal.

coulomb A coulomb is a quantity of electric charge. One coulomb is roughly equivalent to the charge of 6.242Œ10^{1}8 protons. The same number of electrons produces a charge of −1 coulomb. Coulombs are represented by the symbol C.

coupling capacitor A coupling capacitor is a capacitor that links to circuits, usually at different DC offsets. The coupling capacitor transmits changes in voltage (i.e., AC) while blocking the DC offset voltages from influencing each other.

datasheet The documentation provided by a component or an integrated circuit which provides technical details about the component's operation.

debugging The process of finding errors in electronic circuits or computer code.

DC-DC power converter A device which converts voltage levels (like a transformer) but for DC circuits.

DC bias voltage See *DC offset*.

DC See *direct current*.

DC motor A device that converts DC electrical power into mechanical power.

DC offset If an alternating current is centered around a voltage other than zero, the center voltage is the DC offset.

depletion mode A FET which uses depletion mode means that the FET normally conducts between the drain and source, but will be inhibited by sufficient gate-to-source voltage (sufficiently positive for a P-channel or sufficiently negative for an N-channel).

development board A development board is a prebuilt circuit board that makes trying out certain chips and components (and building example projects with them) much easier.

digital logic A convention where voltages (usually a positive voltage and zero voltage) are used to represent "true" and "false" values (or "1" and "0").

diode An electric component that only allows current to flow in one direction.

DIP See *dual in-line package*.

direct current Current where the flow of current maintains the same direction. It can also be viewed as steady voltage from a positive terminal to a negative terminal (i.e., voltage which does not continually vary/change directions).

dissipation Dissipation refers to the ability to get rid of something. Heat dissipation deals with the removal of extra heat generated in circuits.

drain (transistor) One side of the main current pathway of a FET. This is the positive side in an N-channel FET and the negative side in a P-channel FET.

dual in-line package A type of package for integrated circuits which has two parallel sets of pins which fits nicely across the bridge of a breadboard.

electric field This is the force of attraction of opposite charges which are separated but near to each other.

electromagnet A magnet that is created through an inductor. Electromagnets allow electronics to manipulate the larger physical world.

electron current flow Electron current flow traces the flow of negative charges from a negative source or ground to its destination (often a positive terminal on a battery).

electron A negatively charged particle that is usually on the outside of an atom.

energy The ability to do work, usually measured in joules.

enhancement mode A FET which uses enhancement mode means that the FET normally does not conduct between the drain and source, but sufficient gate-to-source voltage will allow conduction (sufficiently positive if it is an N-channel and sufficiently negative if it is a P-channel).

equivalent resistance If multiple resistors are connected in series or in parallel, their operation can be mimicked by a single resistor. This resistor is said to have equivalent resistance of the resistor circuit that it replaces. See also *Thévenin equivalent circuit*.

farad The basic unit of capacitance named after Michael Faraday.

feedback When the output of a process feeds back into the input of a process.

FET Field effect transistor. This is a type of transistor where the gate controls the conduction between the drain and the source.

filtering capacitor A capacitor used to remove signals of a certain range of frequencies from the signal.

flash memory A type of memory in integrated circuits that is retained even after the power to the device is removed.

flux See *magnetic flux*.

flyback diode See *snubber diode*.

forward voltage drop The amount of voltage that a diode utilizes when the current flows forward.

frequency How often a cycle of an oscillator completes a full cycle, measured in hertz (cycles per second).

function In computer programming, a function is a block of code that accomplishes a task and may return a value to the code that invoked the function.

gain The amount of amplification that a component provides to a signal.

gate (logic circuit) See *logic gate*.

gate (transistor) In a FET, the gate is the input that controls the pathway between the drain and the source using voltage levels. Gates generally utilize a negligible amount of current.

ground The chosen point on a circuit by which to measure other voltages. On DC battery circuits, this is usually simply the negative terminal of the battery.

H-Bridge A device which makes it easier to control a two-way motor drive.

headers Places on a circuit board where additional circuits or wires can be attached.

heat Undirected energy. In electronics, heat is usually due to inefficiency in circuits. All circuits are inefficient to some degree, and that inefficiency is released as heat into the environment.

heatsink A heatsink is an object, usually large and metallic, which attaches to a part of a circuit to dissipate heat into the environment and away from the circuit itself.

henry The unit of measure for inductance.

hertz A unit of measurement of frequency/oscillation. Abbreviated Hz. Hertz refers to the number of cycles per second.

IC See *integrated circuit*.

in-system programmer A device that connects your computer to a microcontroller which will transmit a new program to the microcontroller.

inductance The amount of resistance an inductor offers to changes in current. Measured in Henries.

inductive kick When current is suddenly blocked to an inductor, the magnetic field suddenly collapses and generates a sudden large voltage at the cathode.

inductive reactance The reactance that comes from inductor-like components.

inductor A component, usually made of coiled wire, that stores energy in a magnetic field. Inductors resist changes in current.

impedance The amount of resistance a circuit offers to alternating current which combines resistance and reactance. Impedance is usually based on a specific frequency.

inefficiency In energy terms, inefficiency is the amount of energy that is wasted in performing a process. All processes are inefficient to some degree.

integrated circuit A miniaturized circuit that is built on a silicon chip.

International System of Units See *SI Units*.

inverted input or output An input or output is inverted if you send it (or receive from it) the opposite of what you might normally expect.

ISP See *in-system programmer*.

joule A standard unit of work or energy. It is defined as the amount of work performed when a 1-kilogram object is moved 1 meter. It can also be defined as the work performed when moving a coulomb of charge through 1 volt of electric potential difference.

junction The point where two or more wires or components are connected together.

Kirchhoff's current law At any junction, the total amount of current going into a junction is exactly the same as the total amount of current going out of that junction.

Kirchhoff's voltage law Given any two specific points on a circuit (at a particular point in time), no matter what path is traveled to get from one point to the other, the difference in voltage between the two points is the same. This can also be stated equivalently as saying that any complete, closed path around a circuit has a total voltage drop of zero.

latch A simple type of memory that stores a single bit using logic gates.

lead A metallic connection point of a component.

leg See *lead*.

logic function A function that takes in one or more logic (true/false) values as input and produces one or more (usually one) logic values as output.

logic gate A circuit which implements a logic function. This is different from a transistor gate. Confusingly logic gates are built from transistors which can have a gate.

loop In computer programming, a loop is a group of commands that is repeated multiple times.

magnetic flux The energy stored in an electric field.

mechanical fit The ability of two objects to be joined just by pushing them together.

memory The capacity of a circuit to hold on to previous values. Often used in computer programming to store values.

microchip See *integrated circuit*.

microcontroller An integrated circuit which operates as a standalone computer. Usually used for controlling small electronic devices.

milliamp A short way of saying milliampere. See *milliampere*.

milliampere One thousandth of an ampere. See *ampere*.

MOSFET A specific (and common) type of FET transistor.

multimeter A device used to measure a variety of electrical quantities in circuits and devices, usually including voltage, current, and resistance.

N-channel A type of FET. Refers to the physical construction of the FET.

NAND function A logic function which yields a false value only when all of its inputs are true. A combination of the AND and NOT functions.

NAND gate A logic gate which implements the NAND function.

NPN A type of BJT.

neutron An uncharged particle in the nucleus of an atom.

no load RPM The speed at which the shaft of a motor rotates with nothing attached to the shaft at its rated voltage.

no load current The amount of current that a motor utilizes with nothing attached to the shaft at its rated voltage.

non-polarized component A circuit component (such as a resistor) where it does not matter which end is used as the anode or cathode.

NOR function A logic function which yields false if any of its inputs (or combination of inputs) are true. A combination of the OR and NOT functions.

NOR gate A logic gate which implements the NOR function.

NOT function A logic function which takes one input and yields its opposite.

NOT gate A logic gate which implements the NOT function.

nucleus The nucleus is the part of the atom where protons and neutrons reside.

ohm The unit of measurement of resistance.

open circuit An open circuit is a condition where there is no electrical pathway for the current to flow. See also *closed circuit*, *short circuit*.

open collector A type of output from a circuit where the “positive” state is actually disconnected, while the “zero” state is an actual ground voltage. This is often used to allow the user of the circuit to supply their own voltage through a pull-up resistor.

OR function A logic function which yields a true value when any of its inputs are true.

OR gate A logic gate which implements the OR function.

oscillation Oscillate means going back and forth. In electronics, oscillation usually means periodic back-and-forth fluctuations in current or voltage.

oscillator An oscillator is a circuit that switches back and forth between two or more states (e.g., positive voltage to zero voltage) in a regular fashion.

oscilloscope A device used to probe circuits and visualize the behavior of circuits over time.

P-channel A type of FET. Refers to the physical construction of the FET.

package The way that an integrated circuit is encased, including the physical casing, the pinout, and the type of pins.

parallel circuit A circuit is a parallel circuit if one or more components are arranged into multiple branches.

period The length of a full cycle of an oscillating circuit. Usually measured in seconds.

pad See *pin*.

pin On an integrated circuit, this is one of the legs protruding from the chip that you can connect to your circuit. Can also refer to the leg/lead of other types of components.

pinout The pinout refers to the meaning/purpose assigned to each pin of a particular integrated circuit.

PNP A type of BJT.

polarized component A circuit component (such as a diode) which has an explicit anode and cathode (i.e., the sides of the component are not interchangeable).

power The continual supply of energy, usually measured in watts. In DC circuits, power is calculated as the voltage (in volts) multiplied by the current (in amperes).

power buses See *power rails*.

power rails The part of a breadboard (usually indicated by red and blue lines) which is usually used for power connections.

power transistor A transistor made to handle large amounts of voltage and current.

programming environment A set of tools which makes programming for certain devices, or in certain ways, easier.

protection diode A diode that protects a circuit, usually either from putting in a battery backward or, in the case of a snubber diode, from inductive kick.

proton A positively charged particle in the nucleus of an atom.

pull-up resistor A resistor connected to a positive voltage which gives a default positive voltage if no other voltage is connected on the line.

pull-down resistor A resistor connected to a positive voltage which gives a default zero voltage if no other voltage is connected on the line.

pulse-width modulation Sending a signal using a fixed pulse frequency, but where the percentage of time the signal is high vs. low varies. This is a way of outputting voltage levels on devices that don’t support outputting at different voltage levels.

PWM See *pulse-width modulation*.

quiescent current In a transistor amplifier, the quiescent current is the amount of current that is flowing into the base of the transistor when no signal is applied.

RC circuit A resistor in series with a capacitor, usually used for timing.

reactance This is a part of impedance which is similar to resistance but operates by preventing flow rather than dissipating energy. Reactance is usually based on the frequency of the signal.

resistance Resistance measures how much a component resists the flow of electricity. Resistance is measured in ohms (Ω).

resonant frequency The resonant frequency of a circuit is the frequency of the circuit where the inductive and capacitative reactances cancel each other out.

RMS A way of computing averages that focuses on magnitudes.

RPM Revolutions per minute. How often the shaft of a motor rotates in a minute.

RS-232 A protocol for serial communication describing voltage levels, timing, and other important signaling features for sending and receiving bits using two wires.

saturation mode This occurs in a transistor when it is fully on and cannot amplify the signal further. In saturation mode, the transistor acts more like a switch that is on rather than as an amplifier.

schematic See *circuit diagram*.

serial interface A type of input/output mechanism that sends data a single bit at a time, oftentimes using the RS-232 protocol.

series circuit A series circuit is a circuit or part of a circuit where all of the components are connected one after another.

servo motor A motor that, instead of spinning, creates an angle.

set screw A screw whose purpose is to apply pressure to another part to join it together.

shaft The rotating part of a motor.

short circuit A short circuit is what happens when the current pathway has no resistance from the positive to the negative.

SI Units The international standard for physical units of measure.

sink When a component or circuit receives incoming current.

snubber diode A diode that is wired backward across the terminals of an inductor to protect the circuit against inductive kick.

solder (noun) A substance which can be heated up to attach wires, components, and other metallic objects together.

solder (verb) The activity of attaching things together using solder.

solderless breadboard A device consisting of a number of connected terminals where components can be inserted and removed at will, which allows for the construction of circuits in a nonpermanent way.

source (general) When a component or circuit provides current output.

source (transistor) One side of the main current pathway of a FET. This is the negative side in an N-channel FET and the positive side in a P-channel FET.

square wave An oscillating signal where the signal spends almost all of its time either in the high or low state and almost no time in between.

SR latch A simple type of memory which can store a single bit.

stall condition In an electric motor, this is the condition where the motor is not turning while it is exhibiting its maximum torque.

stall current The amount of current that the motor uses in a stall condition.

stator The fixed outside container of a motor.

terminal See *lead*. Can also refer to a female receiver for a lead.

terminal strip On a breadboard, a terminal strip is a row of connection points which are connected together within the breadboard, so that putting in multiple components or wires on a terminal strip connects them together.

Thévenin equivalent circuit A generalization of how one circuit “sees” another circuit, as if it solely consisted of a power source and an impedance/resistance.

TO-220 package A way of packaging an integrated circuit, usually for transistors, voltage regulators, or other power-oriented devices. It consists of three terminals and a heatsink.

torque Rotational power. In a motor, this is the amount of rotational power that the motor applies to the shaft.

transformer A pair of inductors which utilize the magnetic field in one coil to generate a current in the other inductor. Usually used to convert voltage levels in different circuits and to isolate parts of a circuit. Transformers only operate on AC circuits. For DC circuits, see *DC-DC power converter*.

transistor A circuit component used for switching, logic, and amplification. Generally, a transistor operates by having one terminal control the flow of current between two others. See also *FET* and *BJT*.

TTL An acronym for transistor-to-transistor Logic. This is an old standard for logic chips for signaling true and false values, usually operating at 5 V.

unit of measurement A standard marker used for quantification, such as grams (weight), seconds (time), or meters (length).

unit prefix A unit prefix is a modifier that can be added to a word to indicate that it should be multiplied by some amount. For instance, a kilometer means a thousand meters. A millimeter means a thousandth of a meter.

variable In computer programming, a variable is a storage location where a value is held that can change.

variable resistor A resistor whose value changes.

voltage A voltage is the “power” of an electric charge. Formally, it is the ratio of potential energy of a charge to the magnitude of a charge. It can also be described as the change in magnetic flux over time.

voltage divider A voltage divider occurs when there are two components (usually resistors) connected together with a terminal coming out from between them meant to have a voltage between that of the two components.

voltage drop The voltage difference between two points on a circuit. This usually refers to the amount of voltage consumed within a specific component on a circuit.

watt A unit of power. A watt is the delivery of one joule per second.

work Work occurs when force causes a displacement (change of position). Work is often measured in joules.

XOR function A logic function which yields a true value when any one (and only one) of its inputs is true.

XOR gate A logic gate which implements the XOR function.

Zener diode A diode which is meant to be wired in such a way as to take advantage of its breakdown voltage.

APPENDIX B

Electronics Symbols

Symbol	Component	Description
	Battery	A battery is represented by a long line and a short line stacked on top of each other. Sometimes, there are two sets of long and short lines. The long line is the positive terminal, and the short line is the negative terminal (which is usually used as the ground).
	Resistor	A resistor is represented by a sharp, wavy line with wires coming out of each side.
	Potentiometer	A potentiometer is represented by a resistor with an arrow in the middle. This indicates that the positioning of the dial will affect how the voltage is divided.

(*continued*)

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5

Symbol	Component	Description
	Diode	A diode is represented by an arrow with a line across it, indicating that current can flow from positive to negative in the direction of the arrow, but it is blocked going the other way.
	LED	An LED symbol looks similar to a diode (since it is a diode), but it also has two short lines coming out of it, representing the fact that it emits light.
	Zener diode	A Zener diode is represented like a normal diode, but with angled lines coming out of the blocking bar, representing the fact that the "blocking" action is not its only use.
	Button	A button is represented by a line that could connect two wires. This represents the fact that if the button is pushed down, it will connect the two parts of the circuit.
	Switch	A switch is like a button, but it is anchored on one side. This represents the fact that the position of the switch is semipermanent. Unlike a button, which pushes and then releases, the switch will stay where you put it.
	Capacitor (unpolarized)	A capacitor is represented by two parallel lines separated by a space, representing the fact that a capacitor is built from two plates that are not physically touching.

(*continued*)

Symbol	Component	Description
	Capacitor (polarized)	A polarized capacitor is similar to an unpolarized capacitor, except that the negative side of the capacitor has a curve applied to it.
	Inductor	An inductor is represented by a curling line to represent the fact that the wires in an inductor are coiled. This symbol is often used to represent not just basic inductors, but also applications of inductors such as motors and electromagnets.
	BJT NPN	The BJT NPN transistor is a three-terminal device with a line going in from the collector and a line going out to the emitter, with an arrow pointing toward the emitter. The line coming to the solid flat line is the base, which controls the flow. You can remember that this is an NPN transistor because the arrow "Never Points iN."
	N-channel enhancement mode MOSFET transistor	The N-channel enhancement mode MOSFET transistor has a similar symbol to that of the BJT, but the gate doesn't actually touch the line connecting the drain to the source. This is because the gate of a FET does not actually participate in current flow, but only controls the gate itself with voltage.

APPENDIX C

Integrated Circuit Naming Conventions

The naming conventions for ICs can be bewildering at first. In truth, there is no official standard for chip names, but there are some conventions that are often followed. When a chip is invented, the company that invented it assigns it a part number. However, the courts have ruled that part numbers cannot be copyrighted. Therefore, if another manufacturer makes a similar or identical chip with the same pinout, they will often use the same part number.

C.1 Logic Chip Basic Conventions

Logic chips are often broken up into two families based on the voltage levels that they expect and produce. **TTL** (which stands for transistor-to-transistor logic) is an old standard for logic chips which usually operates at 5 V. TTL chips consider a signal to be "false" when it is below 0.8 V and "true" when it is above 2.2 V and can break if they receive voltages significantly higher than 5 V. Between 0.8 V and 2.2 V is a region where the resulting value is unpredictable. TTL originally referred to *how* the logic chips were constructed, but now it usually refers to the expected input/output levels of the chip.

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5

CMOS is a newer technology, and with it came a newer standard for how logic levels are interpreted. CMOS chips support a much wider supply voltage range than TTL, but their logic levels are a little different. For CMOS, false is from 0 V to one-third of the supply voltage (whatever it is—CMOS can usually operate from 3 V to 15 V), and true is from two-thirds of the supply voltage to the full supply voltage.

Chips are often made in a series—a whole set of chips which all perform complementary functions. The most common series of logic chips is the 7400 series originally designed by Texas Instruments. The 7400 series started as a set of TTL chips. Some common chips in this series are the 7400 itself (a quad–NAND gate), the 7408 (a quad–AND gate), and the 7432 (a quad–NOR gate).

Chips names will often have a prefix that relates to either their manufacturer or the company that originally designed them. As some examples, National Semiconductor chips are usually prefixed with LM; Texas Instruments chips have a whole slew of prefixes, including SN and TI; Motorola chips usually have an MC prefix; and Signetics chips usually have an NE prefix. There are many others, but this is just to give you an example. The 7400 series usually has part numbers starting with SN74 because TI built them. So a SN7408 is an AND gate based on designs by TI.

Now, the series is 7400. The last two digits refer to the function and pinout of the chips. That is, in the 7400 series, "08" will refer to quad–AND gates which all have the same pin configuration. However, sometimes they will insert letters in between "74" and "08." This usually refers to some modification to the electrical characteristics of the chip. For instance, a low-power version of the 7400 series has a "74LS" prefix. So the "SN74LS08" chip is a version of the 7408 (i.e., has the same pinout and function) that was originally designed by TI (the SN prefix) but is built for lower-power consumption (LS).

Then, part numbers often have suffixes as well. Suffixes often refer to some external characteristics of the chip. For instance, in Chapter 11, we mentioned different chip packages, such as DIP and SMD. These different packages will have different suffixes. For the 7400 series, the DIP package is usually suffixed with "P," so an SN74LS08P is the DIP version of the SN74LS08, and the NS74LS08NSR is an SMD version. You may also have suffixes which are based on temperature, hardiness, and even occasionally electrical output characteristics.

Sometimes, if a different manufacturer builds the same chip, they may change the manufacturer code and use different suffixes. For instance, Texas Instruments sells a SN74HC08P, which is a DIP 7408 which uses CMOS levels up to 6 V (that's what the HC is for). Essentially the same chip is available from Fairchild, which calls it the MM74HC08N. The MM prefix is one that Fairchild uses, and it is the same 74HC08 chip, and, for Fairchild, they use an "N" suffix to designate a DIP chip.

As I mentioned, these are only conventions, not standards, so they don't always apply. However, they can be helpful, so that you know that if someone specifies a 7432 chip and you see part numbers that say SN74LS32P, you might be able to determine that this at least has some relationship to the chip you are looking for.

APPENDIX D

More Math Than You Wanted to Know

This appendix is a catalog of equations in electronics and where they came from for those who are curious. This book is meant more for an introductory approach, but nonetheless many people are curious. This chapter isn't for the faint of heart, and it may involve lots of math you haven't taken. That's why it is stuck in an appendix.

However, if you are curious, these are the mathematical answers to your questions.

D.1 Basic Formulas

D.1.1 Charge and Current Quantities

- 1 coulomb = $6.241509 * 10^{18}$ electrons (how many electrons in a coulomb)
- $I = \frac{dc}{dt}$ (current is the derivative of charge with respect to time)
- $1A = 1\frac{C}{s}$ (A = ampere; C = coulomb; s = second)
- $3.6C = 1mAh$ (C = coulomb; mAh is milliamp-hour, a common unit for batteries)

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5

D.1.2 Volt Quantities

Volts are basically measures of energy per unit of charge. Volts are also known as electromotive force (EMF), or $\in$. Volts can be expressed in a number of ways:

- $V = \frac{J}{C}$ (J = joules; C = coulombs)
- $V = \frac{\text{potential energy}}{\text{charge}}$
- $V = \frac{N \cdot m}{C}$ (N = newtons; m = meters; C = coulombs)
- $V = \frac{kg \cdot m^2}{A \cdot s^3}$ (kg = kilograms; m = meters; A = amperes; s = seconds)
- $V = \frac{d\phi}{dt}$ (Faraday's law of induction—voltage is the derivative of the flux of the magnetic field with respect to time)

D.1.3 Resistance and Conductance Quantities

Resistance is in ohms. The inverse of resistance is conductance (the ability of current to flow through a wire) and is measured in siemens (S). The siemens unit is also called a mho (ohm spelled backward) and is sometimes marked by an upside-down omega (Ω):

- $G = \frac{1}{R}$ (G = conductance in siemens, R = resistance)
- $G = \frac{I}{V}$ (G = conductance; I is current; V is voltage)
- $R = \frac{V}{I}$ (Ohm's law)

Individual materials have a resistivity *(ρ)*.

$$R = \rho \cdot \frac{\text{length}}{\text{cross-sectional area}} \tag{D.1}$$

In other words, from beginning to end, resistance decreases with cross-sectional area and increases with length.

D.1.4 Ohm's Law

V is voltage (in volts), I is current (in amperes), and R is resistance (in ohms):

$$V = I \cdot R \tag{D.2}$$

D.1.5 Power

P is in watts. The following hold true for DC circuits. For AC circuits, they hold true if the resistance is actually an impedance:

- $P = V \cdot A$
- $P = I^2 R$
- $P = \frac{V^2}{R}$

D.1.6 Capacitance

Capacitance is the ability to store charge.

The fundamental equation for a capacitor is

$$Q = V \cdot C \tag{D.3}$$

Q is the amount of charge stored, V is the voltage across the terminals, and C is the capacitance in farads.

The derivative of this equation with respect to time is

$$\frac{dQ}{dt} = \frac{dV}{dt} \cdot C \tag{D.4}$$

Because current is the derivative of charge, we can then say

$$I = C\frac{dV}{dT} \tag{D.5}$$

The capacitance of capacitors is given by the equation

$$C = \in_r \in_0 \frac{A}{d} \tag{D.6}$$

Here C is capacitance, $\in_r$ is the dielectric constant of whatever separates the capacitor's plates, $\in_0$ is the dielectric constant of free space, A is the area of the plates in square meters, and d is the distance between the plates in meters.

D.1.7 Inductance

The fundamental equation for an inductor is

$$\phi = L \cdot I \tag{D.7}$$

Here, ϕ is the flux of the magnetic field in Webers, L is inductance in Henries, and I is current in amperes. The derivative gives you voltage:

$$\frac{d\phi}{dt} = L\frac{dI}{dt} \tag{D.8}$$

$$V = L\frac{dI}{dt} \tag{D.9}$$

In other words, the voltage produced is proportional to the change in current.

The inductance of a coil of wire can be calculated by

$$L = \frac{\mu \cdot N^2 \cdot A}{l} \tag{D.10}$$

Where N is the number of turns of wire, A is the area of the coil, l is the length of the coil, and μ depends on the core being used.

D.2 Semiconductors

Components made from silicon are known as semiconductors and have very useful nonlinear properties.

D.2.1 Diodes

Diodes do not have a fixed voltage drop as we assume in this book. It is an exponential function, but is steep enough to act like a fixed 0.6 V voltage drop for most purposes. The actual equation is

$$I = I_S\left(e^{\frac{V}{\eta V_T}} - 1\right) \tag{D.11}$$

I_S is the saturation current (depends on the construction of the diode), V is the voltage, η is either 1 for germanium or 2 for silicon, and V_T is known as the thermal voltage (the amount of voltage created just by particles moving around at a given temperature, usually about 0.026 V at room temperature).

D.2.2 NPN BJT

While we discussed general rules about BJTs, the technical model used to model them is known as the Ebers-Moll model. This model is much more complex to use, which is why we don't discuss it much in the chapter.

There are also several different Ebers-Moll models, depending on the level of detail required. The basic Ebers-Moll model for a conducting but unsaturated transistor is as follows:

$$I_E = I_S\left(e^{\frac{V_B E}{V_T}} - 1\right) \tag{D.12}$$

In this I_E is the emitter current (you can also use it for the collector current, since they are approximately equal). I_S is the saturation current of the base-emitter diode, and V_T is the thermal voltage, just like for diodes.

D.3 DC Motor Calculations

The voltage drop across a motor (V_m) is defined by the following equation:

$$V_m = V_b + R_m I_m$$

where V_b is the back EMF of the motor, R_m is the internal resistance of the motor's wiring, and I_m is the current flowing through the motor—so, basically, just Ohm's law plus the back EMF generated by the spinning of the motor.

So how much back EMF is created? We can determine that like this:

$$V_b = K_e \omega$$

In this equation, K_e varies by the motor and is usually given in volts per RPM or volts per radians per second. ω is merely the rotational speed in the units given.

Likewise, the torque generated can be determined from this equation:

$$T = K_T I_m$$

In this equation, K_T is the torque constant for the motor (be careful of the units), and I_m is the current going through the motor. Knowing the peak (stall) current, you can find the maximum torque available for the motor.

Interestingly, you can see that increasing the torque will actually affect, to some degree, the RPM of the motor. The full equation for the voltage across the motor is

$$V_m = K_e \omega + R_m I_m$$

The torque will affect I_m. That, in effect, will increase the voltage drop given by $R_m I_m$. Given a fixed voltage source, this will leave less voltage available for the $K_e \omega$ part of the equation. Since K_e is a constant, that means that ω will be reduced to some extent.

D.4 555 Timer Oscillator Frequency Equation

In Chapter 18, we learned to make oscillators using the 555 timer chip. In the actual chapter, I wanted you to focus on actually learning what was happening with the 555 timer rather than using a formula. However, there is a nice, simple formula that allows you to relate the resistor/capacitor network of the 555 timer to the final output frequency.

The formula is as follows:

$$f = \frac{1.44}{C(R_1 + 2R_2)} \tag{D.13}$$

In this equation, f is the frequency, R_1 is the resistor coming from the supply voltage, R_2 is the resistor next to the capacitor, and C is the timer capacitor.

To understand where this equation comes from, remember that frequency is just $\frac{1}{\text{period}}$. We can use time constant formulas to find the period and then just flip it to find the frequency.

If you recall, the period is just the total time it takes to complete a charge/discharge cycle. The 555 charges through *both* R_1 and R_2, but only discharges through R_2. Additionally, since it is just bouncing back and forth between $\frac{1}{3}$ and $\frac{2}{3}$ full, it only uses 0.693 time constant.

Therefore, we can have two formulas, one for the time charging and one for the time discharging:

$$\begin{aligned} T_{\text{CHARGE}} &= 0.693C(R_1 + R_2) \\ T_{\text{DISCHARGE}} &= 0.693R_2 \end{aligned}$$

The total period is just these two time periods added together. Therefore, you get

$$
\begin{aligned}
T_{\text{PERIOD}} &= 0.693C(R_1 + R_2) + 0.693CR_2 \\
&= 0.693C((R_1 + R_2) + R_2) && \text{Factoring out } 0.693C \\
&= 0.693C(R_1 + 2R_2) && \text{Regrouping}
\end{aligned}
$$

Since $f = \frac{1}{T_{\text{PERIOD}}}$, we can flip the preceding equation and get

$$
\begin{aligned}
f &= \frac{1}{0.693C(R_1 + 2R_2)} \\
&= \frac{1}{0.693}\frac{1}{C(R_1 + 2R_2)} && \text{Regrouping} \\
&\approx 1.44\frac{1}{C(R_1 + 2R_2)} \\
&= \frac{1.44}{C(R_1 + 2R_2)}
\end{aligned}
$$

At the end of the day, this is exactly what you did when you solved those problems; you just did it by hand instead of using a nice little formula. All a formula does is encapsulate the things that you normally do anyway, but simplifies it down to a set of predefined steps.

I have a love/hate relationship with formulas. Formulas are nice because they are easy to use. However, when you use them, it makes it easy to forget the basic facts behind them. The basic facts are more important than the formula, because you can rearrange the basic facts and develop all sorts of formulas depending on your needs. In fact, if you know the basic facts and you know how to make formulas, if you ever forget a formula, it is easy to determine one from the basic facts. Therefore, while memorizing formulas is important, knowing *why* formulas work is just as important, as it allows you to think more deeply and broadly and adapt your knowledge to new situations.

D.5 Output Gain Calculations in BJT Common Emitter Applications

In Chapter 25, we showed how to put together a multistage amplifier for sound coming in from a microphone.

However, we handwaved away a lot of the calculations needed for it. That's because they are, well, difficult.

Anyway, if you don't like handwaving, then this section is for you.

In Chapter 25, we said that, on a common emitter amplifier, the gain on the output current compared to the incoming current was determined by $\frac{R_{B2}R_C}{R_E R_O}$, where R_{B2} is the bottom resistor from the voltage divider that the signal is fed into, R_C is the collector resistor, R_E is the emitter resistor, and R_O is the output resistance (see Figure 25-4 for the diagram).

Recognize that any incoming current into the circuit from the input (as opposed to the quiescent current coming from the voltage source through R_{B1}) will have two alternative paths to take—through R_E or through R_{B2}. The relative amounts that do this are going to be based on the amount of voltage that R_E utilizes.

What we want to do is to analyze the gain between our *incoming* current (let's call that I_{IN}) and the current at the collector (I_C). That is our real gain from the incoming current.

The problem is knowing how much the actual amount of the incoming current (I_{IN}) will be going through R_{B2} or R_E. It will depend on the voltage in R_E. More voltage in R_E will mean that the current is likely to go down R_{B2} instead. This already tells us that the size of R_E will limit the amount of gain, as increased beta in the transistor will also increase the voltage of R_E which will also limit the amount of incoming current, which will have an equivalent effect of reducing gain.

Now, our circuit will primarily be working at a quiescent currentc, Q. We have already noted that this current will be the dominant signal. That means that the voltage between the base and the ground will be a combination of the diode voltage drop, the current in R_E from Q, and the current in R_E from the transistor's beta (βQ). Therefore, the total voltage drop from the base to the ground will be $V_{BG} = QR_E + \beta QR_E + 0.6$.

We can treat this as a "virtual resistance." The current coming in at I_{in} will be small comparatively, so we can reverse Ohm's law to see what this looks like as a resistance to the incoming current. Because $R = \frac{V}{I}$, we can say that the resistance here to new current is

$$R_{BG} = \frac{QR_E + \beta QR_E + 0.6}{Q} = R_E + \beta R_E + \frac{0.6}{Q} \approx R_E + \beta R_E \tag{D.14}$$

We dropped the $\frac{0.6}{Q}$ term because it would give us a very small comparative resistance, and we are trying to simplify our lives.

So now, when we have new current coming in at I_{IN}, it has two branches it can follow, each with its own resistance. Some of it will be wasted through R_{B2}, and some of it will be amplified through R_{BG}. The amount going through R_BG we will call I_U (for *usable* incoming current). The amount going through R_{B2} will just be $I_{IN} - I_U$.

In parallel resistances, the relative amount of current going through each resistor can be calculated as

$$\frac{I_1}{I_2} = \frac{R_2}{R_1} \tag{D.15}$$

You can see this from Ohm's law. Since $I_1 = \frac{V_1}{R_1}$ and $I_2 = \frac{V_2}{R_2}$, the ratio of the currents becomes $\frac{I_1}{I_2} = \frac{\frac{V_1}{R_1}}{\frac{V_2}{R_2}}$. Since $V_1 = V_2$ (the resistors are parallel and so have the same voltage drop), then this reduces to Equation D.15.

So, for this, I_{IN} will be divided between R_{B2} and R_{BG}. Therefore, we can say

$$\frac{I_U}{I_{\mathrm{IN}} - I_U} = \frac{R_{B2}}{R_{BG}} \tag{D.16}$$

$$I_U = I_{\mathrm{IN}} \frac{R_{B2}}{R_{BG}} - I_U \frac{R_{B2}}{R_{BG}} \tag{D.17}$$

$$I_U + I_U \frac{R_{B2}}{R_{BG}} = I_{\mathrm{IN}} \frac{R_{B2}}{R_{BG}} \tag{D.18}$$

$$I_U = \frac{I_{\mathrm{IN}} R_{B2}}{R_{BG}\left(1 + \frac{R_{B2}}{R_{BG}}\right)} \tag{D.19}$$

$$I_U = \frac{I_{\mathrm{IN}} R_{B2}}{R_{BG} + R_{B2}} \tag{D.20}$$

The amount of current through the collector that comes through the usable current from the signal (and not from the quiescent current, Q) we can denote as I_{CQ}. Therefore

$$I_{CQ} = \beta I_U \tag{D.21}$$

So the total amplification of our signal will be the ratio of the amplified output I_{CQ} to the incoming current I_{IN}:

$$\frac{I_{CQ}}{I_{\mathrm{IN}}} = \frac{\beta I_U}{I_{\mathrm{IN}}} \tag{D.22}$$

$$= \frac{\beta\left(\dfrac{I_{\mathrm{IN}} R_{B2}}{R_{BG} + R_{B2}}\right)}{I_{\mathrm{IN}}} \tag{D.23}$$

$$= \frac{\beta}{I_{\mathrm{IN}}} \frac{I_{\mathrm{IN}} R_{B2}}{R_{BG} + R_{B2}} \tag{D.24}$$

$$= \frac{\beta R_{B2}}{R_{BG} + R_{B2}} \tag{D.25}$$

$$\approx \frac{\beta R_{B2}}{R_E + \beta R_E + R_{B2}} \tag{D.26}$$

As you can see, this attenuates the action of β since it is in both the numerator and the denominator.

To see the extremes, if the β is low (i.e., single digits) and R_E is small compared to R_{B2}, this reduces to

$$\frac{I_{CQ}}{I_{\mathrm{IN}}} \approx \beta \frac{R_{B2}}{R_{B2}} = \beta \tag{D.27}$$

As β increases, the dominating terms become

$$\frac{I_{CQ}}{I_{\mathrm{IN}}} \approx \frac{\beta R_{B2}}{\beta R_E} = \frac{R_{B2}}{R_E} \tag{D.28}$$

We will call this particular gain γ (a lowercase Greek “g”). So therefore

$$\gamma = \frac{R_{B2}}{R_E} \tag{D.29}$$

Now, the actual output current (that goes through the capacitor to the next stage or to the speaker) is actually going to be determined largely by the resistance of the next stage!

What we have determined so far is the amount of current that goes through I_C from I_{IN}. The total amount of current in I_C is going to be $\beta(Q + I_U)$. However, Q is going to be essentially stable and therefore is not going to change the voltage on R_C, and capacitors only see voltage *changes*. Therefore, the only part of that which will be transmitted through the capacitor is the voltage change on R_C due to I_U, which will be βI_U or, in terms of our actual input signal, γI_{IN}.

Next, we have to figure out how much current we will actually be transmitting out of our amplification stage. This is the current that goes out through the coupling capacitor. Now, since the coupling capacitor is *only* transmitting changes, the only current that goes through that branch of the circuit is changing current. Therefore, the quiescent current does not travel through the capacitor.

So what we have to do is figure out how to estimate the amount of current coming into the capacitor. We have already designated I_{IN} as our input current, I_U as the usable current that is amplified at the base, and I_C as the current coming in to the collector.

Current coming out of R_C has two choices of where to go. It can either go out to the next part of the circuit through the capacitor, or it can go through the transistor. This will depend on the resistance of each route.

We need to start by calculating the quiescent resistance of the route that goes through the transistor and R_E. If V is our positive voltage, then, when the current goes through R_C, it will have dropped. Then it will drop again in the rest of the circuit.

The amount that the voltage drops going through R_C is $I_T R_C$ (because the total voltage goes through R_C). We can replace I_T with $I_O + I_C$, which means the voltage drop will be $(I_O + I_C)R_C$. The rest of the voltage drop we will call the "transistor path" voltage. It is simply

$$V_{\text{TPATH}} = V - \left(\left(I_O + I_C\right)R_C\right) \tag{D.30}$$

Ohm's law says that $R = \frac{V}{I}$, so the resistance on this path will be

$$R_{\text{TPATH}} = \frac{V - \left(\left(I_O + I_C\right)R_C\right)}{I_C} \tag{D.31}$$

Since $I_C = \beta Q$, then

$$R_{\text{TPATH}} = \frac{V - \left(\left(I_O + \beta Q\right)R_C\right)}{\beta Q} \tag{D.32}$$

The resistance of the other path will essentially be the Thévenin resistance of the output circuit (whatever lies beyond the capacitor). We will talk about what it should be shortly, but for now let's just call it R_O.

So that gives us two resistance values: R_O and R_{TPATH}. When we have a change in current (i.e., from I_{IN}), it will draw extra current, which will go down both paths. The amount that goes down each path will depend on the resistance of each path.

Because the current changes are small compared to the quiescent current, we can ignore the impact that these changes have on the resistances themselves (i.e., how the change in current affects R_{TPATH}). We will use I_T to represent the total *additional* current that comes across R_C due to the currents coming in at I_{IN}. I_O will be the amount that actually goes on out of the circuit.

As mentioned earlier, given two parallel resistances, R_1 and R_2, $\frac{I_1}{I_2} = \frac{R_2}{R_1}$. Therefore, we can say that the relative amount of current between the amount of current that goes out I_O and the amount of current that goes through the transistor (γI_{IN}) is

$$\frac{I_O}{\gamma I_{\mathrm{IN}}} = \frac{\dfrac{V - \left(\left(I_O + \beta Q\right)R_C\right)}{\beta Q}}{R_O} = \frac{V - \left(\left(I_O + \beta Q\right)R_C\right)}{\beta Q R_O} \tag{D.33}$$

We can then solve for I_O:

$$I_O \beta Q R_O = \left(V - \left(\left(I_O + \beta Q\right)R_C\right)\right)\gamma I_{\mathrm{IN}} \tag{D.34}$$

$$I_O \beta Q R_O = V\gamma I_{\mathrm{IN}} - \gamma I_{\mathrm{IN}} R_C I_O - \gamma I_{\mathrm{IN}} \beta Q R_C \tag{D.35}$$

$$I_O \beta Q R_O + \gamma I_{\mathrm{IN}} R_C I_O = V\gamma I_{\mathrm{IN}} - \gamma I_{\mathrm{IN}} \beta Q R_C \tag{D.36}$$

$$I_O\left(\beta Q R_O + \gamma I_{\mathrm{IN}} R_C\right) = I_{\mathrm{IN}}\gamma\left(V - \beta Q R_C\right) \tag{D.37}$$

$$I_O = \frac{I_{\mathrm{IN}}\gamma\left(V - \beta Q R_C\right)}{\beta Q R_O + \gamma I_{\mathrm{IN}} R_C} \tag{D.38}$$

Therefore, the complete gain (we will denote with a capital gamma, Γ) will be the ratio of I_{IN} (the actual input signal) to I_O (the actual output to the next stage). By using the preceding equivalency for I_O, we can determine

$$\Gamma = \frac{I_O}{I_{\mathrm{IN}}} = \frac{\dfrac{I_{\mathrm{IN}}\gamma\left(V - \beta Q R_C\right)}{\beta Q R_O + \gamma I_{\mathrm{IN}} R_C}}{I_{\mathrm{IN}}} \tag{D.39}$$

$$= \frac{I_{\mathrm{IN}}\gamma\left(V - \beta Q R_C\right)}{\left(\beta Q R_O + \gamma I_{\mathrm{IN}} R_C\right) I_{IN}} \tag{D.40}$$

$$= \frac{\gamma\left(V - \beta Q R_C\right)}{\beta Q R_O + \gamma I_{\mathrm{IN}} R_C} \tag{D.41}$$

Because we are using relatively low voltages, V is going to be essentially irrelevant and can be removed. Because I_{IN} is small and R_C is likely small compared to R_O, we can remove the term $\gamma I_{\mathrm{IN}} R_C$. Therefore, that leaves

$$\Gamma = \frac{I_O}{I_{\mathrm{IN}}} \approx \frac{-\gamma\beta Q R_C}{\beta Q R_O} \tag{D.42}$$

$$\approx -\gamma\frac{R_C}{R_O} \tag{D.43}$$

Since $\gamma = \frac{R_{B2}}{R_E}$, we can also write this as

$$\Gamma = \frac{I_O}{I_{\text{IN}}} \approx -\gamma \frac{R_C}{R_O} = -\frac{R_{B2} R_C}{R_E R_O} \tag{D.44}$$

Also note that this assumes that $R_O > R_C$ and $R_C > R_E$.

This is the total current gain from the input to the output. Notice that this value is negative. As we mentioned earlier, this kind of amplifier *inverts* the signal. Therefore, the gain is negative.

As you probably noticed, there were a lot of steps and a lot of simplifications. There were a lot of things where we handwaved away "insignificant" values and the sort. That's the way that electronics often works—you have to figure out which pieces really matter.

Now, thankfully, not everyone has to write these equations out because someone came in before them and deduced them. Personally, I think it's fun, but I recognize that isn't everyone's experience. Most electronics projects utilize more basic and straightforward applications of Ohm's law. But, occasionally, you have to pull out your whiteboard and go to town.

Of course, one thing I left out was how to determine R_{O}, the resistance of the circuit that follows.

If the output goes to another amplification stage, you may have to do more math to find the resistance of the next stage. The hard way is to look at the calculations earlier in this section for calculating R_{BG} and R_{B2} and calculate them for the next stage and treat them as parallel resistors. However, an easy way is to simply use R_{B2} to stand in for R_O. It's not exactly correct, but then that isn't what we are aiming for. We're just looking for the ballpark.

If the output goes to your headphones, then all you need to do is plug in the resistance of your headphones. Most headphones are less than 50Ω, with 16Ω being a fairly typical value.

D.6 The Thévenin Formula

In Chapter 26, we used two formulas which allowed us to calculate the Thévenin equivalent circuit for circuits experimentally. Equations 26.1 and 26.2 seem strange and complicated, but they are actually directly deducible from Ohm's law and the concept of an equivalent circuit.

The Thévenin Theorem states that any combinations of voltage sources and resistances can be replaced by a single voltage source and a single resistance. We will call this our Thévenin voltage source (V_T) and our Thévenin impedance (R_T). If we hook up a load (i.e., a fixed resistance) across the output terminals of this circuit, we will know the resistance that was added (because *we* added it), and we can measure the voltage drop across the resistor easily enough with a multimeter or oscilloscope.

We will need to measure this using two different loads because we have two unknowns—V_T and R_T. Using two different loads will give us two different equations using Ohm's law that will allow us to solve for two variables. We will call our lower-resistance load R_L, and the voltage drop across the R_L resistor will be V_L. Likewise, our higher-resistance load we will call R_H, and the voltage drop across it will be V_H. The current running through each of these loads (I_L and I_H) can be given by

$$V_L = I_L \cdot R_L$$
$$V_H = I_H \cdot R_H$$

That is just simply Ohm's law. We can also use Ohm's law to develop equations for the whole circuit, including the Thévenin equivalent voltage and impedance. Remember, because of the current rules, whatever current is flowing through our resistor must also be flowing in our Thévenin equivalent impedance. Therefore, the Thévenin equivalent voltage will be the current multiplied by the two impedances together. Therefore, this yields the following equations:

$$V_T = I_L\left(R_L + R_T\right)$$
$$V_T = I_H\left(R_H + R_T\right)$$

Both of these equations solve for V_T, given an unknown of R_T. We can also rearrange either of these to solve for R_T. Let's rearrange the first one to do that:

$$\begin{aligned} V_T &= I_L\left(R_L + R_T\right) && \text{Original equation} \\ \frac{V_T}{I_L} &= R_L + R_T && \text{Divide both sides} \\ \frac{V_T}{I_L} - R_L &= R_T && \text{Subtract } R_L \\ R_T &= \frac{V_T}{I_L} - R_L && \text{Solved for } R_T \end{aligned}$$

This is the same as Equation 26.2. However, it requires V_T to work. Now that we have an equation for R_T, we can substitute that back in and get an equation for V_T without using R_T. Using basic algebra manipulations, we can do the following:

$$\begin{aligned} V_T &= I_H\left(R_T + R_H\right) && \text{Original equation} \\ V_T &= I_H R_T + I_H R_H && \text{Distributive rule} \\ V_T &= I_H\left(\frac{V_T}{I_L} - R_L\right) + I_H R_H && \text{Substituting for } R_T \end{aligned}$$

$$V_T = I_H \frac{V_T}{I_L} - I_H R_L + I_H R_H \quad \text{Distributing}$$

$$V_T - I_H \frac{V_T}{I_L} = -I_H R_L + I_H R_H \quad \text{Get the} V_T \text{s together}$$

$$V_T \left(1 - \frac{I_H}{I_L}\right) = I_H \left(R_H - R_L\right) \quad \text{Factor both sides}$$

$$\frac{V_T}{I_L} = R_L + R_T \qquad \text{Divide both sides}$$

$$V_T = \frac{\frac{V_H}{R_H}\left(R_H - R_L\right)}{1 - \frac{V_H R_L}{R_H V_L}} \quad \text{Replace currents with Ohm's law equivalents} \left(\frac{V}{R}\right)$$

As you can see, this is Equation 26.1.

D.7 Electronics and Calculus

Calculus is a favorite subject of mine, and many parts of electronics make a lot of sense in the light of calculus.

D.7.1 Current and Voltage

First of all, recognize that electronics includes both static and dynamic quantities. Charge, for instance, is a static quantity. Current, though, is the *movement* of charge and thus is a dynamic quantity. Current entering or leaving a point can be written as a differential:

$$I = \frac{\mathrm{d}Q}{\mathrm{d}t} \tag{D.45}$$

Like current, voltage is a dynamic quantity, which is the change in the magnetic flux (ϕ):

$$V = \frac{\mathrm{d}\phi}{\mathrm{d}t} \tag{D.46}$$

D.7.2 Capacitors and Inductors

The static equation governing a capacitor is

$$Q = V \cdot C \tag{D.47}$$

where Q is the charge, V is the voltage, and C is the capacitance. Taking the derivative of both sides, this can be converted into a dynamic equation:

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = C\frac{\mathrm{d}V}{\mathrm{d}t} \tag{D.48}$$

Since $\frac{\mathrm{d}Q}{\mathrm{d}t} = I$, we can rewrite this as

$$I = C\frac{\mathrm{d}V}{\mathrm{d}t}. \tag{D.49}$$

What this means is that the current is proportional to the *change* in voltage.

The static equation governing an inductor is similar:

$$\phi = L \cdot I \tag{D.50}$$

Taking the derivative of both sides yields

$$\frac{\mathrm{d}\phi}{\mathrm{d}t} = L \cdot \frac{\mathrm{d}I}{\mathrm{d}t} \tag{D.51}$$

Since $V = \frac{\mathrm{d}\phi}{\mathrm{d}t}$, this can be rewritten as

$$V = L \cdot \frac{\mathrm{d}I}{\mathrm{d}t}. \tag{D.52}$$

In other words, on inductors, the voltage is proportional to the change in current.

D.7.3 Time Constants

If an ideal capacitor were connected to an ideal voltage source, then the capacitor would charge instantaneously. However, as described in Chapter 17, when charged through a resistor, it takes a certain amount of time to do the charging. The RC time constant combined with Figure 17-1 gives a simple way of figuring out these timings.

A more complete way of understanding this is with the following equation:

$$V_C = V_S\left(1 - e^{\frac{-t}{RC}}\right) \tag{D.53}$$

Here, V_C is the voltage across the capacitor, V_S is the voltage source, t is the time from the start of charging (in seconds), and R and C are the resistance and capacitance. e is Euler's constant. To find the amount of time, we can solve for t:

$$t = -RC\ln\left(1 - \frac{V_C}{V_S}\right) \tag{D.54}$$

Here, $\frac{V_C}{V_S}$ is the voltage percentage (expressed as a decimal). Therefore, the number of time constants is given by $-\ln\left(1 - \frac{V_C}{V_S}\right)$.

So how was Equation D.53 even determined? Since the voltage across the capacitor depends on the charge in the capacitor, then $V_C = \frac{Q}{C}$. Since the amount of current flowing through the resistor can be determined by the voltage and the voltage will be based on the difference between the source and the capacitor, then $I = \frac{V_S - V_C}{R}$. From the capacitor side, $I = C\frac{dV}{dt}$. Since the current had to come from somewhere, it had to come from the resistor. So that means these currents are equal. Therefore, $\frac{V_S - V_C}{R} = C\frac{dV_C}{dt}$.

We can solve this as a differential equation, by separating the variables. This gives $\frac{1}{R}dt = \frac{dV_C}{V_S - V_C}$. Since battery voltages are constant, V_S is a constant, so this integrates to $\frac{t}{R} + D = -C\ln\left(V_S - V_C\right)$, where D is the constant of integration.[1] Rearranging, this becomes $\frac{-t}{RC} + D = \ln\left(V_S - V_C\right)$. Exponentiating both sides gives $De^{\frac{-t}{RC}} = V_S - V_C$. At time $t = 0$, $D = VS - \text{VC}$. Since we are assuming that the starting capacitor voltage is zero, this means at that time, $D = V_S$. Now this becomes $V_S e^{\frac{-t}{RC}} = V_S - V_C$. Rearranging to solve for V_C yields $V_C = V_S - V_S e^{\frac{-t}{RC}}$. This can be simplified to yield Equation D.53.

---

[1] *D* undergoes lots of changes, and I'm not going to justify them all, but they are based on the fact that *D* is an unknown constant, and any manipulation of other constants will still yield an unknown constant.

APPENDIX E

Simplified Datasheets for Common Devices

Datasheets are what electronics manufacturers use to communicate the specifications of their components to the engineers who will use them in projects and products. However, datasheets tend to be horrendously complex. Typical datasheets run about 10–30 pages, and most of that is completely useless for someone just trying to get a circuit to work. Sometimes the first pages of the datasheet are all of the different packages the chip is available in, and the pages detailing what the component *actually does* are almost in the very back. I've even seen many sheets that never speak of what a device is for or why you would want to use it.

So, to simplify your life, I have created some simplified datasheets. All of these focus on the typical component styles used in solderless breadboards. These datasheets are also oriented toward *generic* parts. Each manufacturer has their own parts with their own specs and their own benefits and drawbacks. Some manufacturers may have higher or lower current specifications, faster or slower switching times, or other variations. These datasheets should be used as a starting point, but not as a final authority.

Use these datasheets to find the component you want and find its general characteristics, what each of the pins are for, and what they should be hooked up to. However, the manufacturer's datasheet should be consulted for final specifications.

E.1 Batteries

E.1.1 Overview

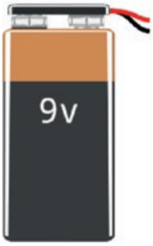
A battery is a voltage source, meaning that it provides a fixed voltage over a wide range of currents.

Batteries have two terminals—positive and negative (or ground). The rated voltage for the battery is the typical voltage between these two terminals. However, a battery's actual voltage will vary quite a bit over the battery's lifetime.

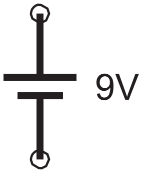
Batteries also exhibit a small amount of *internal resistance* (also known as *equivalent series resistance*) which limits the amount of current they can provide.

E.1.2 Variations

Battery Type	**Typical Voltage**	**Voltage Range**	**Typical Capacity**
AAA	1.5	1.1–1.5	540 mAh
AA	1.5	1.1–1.5	1100 mAh
C	1.5	1.1–1.5	3800 mAh
D	1.5	1.1–1.5	8000 mAh
E(9 V)	9	7.2–9.6	1200 mAh
Coin cell (all sizes)	3	2–3.6	30–620 mAh



Battery



Schematic Symbol

E.1.3 Notes

Putting batteries together in parallel increases their available current but does not alter their voltage. Putting batteries together in series adds their voltages but does not change the available current.

Coin cell batteries are designated CRxxxx, where the first two digits of xxxx are the diameter in millimeters and the remaining digits tell the height in tenths of millimeters.

E.2 Resistors

E.2.1 Overview

Resistors are devices that resist the flow of current from one terminal to the other. The resistance of a resistor is measured in ohms.

The power (in watts) dissipated by a resistor is measured by the current flowing through it multiplied by the voltage drop across it. Resistors are rated for their maximum safe amount of power dissipation.

Resistors are often used to provide a safe limit to the amount of current flowing in a circuit or to provide a voltage drop for an input to another circuit.

E.2.2 Finding a Resistor Value

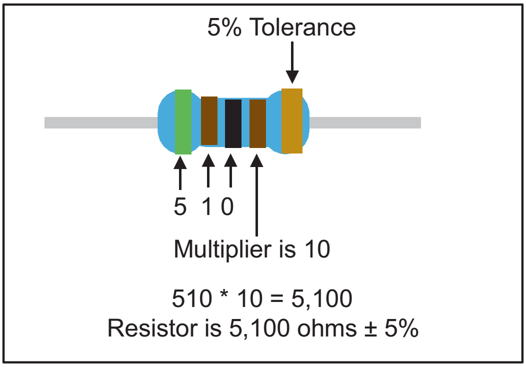
The colored bands on a resistor tell you how much resistance it has. However, these are very tiny, and sometimes it is easier just to measure it with a multimeter.

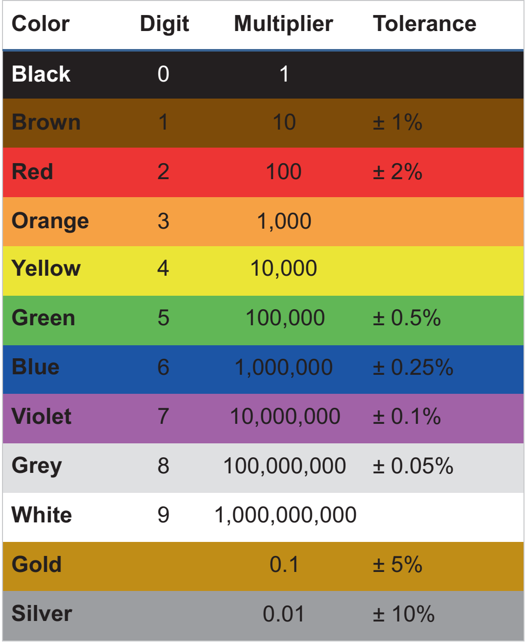
To interpret the colored bands, you first need to orient your resistor so that the last band is on the right (it is usually slightly thicker and set off from the others). This band is the *tolerance* band (use the tolerance column on the right).

The next band to the left is the *multiplier*. Use the multiplier column to read this value. The other bands are used as digits of a number which are then multiplied by the multiplier.

Resistor

Schematic Symbol





Color	Digit	Multiplier	Tolerance
Black	0	1	
Brown	1	10	± 1%
Red	2	100	± 2%
Orange	3	1,000	
Yellow	4	10,000	
Green	5	100,000	± 0.5%
Blue	6	1,000,000	± 0.25%
Violet	7	10,000,000	± 0.1%
Grey	8	100,000,000	± 0.05%
White	9	1,000,000,000	
Gold		0.1	± 5%
Silver		0.01	± 10%

E.3 Diodes

E.3.1 Overview

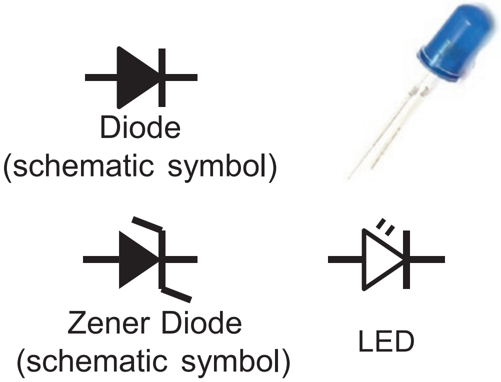
A diode is a device that only permits current to flow in one direction and blocks current in the other direction.

All diodes exhibit a *forward voltage drop*, which is the amount of voltage they consume when current is flowing. This is typically 0.6 V, though it varies a little based on current flow.

Diodes also have a *reverse breakdown voltage* which is the amount of voltage they can handle in the blocking direction before they start conducting anyway.

E.3.2 Variations

- An LED is a light-emitting diode. LEDs vary in their forward voltage drop based on their color (red=1.8; blue=3.3).
- A Zener diode is a diode that is built for a specific (usually lower than usual) reverse breakdown voltage. The reverse breakdown voltage of a Zener is more fixed/reliable than its forward voltage drop.
- A Schottky diode has a lower forward voltage drop (0.15–0.45V) and is able to turn on and off faster than ordinary diodes and accordingly also dissipates less heat.



E.3.3 Forward Voltage Drop

Diodes are often considered to not have a resistance, but instead to have a simple voltage drop. That is, you apply the voltage drop and ignore resistance. That works for the math, but the reality is a bit different. Essentially, a diode is a variable resistor, where the resistance varies in order to keep the voltage drop essentially fixed. Therefore, diodes dissipate power just like other components, with the voltage drop multiplied by the current flowing through them.

E.3.4 Usages

- Prevent batteries from being inserted backward in a circuit
- Provide a fixed voltage drop between two points on a circuit, either through the forward voltage drop (regular diode) or the reverse breakdown voltage (Zener diode)
- Convert AC to DC by only allowing the positive flows through the circuit

E.4 Capacitors

E.4.1 Overview

A capacitor is a device that stores energy using a charged electric field. The size of the capacitor is proportional to the amount of charge that it can store. This size is measured in farads.

Changes in the voltage of one side of the capacitor will be transmitted through to the other side, but a steady-state DC voltage will not after the capacitor initially charges up.

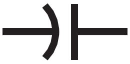
This means that capacitors are ideal for sending AC signals through different DC bias levels, as merely the changes in voltage (the AC component) will be transmitted through the capacitor, while the bias voltages themselves will be blocked. A simplified description says that capacitors allow AC and block DC.

E.4.2 Variations

- Capacitors can be made of a variety of materials, which affect several of their properties.
- Capacitors can be non-polar (it doesn't matter which side is which) or polar (one side should always be more positive than the other).
- Ceramic disk capacitors are the classic example of non-polar capacitors, and electrolytic capacitors are the classic example of polar capacitors.
- Capacitors also vary in the amount of voltage that can be used with them.

Common Capacitor Types
(tantalum, electrolytic, ceramic disk)

Schematic Symbol (nonpolar)



Schematic Symbol (polar)
(straight line is the positive side)

E.4.3 Finding Capacitance Values

Larger capacitors simply have their capacitance values printed on them. Smaller capacitors just have a set of digits printed on them, such as “104,” sometimes with a letter after them. These are a little harder to interpret.

On these capacitors, the first digits should be read as is, and the last digit is the number of additional zeroes that should be tacked onto the end. This value is then interpreted as picofarads.

So the value “104” means we take “10” and then add “4” zeroes, giving us “100000.” This is the capacitance in picofarads. This is the same as 100 nanofarads. If there is any code starting with a letter, this is a tolerance marking.

E.5 Inductors

E.5.1 Overview

An inductor is a device that stores energy in its magnetic field. The size of the inductor (in Henries) is proportional to the size of the magnetic flux it can create for a given level of current.

Inductors prevent changes in current by varying their electric field. Reducing the current through an inductor causes a partial collapse of the field, creating a voltage on the other side, which feeds current.

A simplified way of understanding inductors is to think of them as allowing DC but blocking AC.

Inductors are generally constructed by winding wire around an iron core material.

E.5.2 Uses

- Inductors serve as the main gateway between electrical and mechanical actions through the magnetic field.
- Inductors are used to open and close valves and switches magnetically.
- Inductors are used to drive electric motors.
- Inductors are used to limit certain frequencies in circuits.
- Inductors are used in speakers, where changes in magnetism cause the speakers to move.
- Inductors can be used as transformers to convert power from one voltage/current combination to another of equal power.

Various styles of inductors

Schematic Symbol

E.5.3 Inductive Kick

Inductors use current to maintain their magnetic fields. When the current decreases suddenly, the magnetic field is converted into a large voltage, creating what is known as an inductive kick.

This kick can be damaging to electronic components. To mitigate this, a diode can be placed backward across the inductor so that, under normal circumstances, it does not conduct, but when an inductor produces a voltage spike, it re-routes the current back through the inductor where it can dissipate slowly in a loop rather than building up and damaging other components with a large voltage spike.

E.5.4 Inductor Color Codes

Simple inductors (i.e., those in packaged casings) are marked identically to resistors, except that the resulting value is in *micro*henries rather than just Henries.

E.6 NPN BJTs

E.6.1 Overview

Transistors come in a variety of configurations. BJTs (bipolar junction transistors) are *current-amplifying* devices.

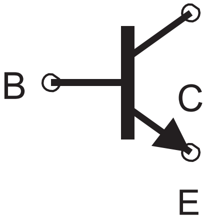
In an NPN (negative-positive-negative) transistor, small changes to the current at the base result in large changes in current coming into the collector.

In a transistor, the voltage at the emitter is one diode drop (0.6 V) below the base, and if it is not, the transistor does not conduct. The transistor's beta is the multiplier between the base current and the collector current. The collector's voltage must be above the base voltage, or the transistor is saturated (acts as a short circuit from collector to emitter).

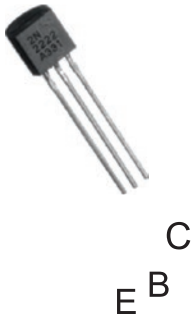
If these conditions are met, the transistor acts as a variable resistor which keeps the collector current as an amplification of the base current.

E.6.2 Variations

- A PNP transistor is the opposite of an NPN—the current applied at the base *reduces* the flow of current into the collector.
- A FET (field effect transistor) operates using voltages rather than current. This allows for negligible current usage on the inputs, but also reduced gain and more complicated support considerations.



Schematic Symbol



Transistor

E.6.3 Pin Configuration

- Base (B): This is the terminal that contains the current to be amplified.
- Collector (C): This is the terminal where the amplified current will flow into.

- Emitter (E): This is the terminal where the currents from both the base and the collector will flow out of, at a voltage level of one diode drop (0.6 V) less than the base.

E.6.4 Design Considerations

Transistor designs are based on which terminals the signal itself passes through (the third terminal is referred to as the “common” terminal).

In common collector configurations (also called emitter followers), the signal passes from base to emitter with an increased current but no increased voltage.

In common emitter configurations, the signal passes from the base to the collector, with the increase in current converted to a voltage through a collector on the resistor.

E.7 YwRobot Power Module

E.7.1 Overview

This device allows you to supply power to your breadboard projects from a variety of sources through its barrel jack. The module down-steps the voltage to 5 V or 3.3 V (selectable with jumpers).

The power module comes with an on/off switch and a set of header pins that can be used to wire power to other places.

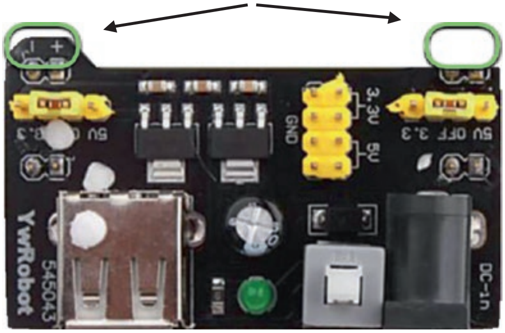
The module is made to fit on a standard breadboard, where the output pins align directly onto the power rails of the breadboard.

Be sure to align the positive and negative markings on the module with their matching power rails!

Note that this part is not technically part of any schematic and simply acts as a voltage source within a schematic.

E.7.2 Variations

- On some boards, the USB jack can be used as a power input, and on some it is a power output only.
- The popularity of this module has prompted a number of manufacturers to build similar devices with a variety of shapes and input/output methods.



Align these with the +/- power rails on your breadboard

E.7.3 Pin Configuration

The power module connects directly to your breadboard. Each side can be independently selected for 3.3 V or 5 V power via jumpers.

In the middle is a set of male headers for 3.3 V, 5 V, and ground.

E.7.4 Limitations

- Minimum input voltage: 6.5 V (DC)
- Maximum input voltage: 12 V (DC)

- Output voltage: 3.3/5 V (selectable)
- Maximum output current: 700 mA
- Barrel jack plug size: 5.5 mm × 2.1 mm

E.8 555 Timer

E.8.1 Overview

The 555 timer is a collection of components that can be configured to provide timings and oscillations.

It uses two voltage levels—one-third supply voltage and two-thirds supply voltage. Internally, it consists of

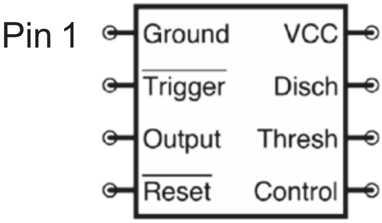
- Two comparators (one for each voltage level)
- A flip-flop (single-bit storage) to know what state it is in and to switch states at the appropriate time
- An output driver
- A reset input

The timer relies on external circuitry (such as an RC time circuit) to supply timings.

The timer effectively has two states. In the “charging” state, the **Discharge** pin is disconnected, and the **Threshold** pin is waiting for a high (2/3) voltage. In the “discharging” state, the **Discharge** pin is connected to ground, and the **Trigger** pin is waiting for a low (1/3) voltage. The typical usage is to provide an oscillating circuit.

E.8.2 Variations

- Can be implemented using CMOS/FETs or BJTs. FET implementation consumes less power, but can source less output.
- Many variations in maximum oscillation frequency.



E.8.3 Pin Configuration

- **Trigger** and **Threshold** detect going below 1/3 and above 2/3 voltage, respectively.
- **Discharge** provides a ground that is only attached when the chip is in the discharging state.
- **Output** supplies a high voltage when the chip is in the charging state and a low voltage when it is in the discharging state.
- **Reset** should be normally tied to a positive supply—it resets the circuit when it goes low.
- **Control** is normally connected to ground with a capacitor (10 μF recommended).

E.8.4 Specifications

- Supply Voltage: Usually 2–15 V
- Output Current: 100–200 mA

E.9 LM393 and LM339 Voltage Comparator

E.9.1 Overview

The LM393 is a dual voltage comparator. Each channel has two inputs—designated IN+ and IN-. When the voltage at IN+ is greater than the voltage at IN-, the output (OUT) is positive (actually, it is disconnected; see more later). Otherwise, the output is connected to ground.

The output is called an "open collector" output, which means that the "positive" state has no output current and is essentially disconnected. However, in the negative state, the output is connected to ground. This means that to use the output, you need to provide your own positive voltage through a pull-up resistor (this allows you to set your own output voltage).

The LM339 is identical except that it has four channels instead of two. Note that the schematic symbol for this is the same as that of an op-amp, largely because they perform similar (though not identical) functions.

E.9.2 Variations

Various chips differ in the amount of current they can sink, how fast they respond to changes in input voltage, how smooth the transition is from one state to the other, and the minimum amount of difference required to trigger.

E.10 CD4081 and 7408 Quad-AND Gate

E.10.1 Overview

The quad-AND gate is a set of four AND logic gates on a single chip. The output (Y) will be high only if *both* inputs (A and B) are high.

The required voltages for low and high on input and the guaranteed voltages for low and high on output are listed in the specifications section.

For the output to be high, both A and B must be high. Otherwise, the output (Y) will be low.

The 7408 and the CD4081 are the TTL and CMOS versions of the chip, respectively.

E.10.2 Variations

- 74HC08: Pin compatible with the 7408; voltage and current characteristics of the CD4081

- 74HCT08: Pin compatible and voltage-level compatible with 7408; similar current usage as the CD4081
- 74LS08: Fast-switching version of the 7408

E.11 CD4071 and 7432 Quad-OR Gate

E.11.1 Overview

The quad-OR gate is a set of four OR logic gates on a single chip. The output (Y) will be high if *either or both* inputs (A and B) are high.

The required voltages for low and high on input and the guaranteed voltages for low and high on output are listed in the specifications section.

For the output to be high, either A or B (or both) must be high. Otherwise, the output (Y) will be low.

The 7432 and the CD4071 are the TTL and CMOS versions of the chip, respectively.

E.11.2 Variations

- 74HC32: Pin compatible with the 7432; voltage and current characteristics of the CD4071
- 74HCT32: Pin compatible and voltage-level compatible with 7432; similar current usage as the CD4071

- Input (High) Voltage: > 2/3 supply
- Output (High) Voltage: Supply – 0.05
- Input (Low) Voltage: < 1/3 supply
- Output (Low) Voltage: 0–0.5 V
- Maximum Output Current: ~5 mA

E.11.4 Specifications (7432)

- Supply Voltage: 5 V
- Input (High) Voltage: > 2 V

- Output (High) Voltage: > 2.7 V
- Input (Low) Voltage: < 0.8 V
- Output (Low) Voltage: < 0.4 V
- Maximum Output Current: 100 mA

E.12 CD4001 and 7402 Quad-NOR Gate

E.12.1 Overview

The quad-NOR gate is a set of four NOR logic gates on a single chip. The output (Y) will be high if *both* inputs (A and B) are high or if *both* inputs are low.

The required voltages for low and high on input and the guaranteed voltages for low and high on output are listed in the specifications section.

For the output to be high, either both A and B must be high or neither must be high. Otherwise, the output (Y) will be low.

The 7402 and the CD4001 are the TTL and CMOS versions of the chip, respectively.

E.12.2 Variations

- 74HC02: Pin compatible with the 7402; voltage and current characteristics of the CD4001
- 74HCT02: Pin compatible and voltage-level compatible with 7402; similar current usage as the CD4001
- 74LS02: Fast-switching version of the 7402

- Output (Low) Voltage: < 0.4 V
- Maximum Output Current: 100 mA

E.13 CD4011 and 7400 Quad-NAND Gate

E.13.1 Overview

The quad-NAND gate is a set of four NAND logic gates on a single chip. The output (Y) will be low unless *both* inputs (A and B) are high.

The required voltages for low and high on input and the guaranteed voltages for low and high on output are listed in the specifications section.

For the output to be high, A and B can be anything as long as they are not both high. Otherwise, the output (Y) will be low.

The 7400 and the CD4011 are the TTL and CMOS versions of the chip, respectively.

E.13.2 Variations

- 74HC00: Pin compatible with the 7400; voltage and current characteristics of the CD4011
- 74HCT00: Pin compatible and voltage-level compatible with 7400; similar current usage as the CD4011
- 74LS00: Fast-switching version of the 7400

E.14 CD4070 and 7486 Quad-XOR Gate

E.14.1 Overview

The quad-XOR (exclusive OR) gate is a set of four XOR logic gates on a single chip. The output (Y) will be high if either input (A or B) *but not both* is high.

The required voltages for low and high on input and the guaranteed voltages for low and high on output are listed in the specifications section.

For the output to be high, either A or B must be high but not both of them. Otherwise, the output (Y) will be low.

The 7486 and the CD4070 are the TTL and CMOS versions of the chip, respectively.

E.14.2 Variations

- 74HC86: Pin compatible with the 7486; voltage and current characteristics of the CD4070
- 74HCT86: Pin compatible and voltage-level compatible with 7486; similar current usage as the CD4070
- 74LS86: Fast-switching version of the 7486

- Output (High) Voltage: > 2.7 V
- Input (Low) Voltage: < 0.8 V
- Output (Low) Voltage: < 0.4 V
- Maximum Output Current: 100 mA

E.15 LM78xx Voltage Regulator

E.15.1 Overview

The LM78xx voltage regulator is actually a series of chips to provide a consistent voltage output from a variety of voltage inputs. Each chip is named with the number of volts it supplies in its output. For instance, the LM7805 outputs a constant 5 V, and the LM7812 outputs a constant 12 V.

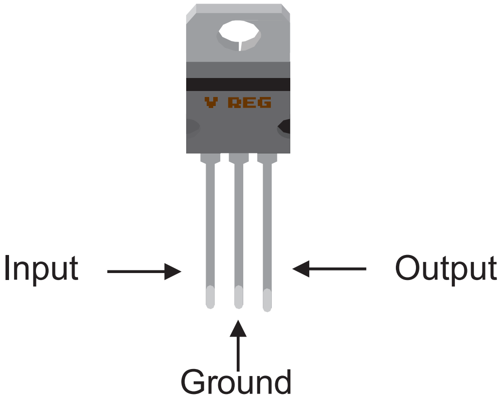
These chips are linear voltage regulators, which means that they regulate voltage by dissipating excess power as heat. If significant heat develops, the LM78xx can have a heatsink attached to the back plate, which also serves as a second ground.

The LM78xx requires an input voltage at least 2.5 V above the regulated voltage. This is known as the “drop-out” voltage of the chip.

E.15.2 Variations

- The 78xxSR is a line of switching regulators, meaning that they do not dissipate significant power when regulating (they operate by turning the power on and off quickly rather than dissipating excess power). They waste significantly less current but do have a significant cost.

- The TL750Mxx chips are similar to the LM78xx chips, but have a very low “drop-out” voltage (~0.6 V).
- The LM79xx chips are similar to the LM78xx chips, but act as *negative* voltage supplies (-5 V, etc.).



E.15.3 Specifications

- Maximum Input Voltage: 35 V
- Maximum Output Current: 1 A
- Built-in overcurrent protection
- Protection against short circuits
- Overheating protection (shuts off when overheating)

E.15.4 Usage Notes

- The specifications require two capacitors for operation—a 330 nF capacitor on the input and a 100 nF capacitor on the output (see below).
- These capacitors are generally not required for very simple projects—you can simply hook the input directly to your positive power source, the ground to your ground, and the output to your project.

Preface

The time of the electrician dealing only with simple components such as wires, outlets, switches, and incandescent lamps in his daily work is gone. Each day, electronics extends its branches to other activities. The home and industrial electrician, the automobile electrician, the construction engineer, and the architect are now finding strange components they may not be able to identify, which can cause embarrassing situations.

Electronic components in electric circuits and installations are becoming more common. Timers, dimmers, heater controls, intercom phones, alarms, doorbells, battery chargers, emergency lights, illumination controls, air conditioners, washing machines, and electronic injection systems are all electric devices and appliances where electronic circuits are found. The electrician and other professionals who come into contact with electric installations and who want to be updated with new technologies in these fields must know how these circuits work. This means learning a new science: electronics.

Until some years ago electronics and electricity were independent fields. The electronics technician fixed and repaired only electronic devices, concentrating his efforts in radio and TV, while the electrician worked with cars, home and industrial installations, and energy distribution. They were entirely different fields. Now the electrician must know how a timer or a dimmer works because he needs to know how to repair one if necessary, and a timer is a device of the other field—electronics. Other professionals such as architects and construction engineers must also know about many electronics devices because they must include them in their projects.

Of course, an electronics person, electrician, and other professionals in these areas must know these devices are not as advanced as the ones needed by a telecommunications, hardware, or other advanced specialist in the electronics field. Electricians must know the basic electronics devices found in their work. They must know how to recognize components and devices, how to work with simple circuits, and even detect problems in them. The electrician must know the basic electronics of common circuits used in electric installations of homes, industries, and cars to be secure when installing devices using this technology. The electrician also must know how to examine electronic circuits found in electric installations using basic instruments such as the multimeter.

Where can the electrician and other professionals find basic information about electronics used in electric installations? It was in thinking about this matter that I decided to prepare this book. It gives the reader the fundamentals of electronics, but with an approach familiar to the electrician and professionals who have had some contact with electric installations. The book explains how the basic electronic components work, how they are used in practical applications (homes, cars and industries), and how the electrician can work with them.

This isn't a simple book of electronics directed to all people. It is a book of electronics for electricians and other professionals from construction engineers to architects. It starts with knowledge about electricity and installations that electricians use. Eliminating some steps and going directly to the level where the reader is makes it easier to add important information about electronic circuits and devices. This makes the electrician much more prepared to make money when finding devices with new technology in his work.

This book is intended to give professionals basic knowledge about electronics in order to understand how electronic circuits and devices work in electric installations. The only thing I recommend to the reader is to proceed, and keep in mind that electronics will be increasingly present each day and that electric installations are not the exception.

About the Author

Newton C. Braga has written more than 50 books about electronics and electricity that have been published in his native Brazil as well as Europe and the United States. The main training network of the Brazilian Federation of Industries (SENAI) recommended *Electric Installations For Beginners* and *The Basic Electronics Course,* published in Brazil, as basic texts in its courses.

Electronics for the Electrician

Section I

The Differences Between Electricity and Electronics

The aim of this book is to explain how electronic circuits and devices work without assuming the reader has prior knowledge. Many electricians or professionals of nonelectronic areas probably have some elementary knowledge of electricity. We must assume there are many differences between the work of an electrician and an electronics technician. Not only are the components different, but in many cases the way they work is different as well.

So, it is normal that the first thing the electrician should consider when starting with these studies in electronics is if the knowledge he has about electricity is the same knowledge necessary to learn electronics.

The answer is yes.

The small differences that exist are in the way electricity is used in a domestic, industrial, or automobile installation and the way it is used in an electronic circuit. In essence the electricity is the same.

This means that the basic principles of electricity one needs to know when working on electronic devices and circuits are also the same. The electricians who want to upgrade their knowledge starting with a new science don't have to begin at zero and forget everything studied prior or learned during years of work experience. But, to be successful when learning electronics, it is a good idea to change some points of view about the way the principles are studied, especially when applied to electronics.

Other than electricians who are more practical than theoretical, two other kinds of electricians had to be considered. First, I considered those with a solid base of the theory and apply it in their profession, and secondly, those with a theoretical knowledge that perhaps has been dulled by time. For the first and third groups, a section on the fundamentals of electricity is included.

A section on approaches of the electricity principles applied to electronics is also included for that second group with the solid concept base. Perhaps you may not need this review of basic concepts, but a review is not a bad idea. After all, nobody is free from small slips in memory.

Through a different approach that involves redirecting the ideas, laws, principles, and concepts of electronics, the reader who is familiar with applications in electric installations can form a new image of electricity. This is very important when trying to understand how devices and circuits of a newer science work.

Finally, please realize a complete course of all basic principles needed to know about electronics needs much more space than is available here. Of course, my efforts were directed to include all the essential information a reader needs to have to understand how the main electronic circuits and devices work. If the reader wants to go a step further, much more detailed explanations can be found in many of the books offered by PROMPT®.

Fundamentals

Both electricians and electronics technicians work with the same kind of energy or "fluid" electricity.

As previously stated, the basic differences between an electronic device and an electric device are in the way they are mounted, the parts they use, and the way the electricity is used. Although the ends and the components used to find them are different, the principles of operation of each part of an electronic device and an electric device are the same.

Electricity is not found in different types. This means that the laws of physics that determine how electricity works and can be used are, in essence, universal. This is very important for the electrician who wants to learn about electronics. There are no differences between the laws and principles applied to electronic circuits and devices and the electric circuits and devices.

The Electric Current

Every material substance is made up of small particles called atoms. Atoms are so small that they are not visible under normal conditions. Then scientists discovered that atoms are made of even tinier particles called elementary or atomic particles as shown in Figure 1.

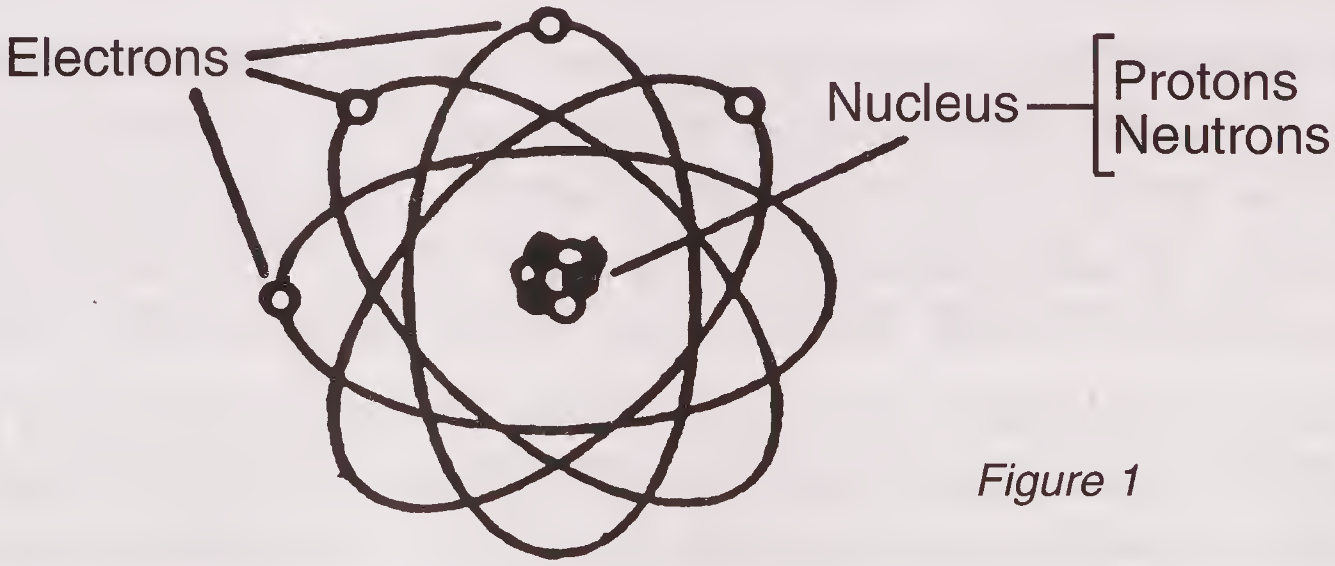

Figure 1

The nucleus of an atom is formed by protons and neutrons surrounded by electrons in an orbital shell. Electrons and protons manifest a special property; they are electrically charged. Electric properties of electrons are negative (–) whereas protons are positively charged (+). Bodies with different charges attract each other, and bodies having charges of the same type, either positive or negative, repel each other. This is why the electrons stay in an orbital movement attracted by the nucleus' charge.

In normal conditions, the number of electrons of an atom is equal to the number of protons. This means the electric charge of the protons and electrons is the same, so the atom is balanced (Figure 2).

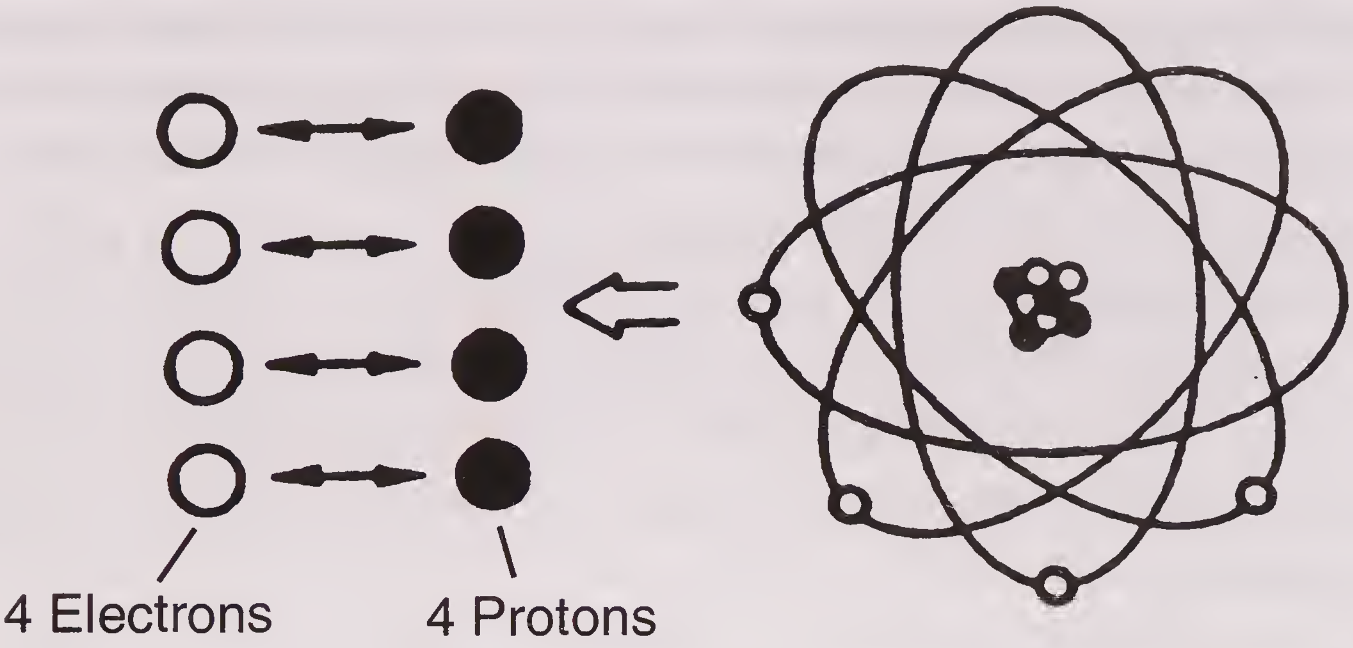

Figure 2

Although the forces act to maintain an atom in neutral or balanced condition, this stability can be upset under certain conditions. Of course, it is impossible to remove protons from the nucleus of an atom without destroying or changing its nature. This involves special conditions such as those created in a nuclear power plant or by an atomic bomb, where a fantastic amount of energy is released.

It is easier to play with the electrons to break the electrical balance of an atom because electrons can be removed from the orbital shell. They can also be added to the orbital shell without large amounts of energy. In some cases, simple natural or artificial processes can remove electrons from the atoms of a body and put them in the atoms of other bodies.

In such a situation, the body losing electrons becomes positively charged with an excess of protons. At the same time, the body that received the electrons now has a negative charge. Each body has a charge so, we say that the bodies have electric charges or are "electrified." An example of this is shown in Figure 3.

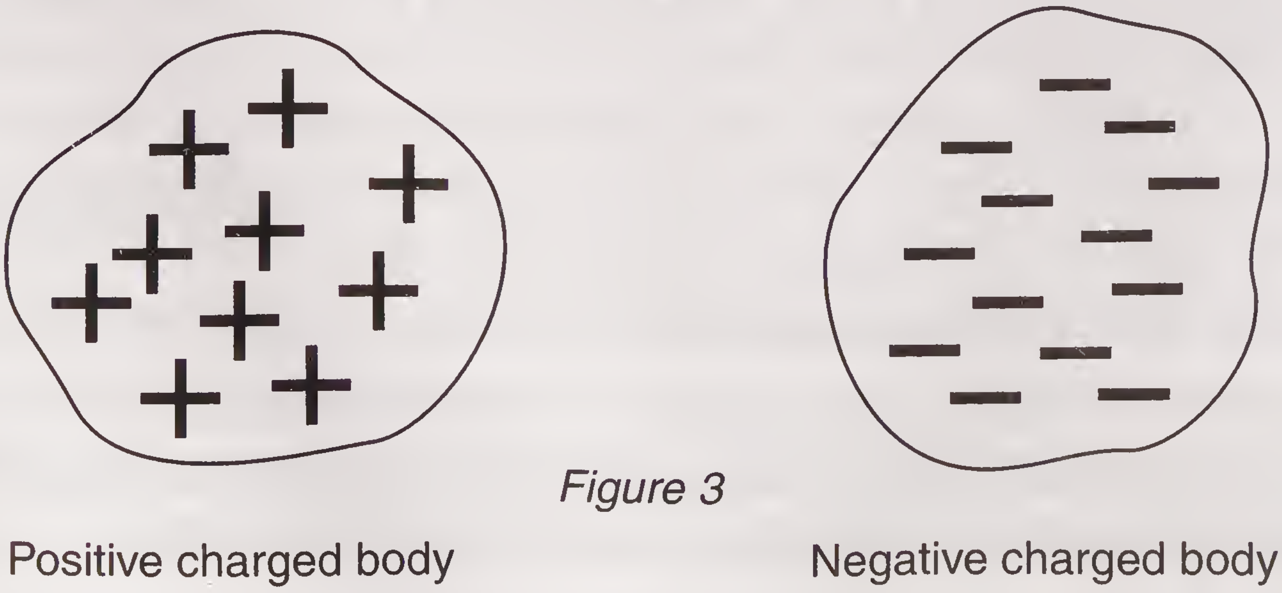

Figure 3

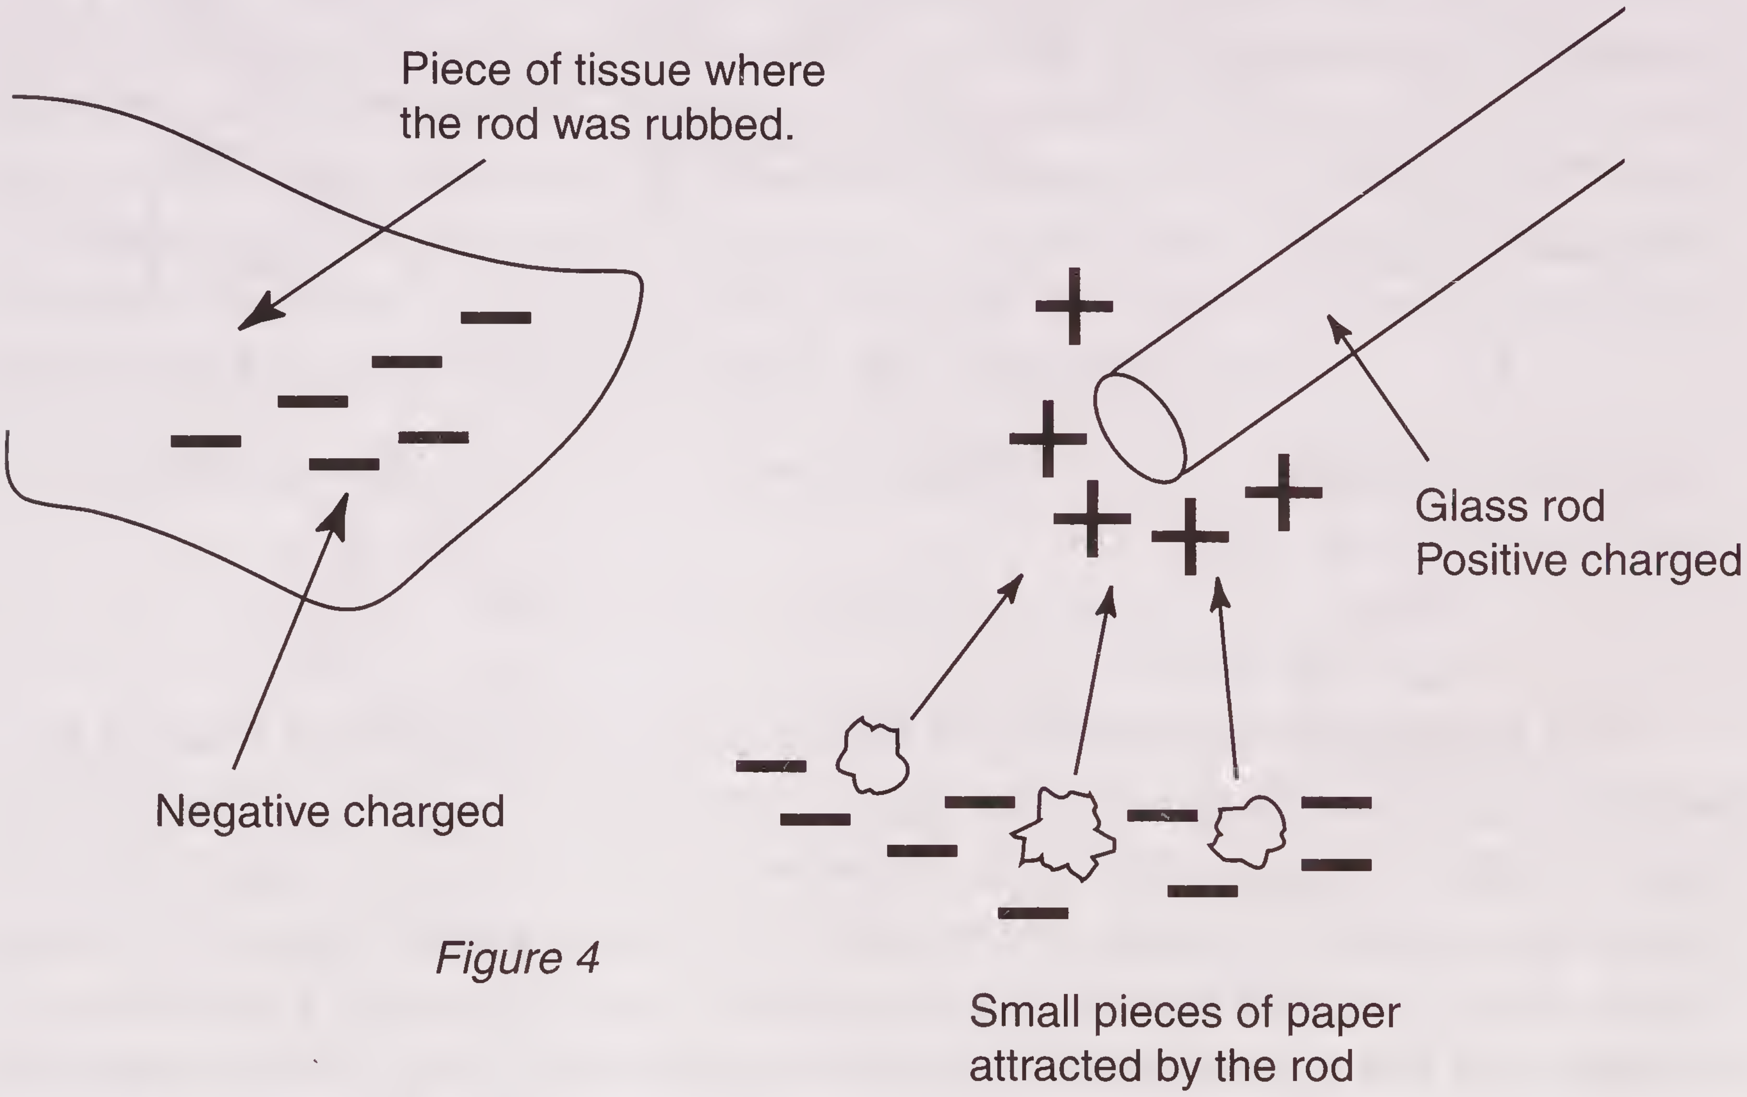
When you rub a plastic pen or glass rod in a piece of tissue (silk or wool works best), electrons are removed from the atoms of the plastic or glass and transferred to the tissue. Both objects become charged, but with opposite charges as shown in Figure 4.

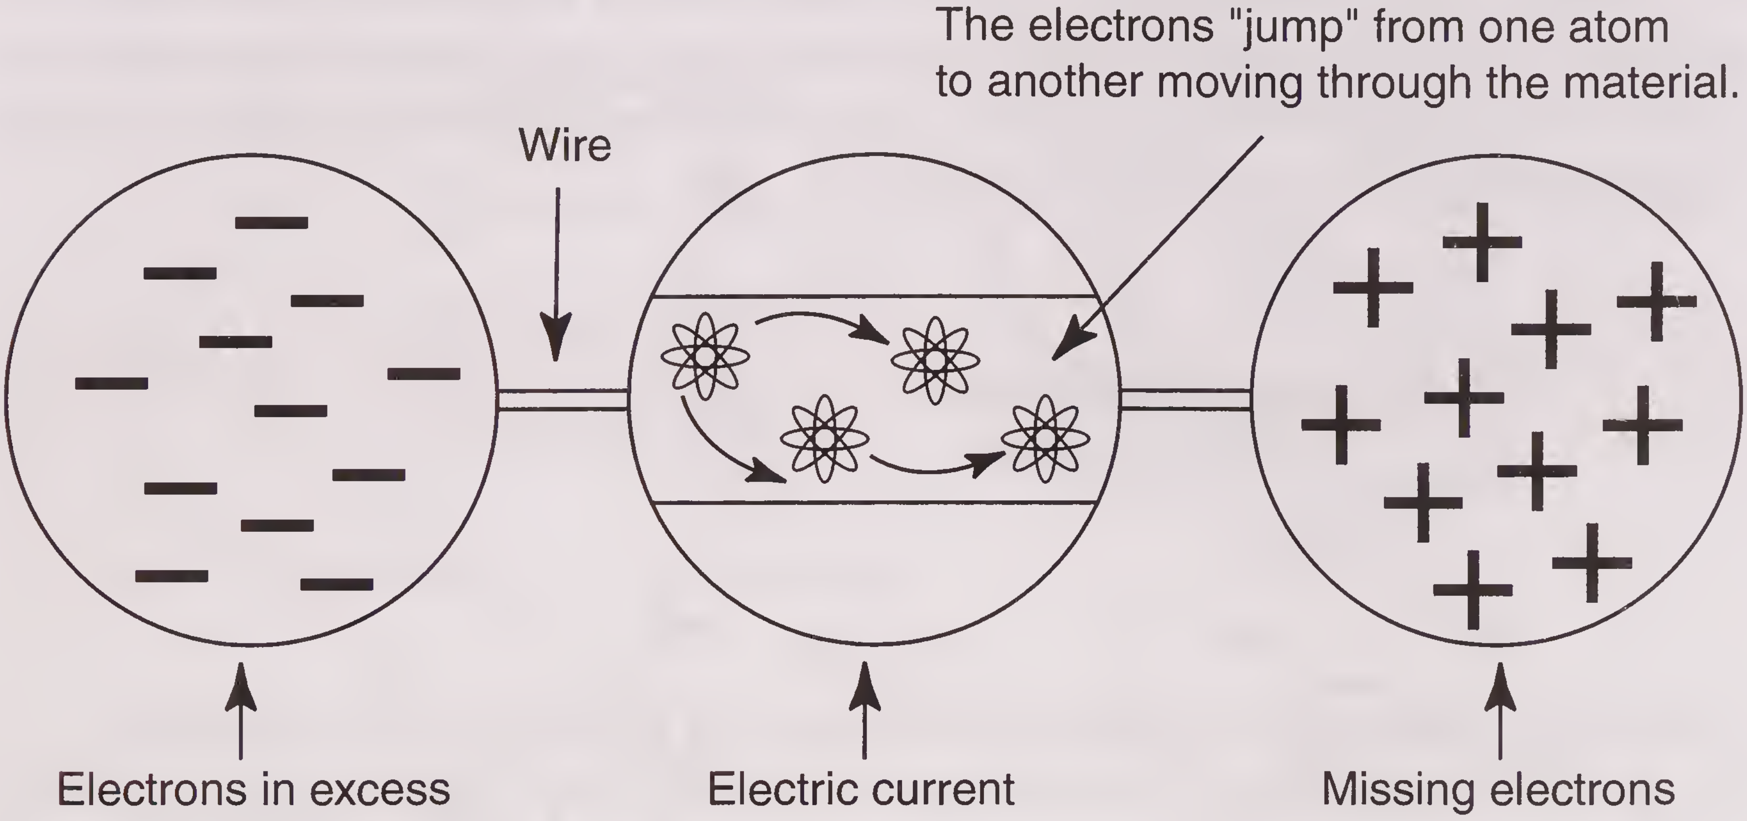


Piece of tissue where the rod was rubbed.
Negative charged
Glass rod Positive charged
Small pieces of paper attracted by the rod

Figure 4

Putting the pen near your hair or small pieces of paper will attract the hair or paper to the pen that is now positively charged. The pen needs the electrons in your hair or the paper to balance its charge. The pen and the piece of tissue have been electrified by attrition, but there are other ways to remove or add electrons to a body, thereby charging them with electricity. The electricity or electric charge in these bodies is fixed or static. The branch of physics that studies the properties of electricity accumulated in objects is static electricity.

Now, going a step farther, if we bridge two charged bodies using a metal wire (a material through which the electrons can move easily—a conductor), a flux of electrons can be noted; the excess electrons in one body move to the body that needs them. This flux of electrons or electron flow is called electric current and is represented in Figure 5.



The electrons "jump" from one atom to another moving through the material.
Wire
Electrons in excess
Electric current
Missing electrons

Figure 5

It is important to note that in this process the electrons flowing between the bodies release energy. In this case, the energy is converted into heat. Another important point to observe in this process is that a flux of current can release energy to be used by devices placed along the way. Notice that in all the described processes the only moving particles or charges are the electrons. This explains why the names of the sciences are “electricity” and “electronics” and not “protoncity” or “protonics”!

Scientists found that the existence of atoms with positively charged electrons and negatively charged protons is possible somewhere in the universe. But, these atoms result in antimatter bodies that explode when in contact with our normal atoms. These “antielectrons,” or positively charged electrons, are called “positrons.”

The current flow between two charged bodies, as shown in Figure 5, is very short. As soon the electrons from one body reach the other body neutralizing any charge, the electron flow stops and the current ceases. The practical use of the energy that is transported by an electric current comes from the fact that we can create ways to maintain the difference in charges between two bodies and maintain a flux of electrons or current between them. Current flow is a dynamic process countering the static electricity.

a) Basic Circuits

The electric current can transport energy from one point to another, maintaining the difference of a charge's concentration between the ends of the wire with a current flowing through it.

In the example, two bodies are shown, one with negative charges and the other with positive charges. This is not the only possible configuration that can produce a current flowing between two bodies. They can both be negative or positive but in different degrees or with a different concentration of charges as shown in Figure 6. The charges in these bodies are in different degrees of compression meaning that different repulsion forces move them, either attracting electrons or repelling them.

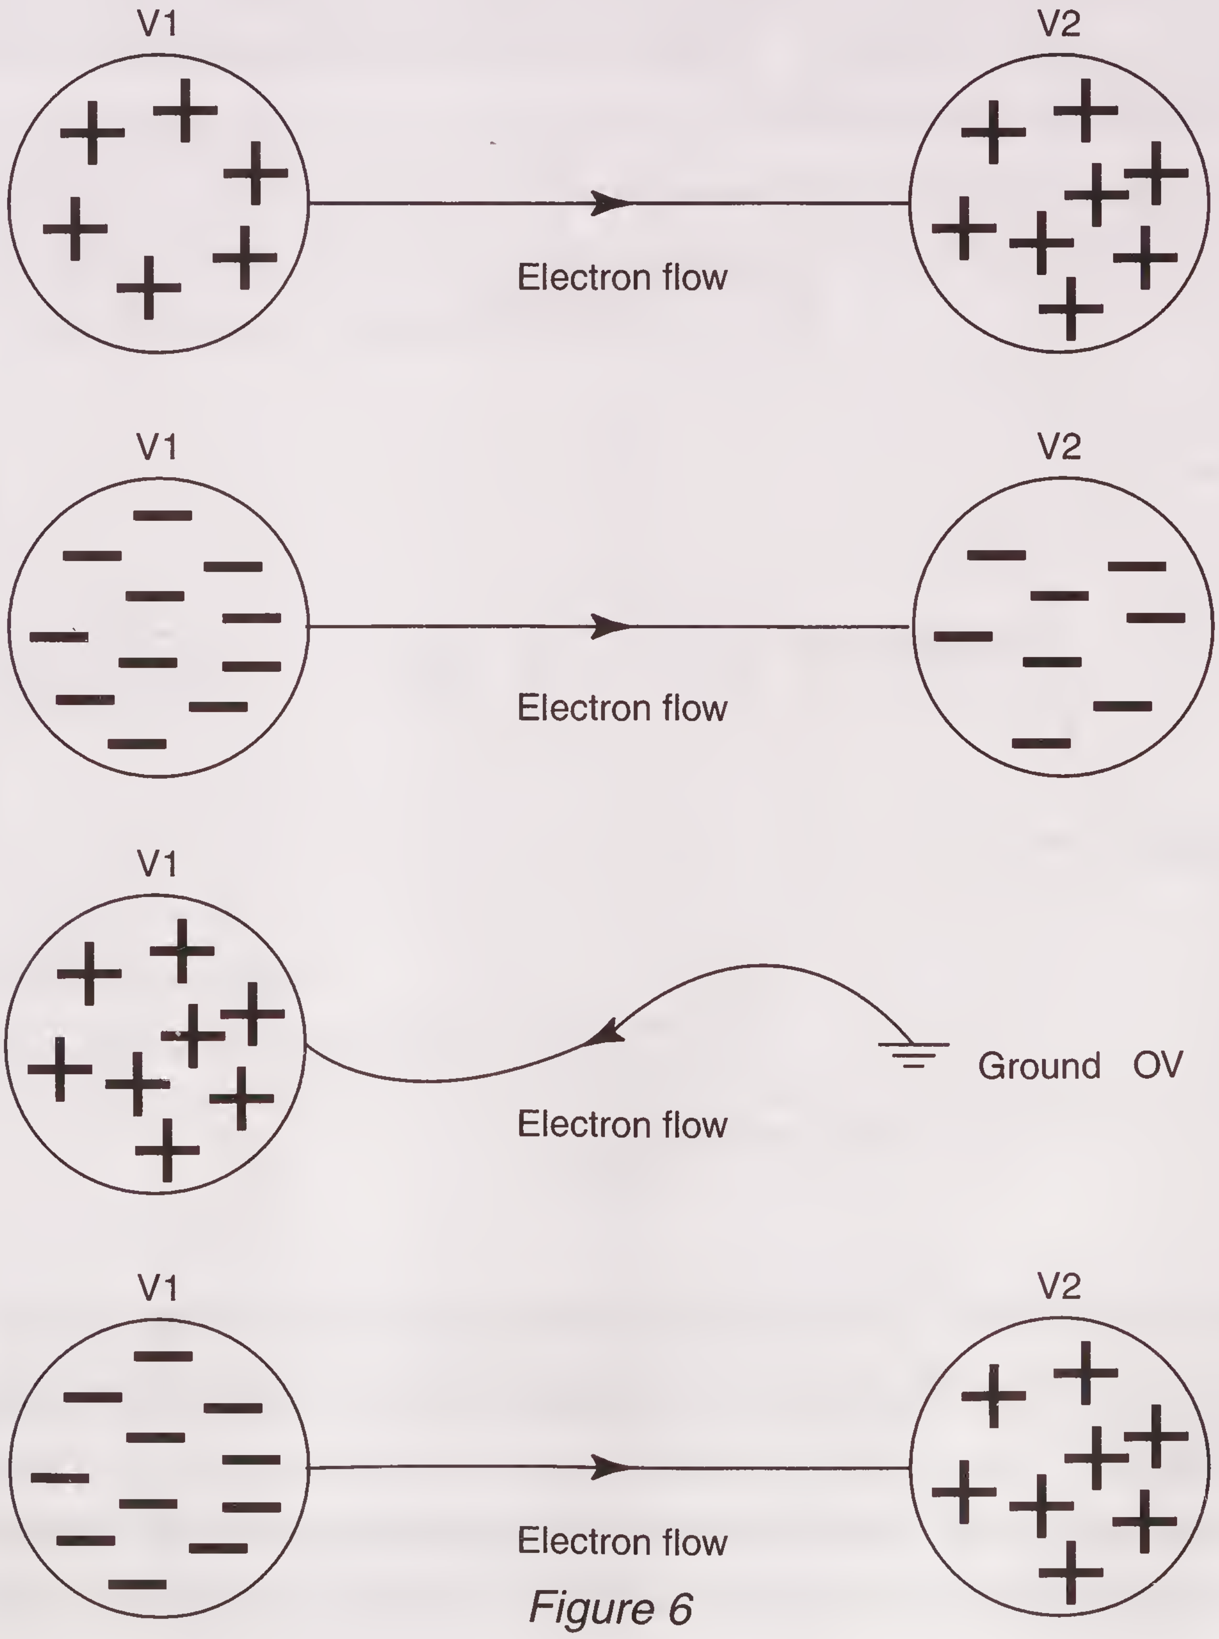


Figure 6

If we place a metal wire between these bodies, a current flow will be formed. The current tends to flow from the more compressed negative charges to the less compressed negative charges. This compression force of charges is very important to establish an electric current. In the case of positively charged bodies, electrons will flow from the body with the least amount of positive charge to where the most electronics are missing. As a practical rule, it is easy to see the natural tendency for a balance to be reached.

Returning to our problem, how do we maintain the current if we want to create a constant supply of energy? First, we need an efficient way to replace the electrons that leave the negatively charged body. Since electrons can't be created from nothing, we need a body that can furnish them as long as they are needed. This problem can be solved by the device shown in Figure 7, a generator.

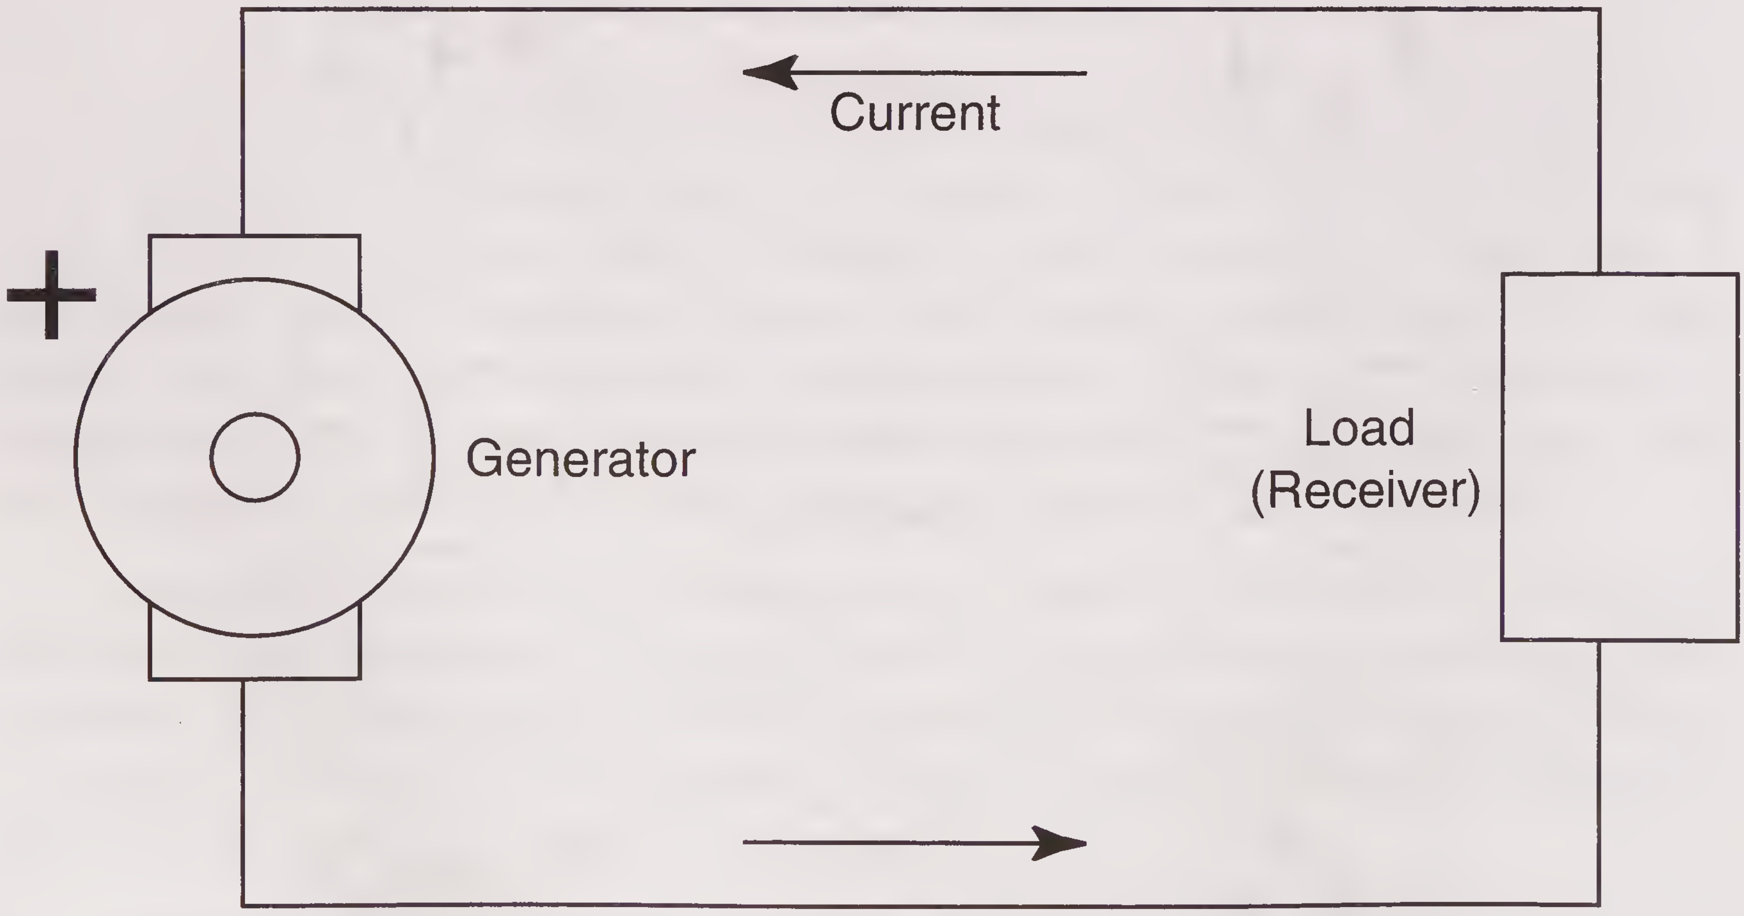

Figure 7

This arrangement is formed by the generator, metal wires, and a device that can absorb the energy transported by the current flow. This is an electric circuit.

So, how do things work in this arrangement and how does the generator supply the electrons to keep the current flowing? The generator can be seen as a two-pole device where one pole is a body with excess electrons (negative pole) and the other has missing electrons (positive pole).

The excess electrons are "pumped" in one direction to the pole where they are missing, passing through a device where the released energy is transformed into heat. Arriving at the pole where the electrons are missing, a replacing process occurs: inside the generator the electrons are taken from the positive pole and replaced to the negative pole again. In this process the generator uses energy. Chemical generators like cells and batteries use energy released in chemical reactions. Mechanical generators known as dynamos use the force applied to a mechanism.

It is important to observe that the generator only needs to replace energy when the current is flowing because in a cell there is no chemical reaction until the moment when it is used. Another important fact to observe is that energy can't be created from nothing and when the current is carrying energy to any device, it must be produced from another kind of energy. The generator doesn't create energy, but transforms one kind of energy into another as suggested in Figure 8.

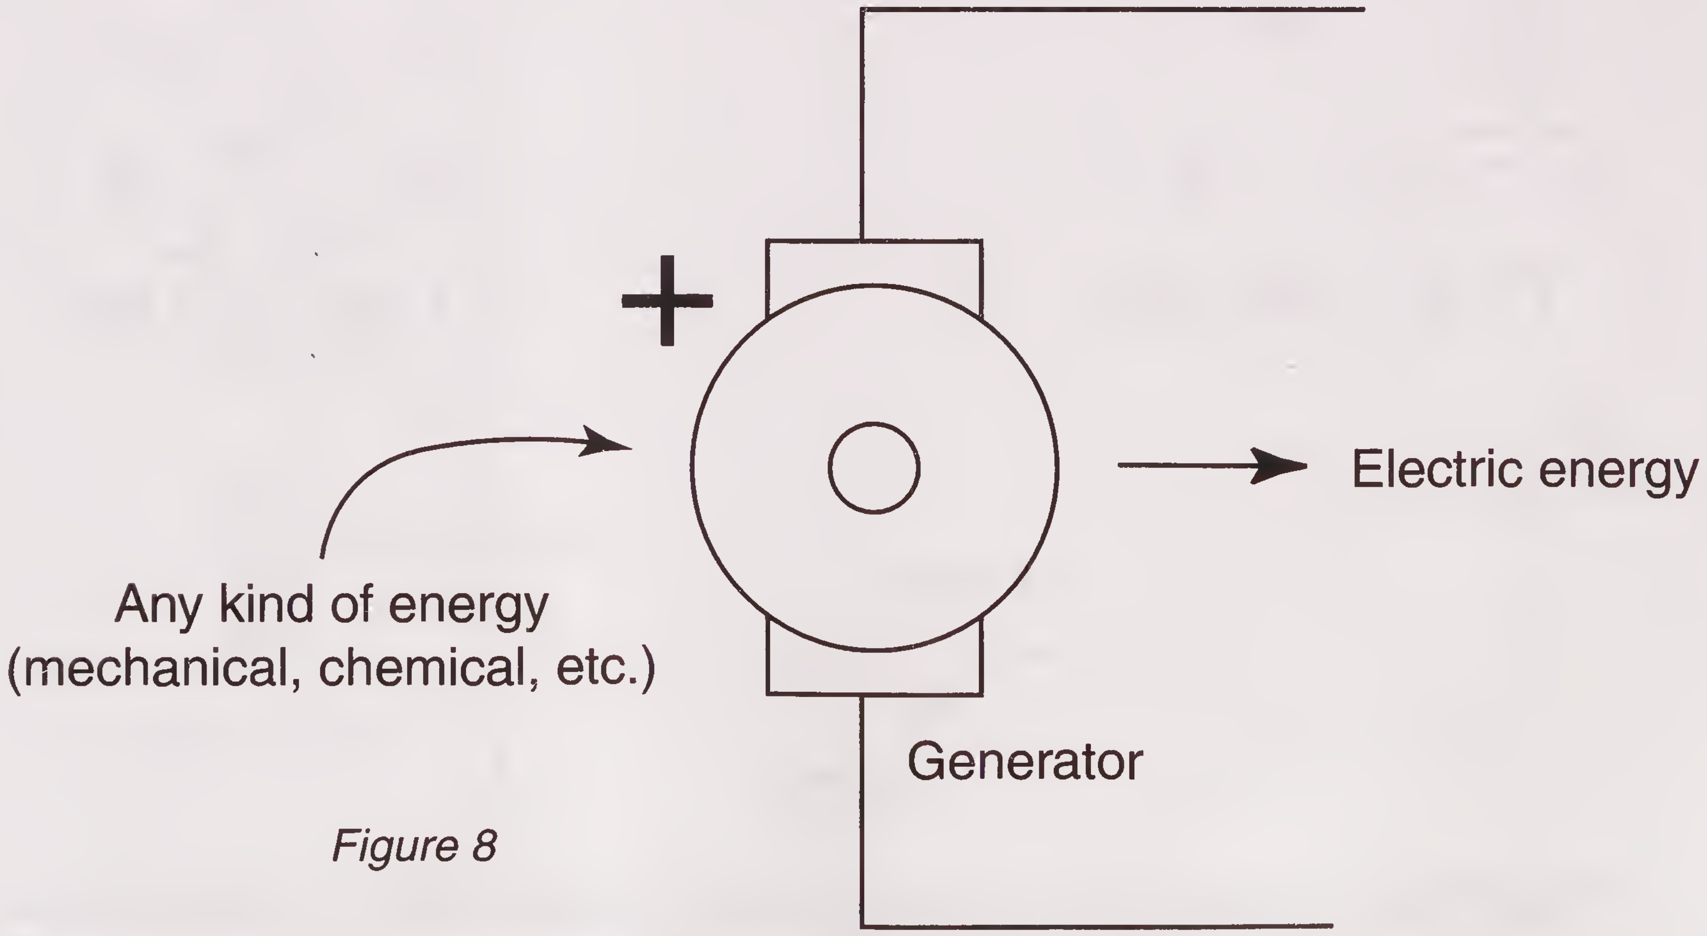

Figure 8

Another important thing to observe in the example is the movement of the electrons and the electric current flowing through a closed loop. This means that the current flow needs a closed circuit to be established. This configuration is called an electric circuit. Going a little bit further with our explanations, a switch can be included in this simple electric circuit to control the current. This is shown in Figure 9.

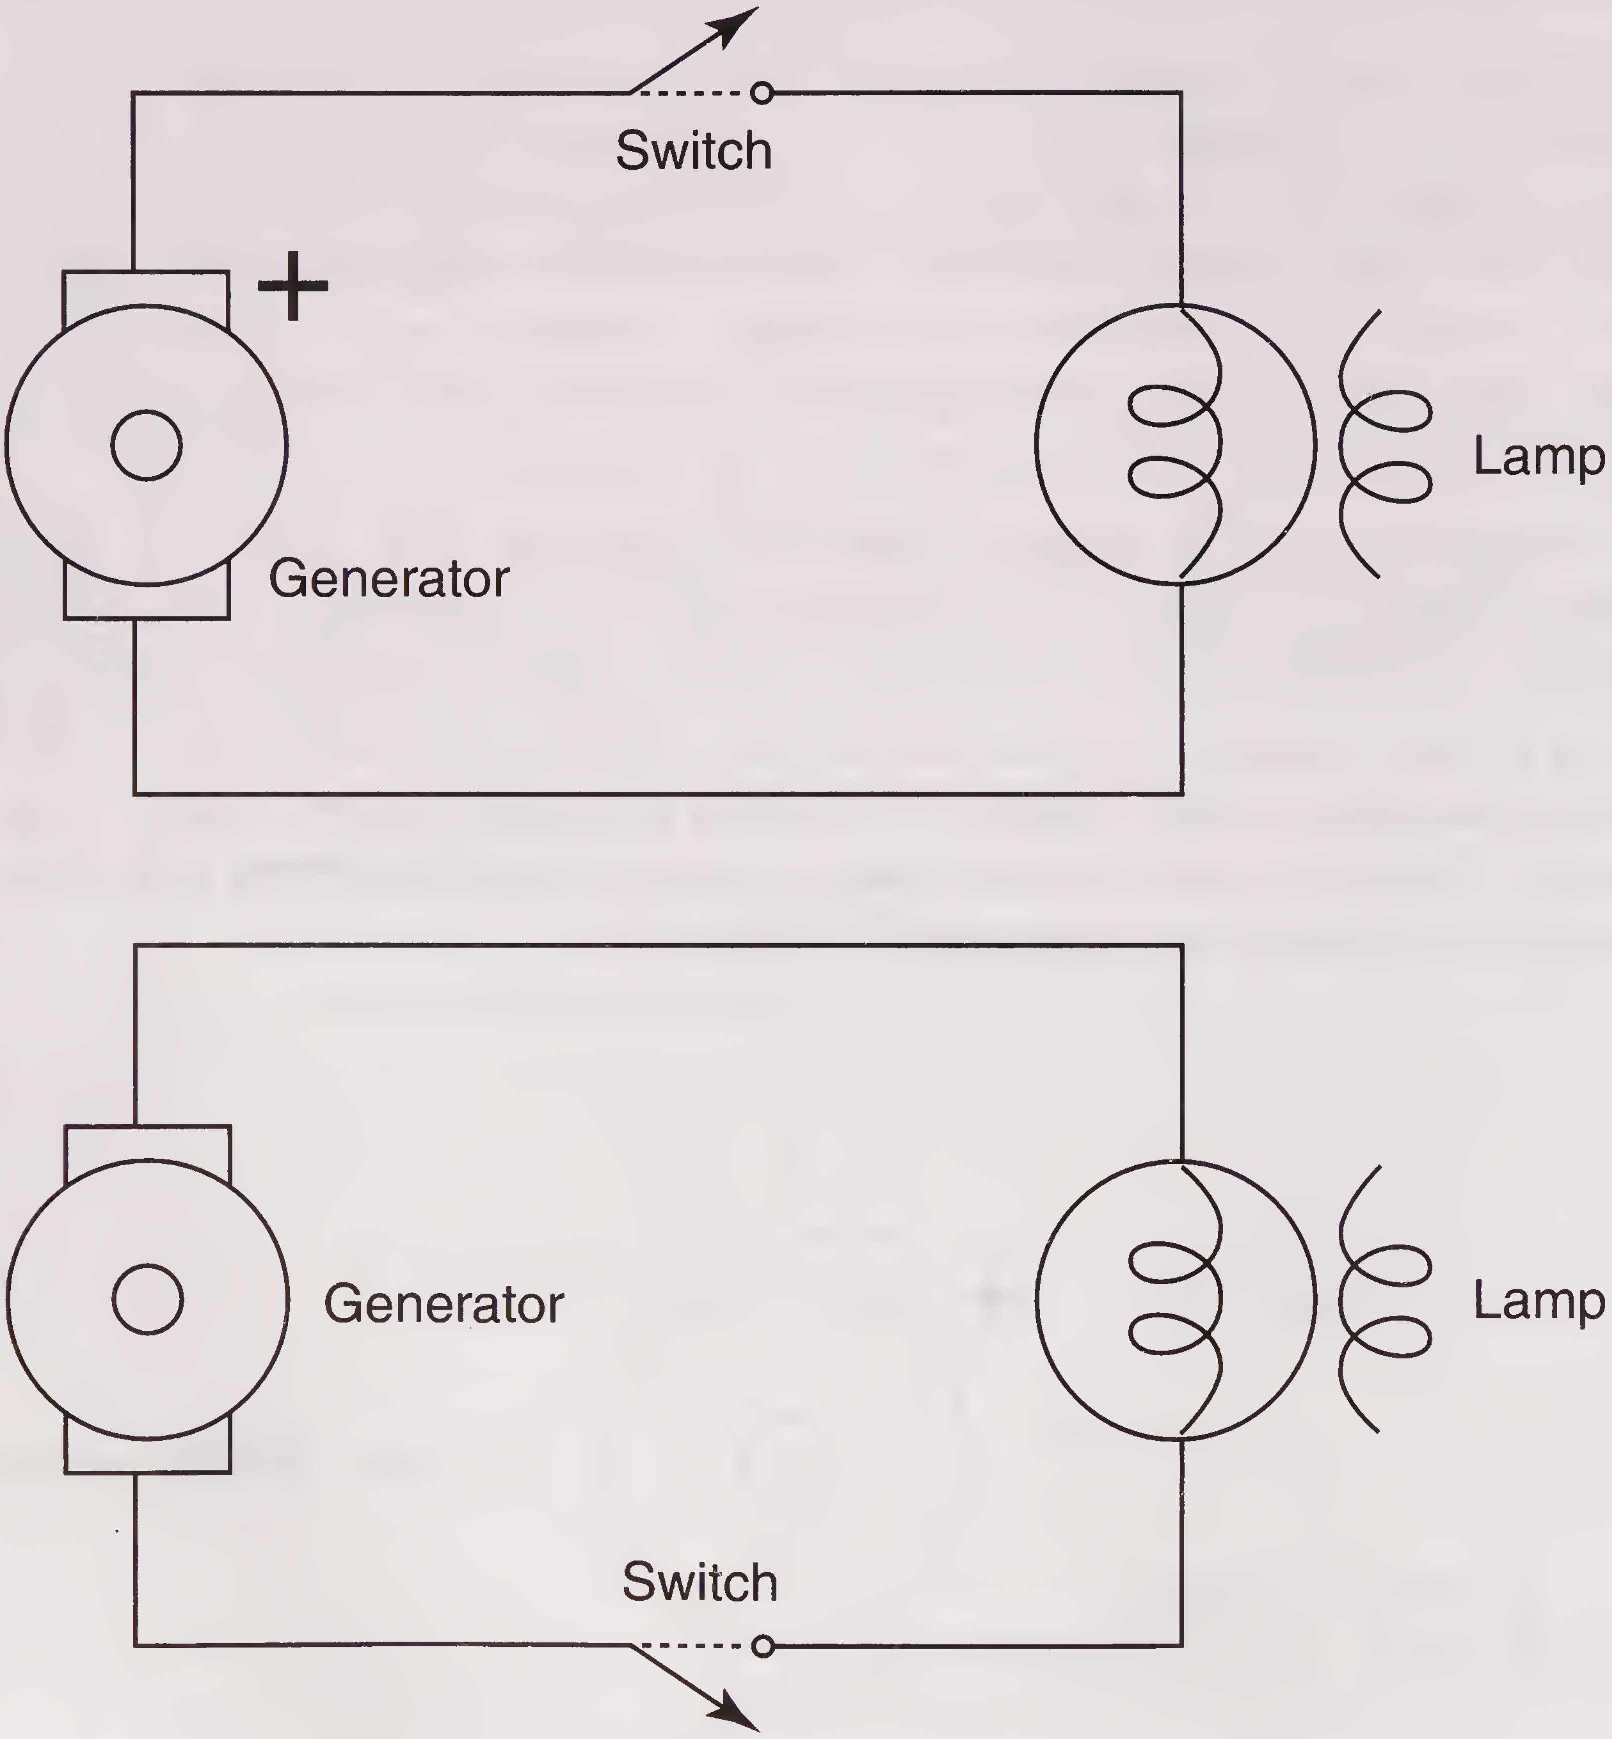

Figure 9

Opening the switch interrupts the current flow and the process of transferring energy to a device. If the device is a lamp we can turn it on and off. Closing the circuit, the current can flow and energy is transferred from the generator to the device; the lamp glows. Opening the switch, no current flows and no energy is transferred to the lamp; it remains off. The important thing to observe in this circuit is the position of the switch. Whether we place the switch after or before the device (having the current flow as reference), the effects are the same. The current can be interrupted in the same manner and the device doesn't receive any energy.

Another point that causes some doubts in electricity students is that the electrons aren't the energy and so they are not consumed when passing through a device. The electrons after and before the device are the same, and the amount of current in the entire circuit is also the same. The electrons are used only to transport energy. They are not the energy!

b) Voltage and Current

The excess electrons in a body and the electrons missing in another body represent a state of compression or tension. The situation can be compared to the situation found in compressed springs. The force that tends to recover the balanced state of a body depends on how the charges are compressed as shown in Figure 10.

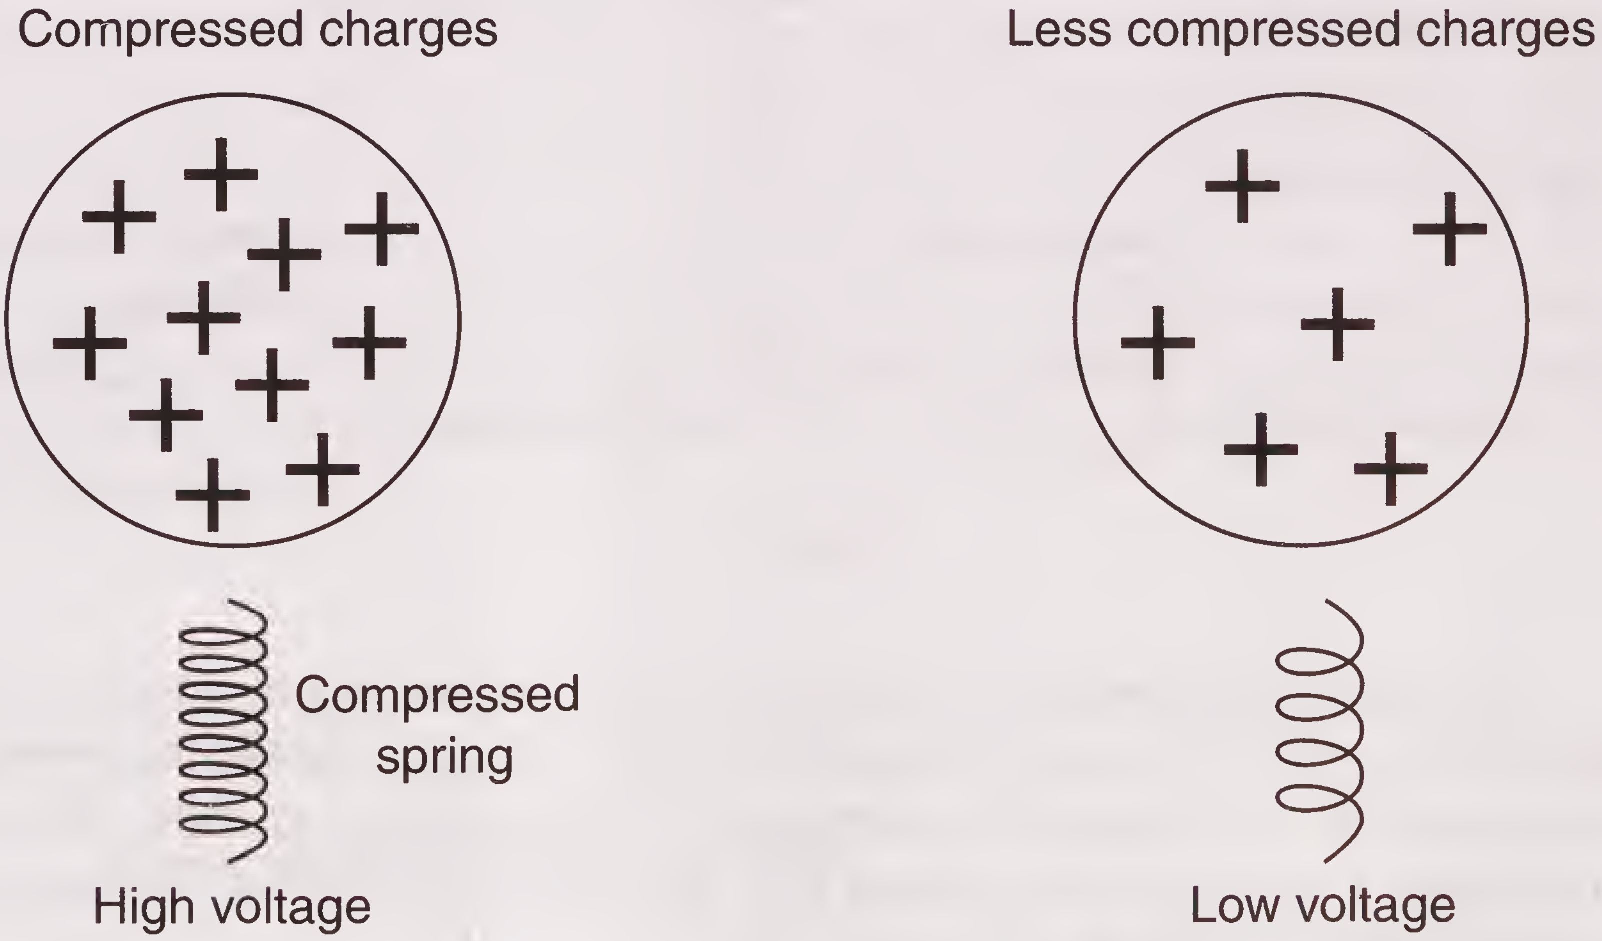

Figure 10

It is this tension that pumps the charges through a metal wire when that body is connected to another. Of course, if the charges in the other bodies are in the same state of tension, the forces pumping the charges are equal and no current flows. It is easy to conclude from this explanation that it is necessary to have a state of tension to produce current. The electric tension is the cause and the current is the effect.

This state of tension or compression is called electric tension or electric voltage and is measured in volts (V).

In a generator, like a cell for instance, there exists a state of tension between its poles—an electric tension. This means that when any circuit is wired between its poles a current can flow. This state of tension in a generator is called electromotive force (emf) and it is also measured in volts. For example, the emf of a single AA cell is 1.5 V. Current is measured in amperes (A).

Figure 11 depicts an analogy between electric current, electric voltage, and the water flowing from a reservoir.

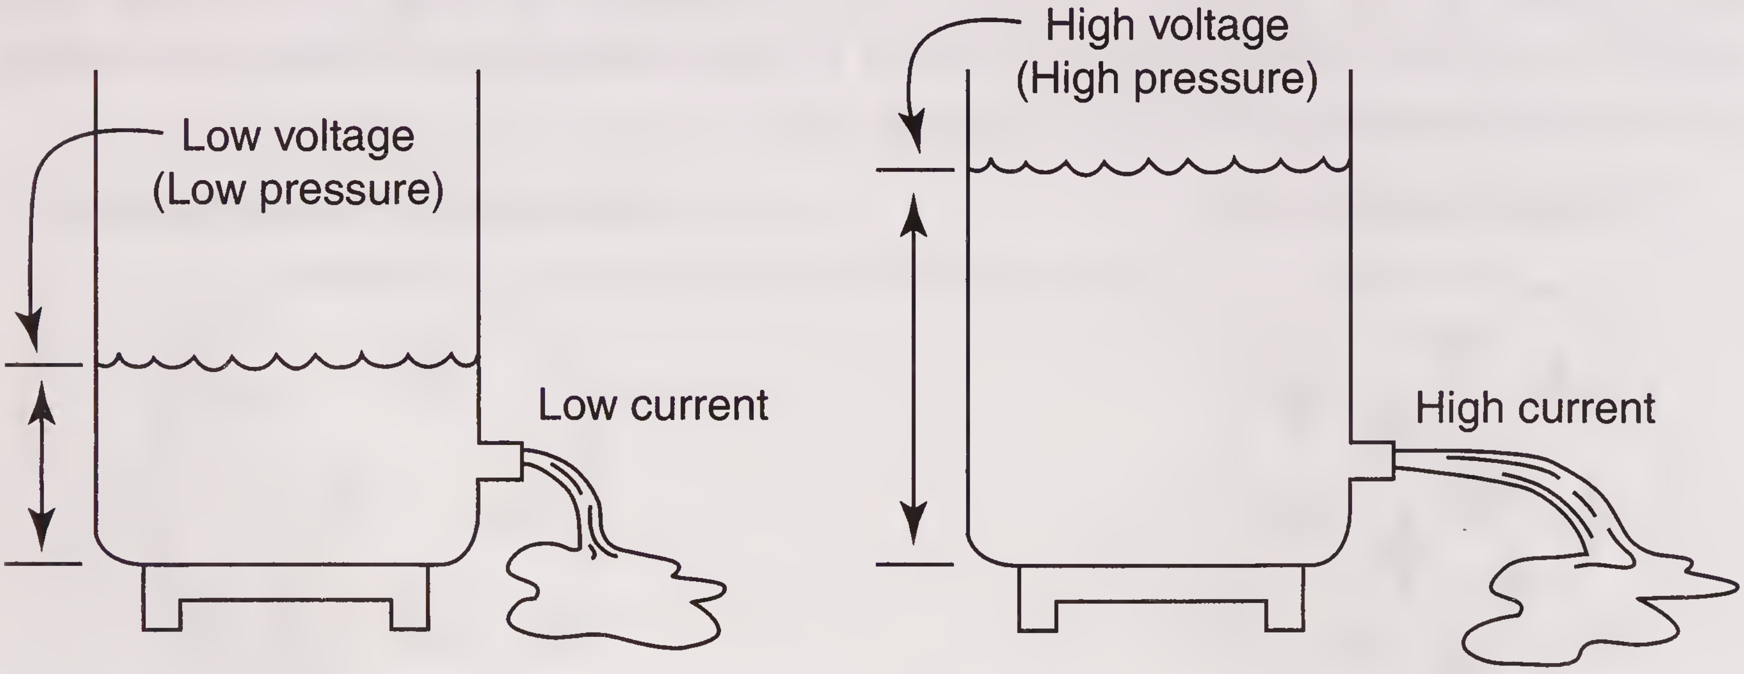

Figure 11

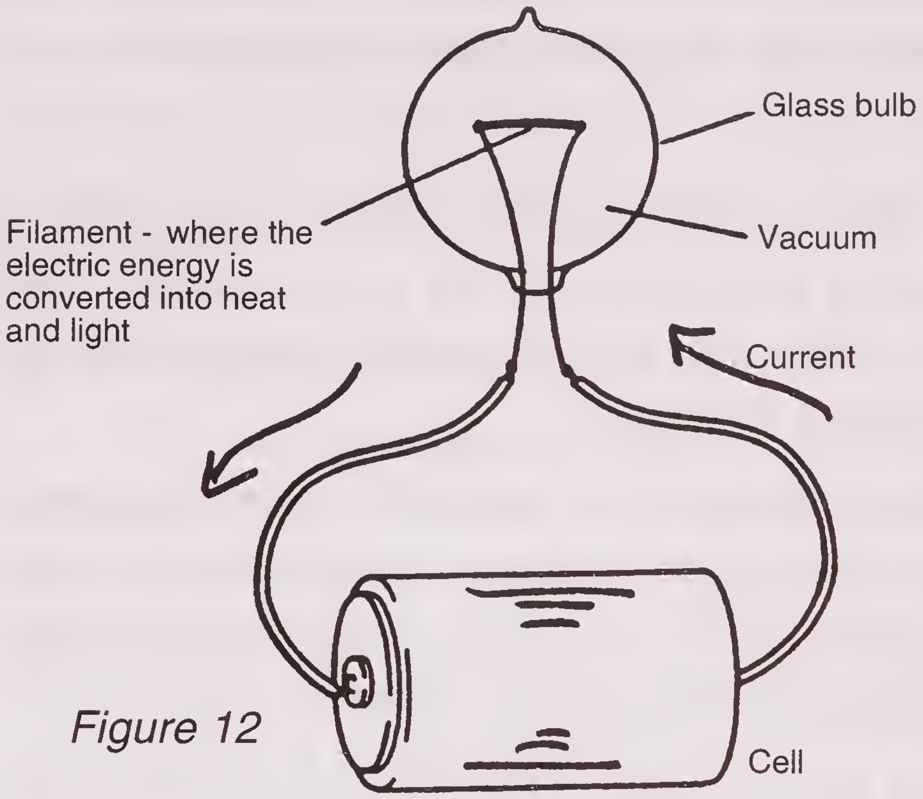
The water compression is compared with the electric tension or voltage and the water flow with the electric current. The higher the water level in the reservoir, the higher the compression and amount of water flow. In comparison, the higher the voltage of a generator, the higher the amount of current flowing through a circuit.

c) Resistance

When describing the basic circuit and the analogy between electric current and water flow, we added an important element: the device that uses the energy released by the generator converting it into heat or light. When reaching this device, the electron flow finds a certain degree of opposition to its movement as suggested in Figure 12.

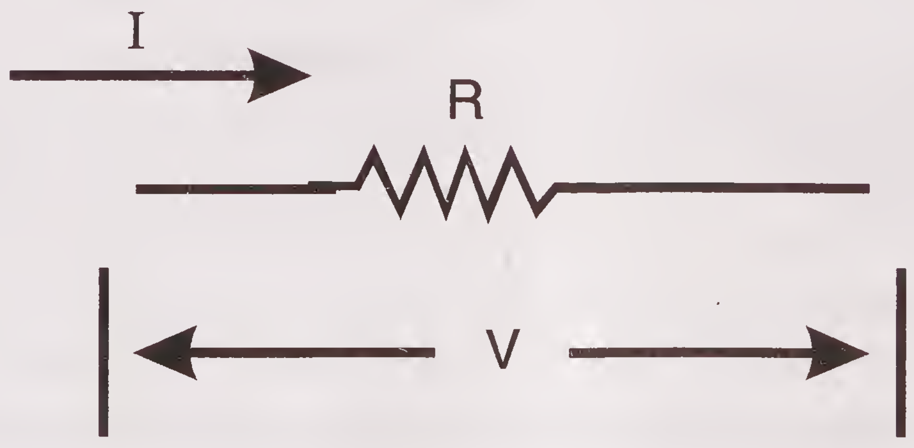


Glass bulb
Filament - where the electric energy is converted into heat and light
Vacuum
Current
Cell

Figure 12

Energy must be released to break this resistance. This energy is converted into heat. The opposition to the current flow is called "electric resistance" and is measured in ohms (Ω). The amount of resistance presented by a device determines how much current can flow through it when a determined voltage is applied to the circuit. The relationship among current, resistance, and voltage in a circuit can be calculated by Ohm's Law (Figure 13).

In a simple manner, considering that the voltage is the cause of a current, we can say that the amount of current flowing through a circuit with a certain resistance is proportional to the applied voltage. The electrician will find that all electronic circuits and devices presenting a resistance will follow this law the same as any other electric device does. In electronic circuits the electrician will also find a device that is used to add a certain resistance to a circuit. It is used in applications where the current flow can be reduced to a determined value. It is a resistor and uses the symbol shown in Figure 13.



$$R = \frac{V}{I}$$

R = Resistance in ohms

I = Current in amperes (A)

V = Voltage in volts (V)

Figure 13

Because resistors are very important devices in electronic circuits, more information about them is presented in the discussion of components.

d) Units

Electricity can be measured. Due to this fact, the use of electricity in many applications is possible. Making calculations, we can preview what happens with electricity in a circuit under any condition and create circuits and devices that produce all the effects we want.

We measure voltages or electric tension in volts (V), the current in amperes (A), and the resistance in ohms (Ω). There are many other electric quantities, each one using its own unit. Of course, many electricians are familiar with these units as they also are used in electric circuits.

Because electricians can also find circuits where voltages and currents are very high or very low, it is important to know how to express high values of current and voltages. Commonly used are the Greek prefixes kilo (k) and mega (M). So, instead of saying 1000 volts, the electrician can say 1 kilovolt (kV) where the kilo (k) represents x 1000. Thus, 1000 volts is also 1 kV.

In electronics high voltages and high resistances are common, but much more common are the small values of currents and other quantities such as capacitances, inductances, etc. To represent the small quantities we can also use Greek prefixes.

Table 1-1 shows the most common Greek prefixes for representing electric quantities:

Prefix	Abbreviation	Times	exponential
Tera	T	1,000,000,000,000	10^{12}
Giga	G	1,000,000,000	10^{9}
Mega	M	1,000,000	10^{6}
Kilo	K	1,000	10^{3}
Deca	D	10	10
Deci	D	0.1	10^{-1}
Mili	M	0.001	10^{-3}
Micro	μ	0.000,001	10^{-6}
Nano	N	0.000,000,001	10^{-9}
Pico	P	0.000,000,000,001	10^{-12}

Table 1-1

In electronic circuits, it is common to see specifications of current like 10μA, meaning 0.000001 A, or specifications of resistances like 2.2 M_{Ω}, meaning 2,200,000 ohms. In some cases, the decimal point can be replaced by the prefix. So, instead of 2.2 k_{Ω} to express 2,200 ohms, we can write 2k2.

e) Effects of Electric Current

The device used as load in our example presents a pure electric resistance or an "Ohmic" resistance, converting all the electric energy into heat. Many devices and electric appliances use this effect of the electric current for heaters, incandescent lamps, etc. But, this is not the only effect of an electric current. When the electrons flow through certain materials or devices other effects can be noted.

Since the electric and electronic devices as well as appliances use all the effects of an electric current it is very important to any electrician to remember what these effects are and how they are used.

Thermal Effect or Joule Effect

When passing through any device or circuit presenting an electric resistance, the result of a current flow is that the energy spent in the process is converted into heat. This effect is also known as Joule's Effect. The amount of energy released can by calculated by Joule's Law.

Joule's Law says that the amount of heat dissipated each second or converted into heat by a device with a constant resistance is given by the voltage applied, multiplied by the current flowing through it.

The energy is measured in joules (J), and the amount of energy in each second is another quantity measured in watts (W). One watt is one joule per second.

$P = V \times I$

Where:

P is the power converted in heat in watts (W)

V is the applied voltage in volts (V)

I is the current through the circuit in amperes (A)

Since current and voltage depend on the resistance, the next formulas are useful to calculate the converted power:

$P = R \times I^2$

and

$P = V^2/R$

Where:

R is the resistance in ohms (Ω)

Be aware there are many other formulas involved in electronic calculations that depend on the application and the complexity of the involved circuit. These are very simple and important to the electrician who wants to start with electronics. To those who want to go on to higher levels and have a useful handbook of electronic formulas and calculations for reference, the *Sourcebook for Electronics Calculations: Formulas and Tables* is an excellent source. (Also written by Newton C. Braga and published by Prompt® Publications.)

Many electronic devices use the Joule Effect as a basis of operation; others have the production of heat only as a result of their operation. Some devices where heat is the basis of operation are incandescent lamps, heaters, and boilers. Other devices produce heat using this effect, but as a consequence of their operation. In this case, the heat must be eliminated in order to avoid causing damage to the device.

Some electronic components producing large amounts of heat must be mounted in heat sinks (Figure 14).

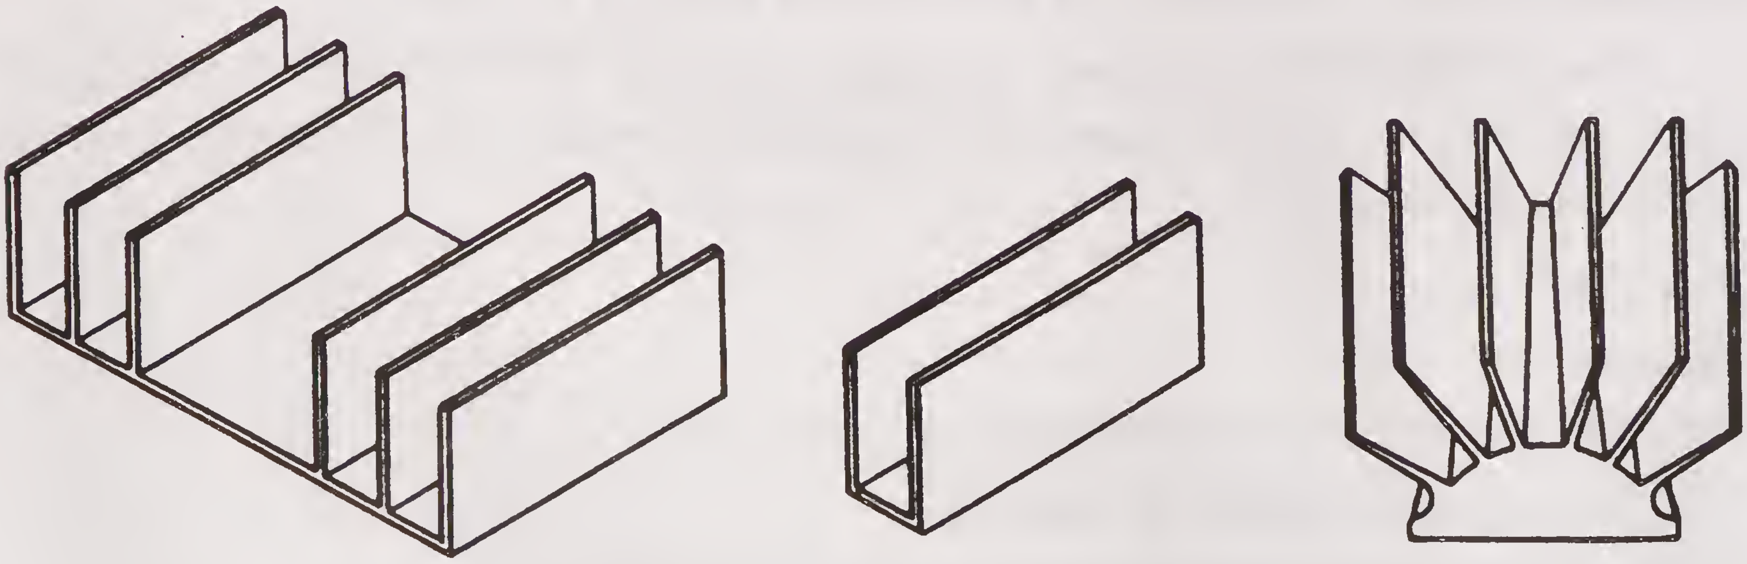


Figure 14

The function of a heat sink is to transfer heat generated by the devices to the air, and in some cases, with the aid of some forced process. Small fans can be used. The electrician will also observe that many circuits are very sensitive to the excess heat produced by components. Heat is the origin of many device failures.

Luminous Effect

There are many ways to produce light from electric energy. The most common way can be considered a consequence of Joule's Effect. In a common incandescent lamp a metal filament (tungsten) is heated by the electric current to a temperature high enough to produce light. Light can also be produced by a current flowing through a gas tube as in neon, xenon and fluorescent lamps. The gas becomes a conductor by ionization and in this process electromagnetic waves in the range of visible, infrared, and ultraviolet are produced. Another way to produce light from electric current is found in electronic components called LEDs (Light Emitting Diodes) whose operation principle is addressed later in the book.

Magnetic Effect

This is the only effect that ever occurs independent of the material in which the electric current flows. A Danish researcher named Oesterd discovered, with a simple experiment, that the movement of electric charges through a wire (current) produces a magnetic field as shown in Figure 15.

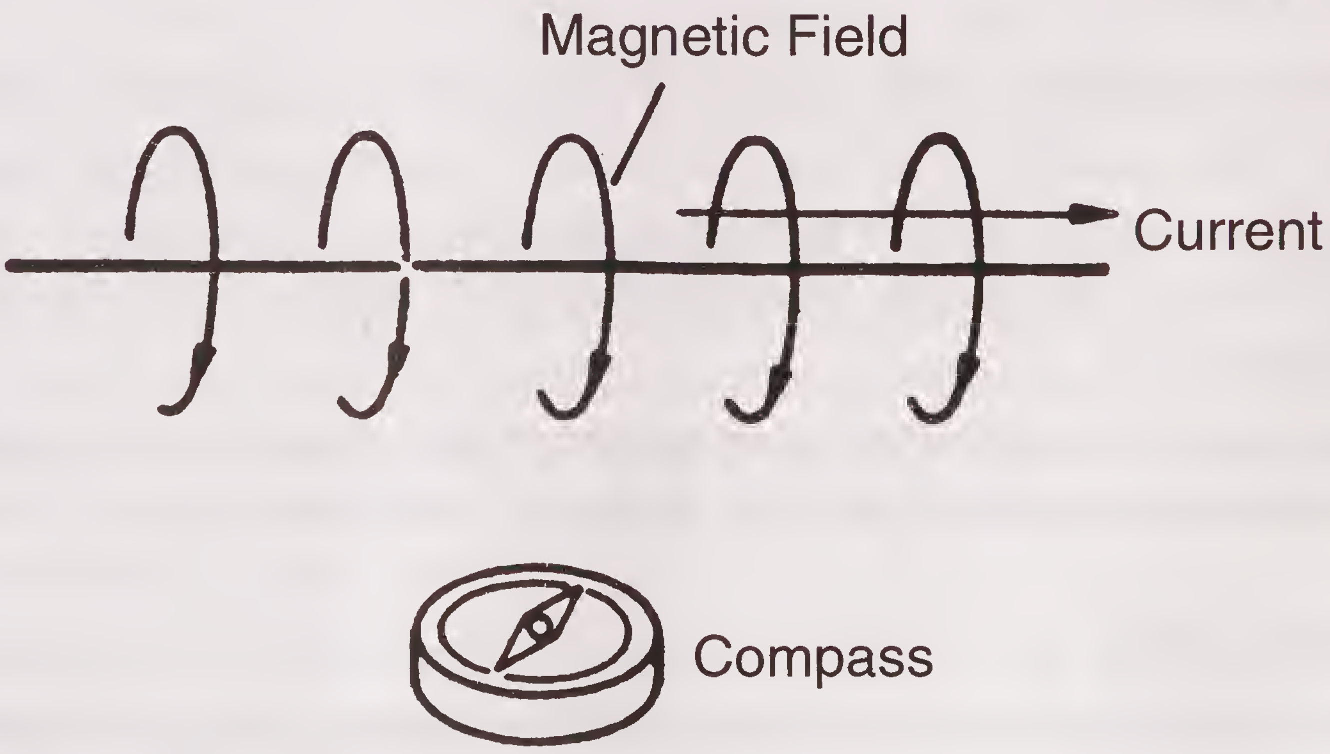

Figure 15

Magnetic field lines involve having the wire oriented in a manner that depends on the direction of the current flow. This effect can be used in many electronic devices. If a current flows through a wire formed into a coil, for example, the magnetic field can be concentrated inside it as shown in Figure 16.

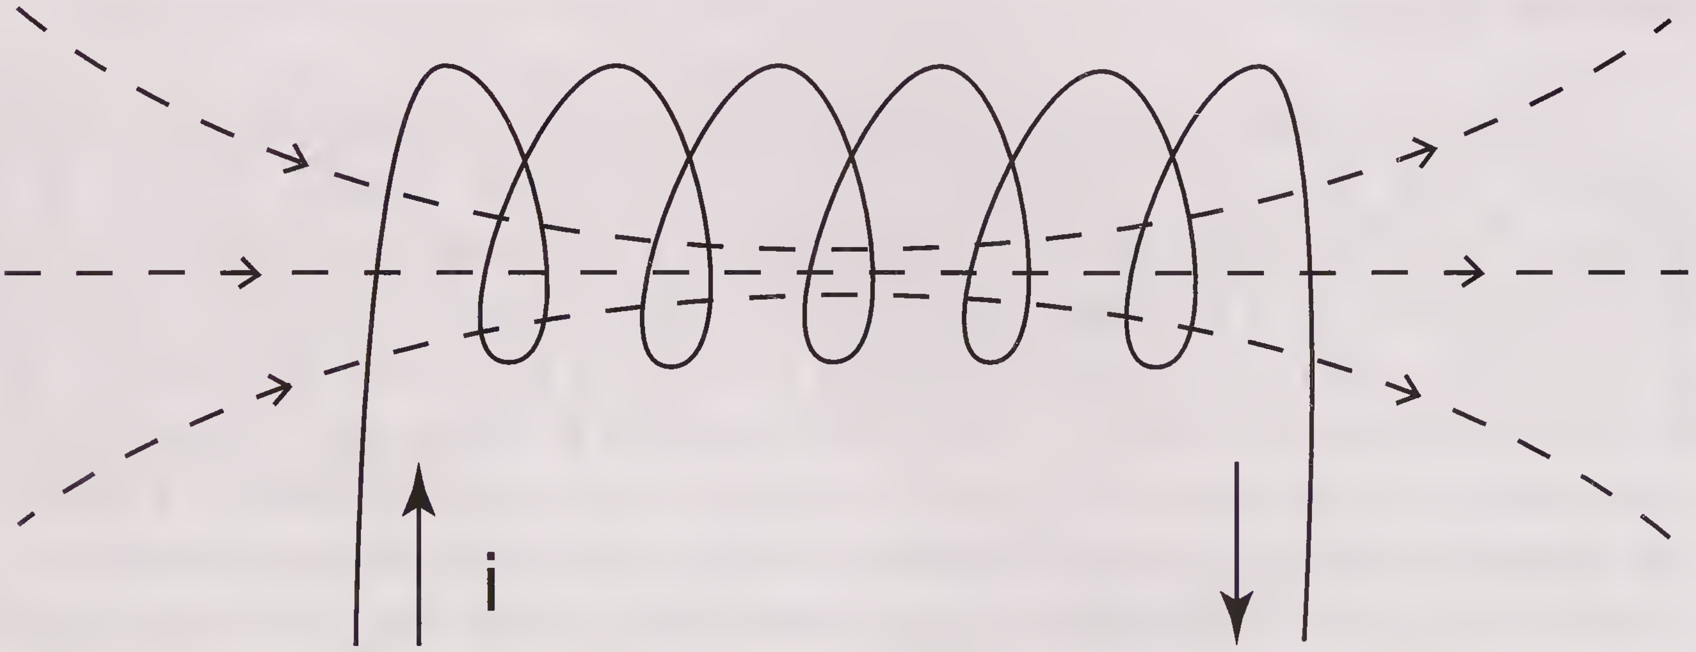

Figure 16

Other researchers found that the inverse effect also exists; if a wire is cut by a magnetic field, an electric current is induced. Devices such as solenoids, electromagnets, relays, motors, loudspeakers, and many others operate based on this effect. These devices include transducers and sensors.

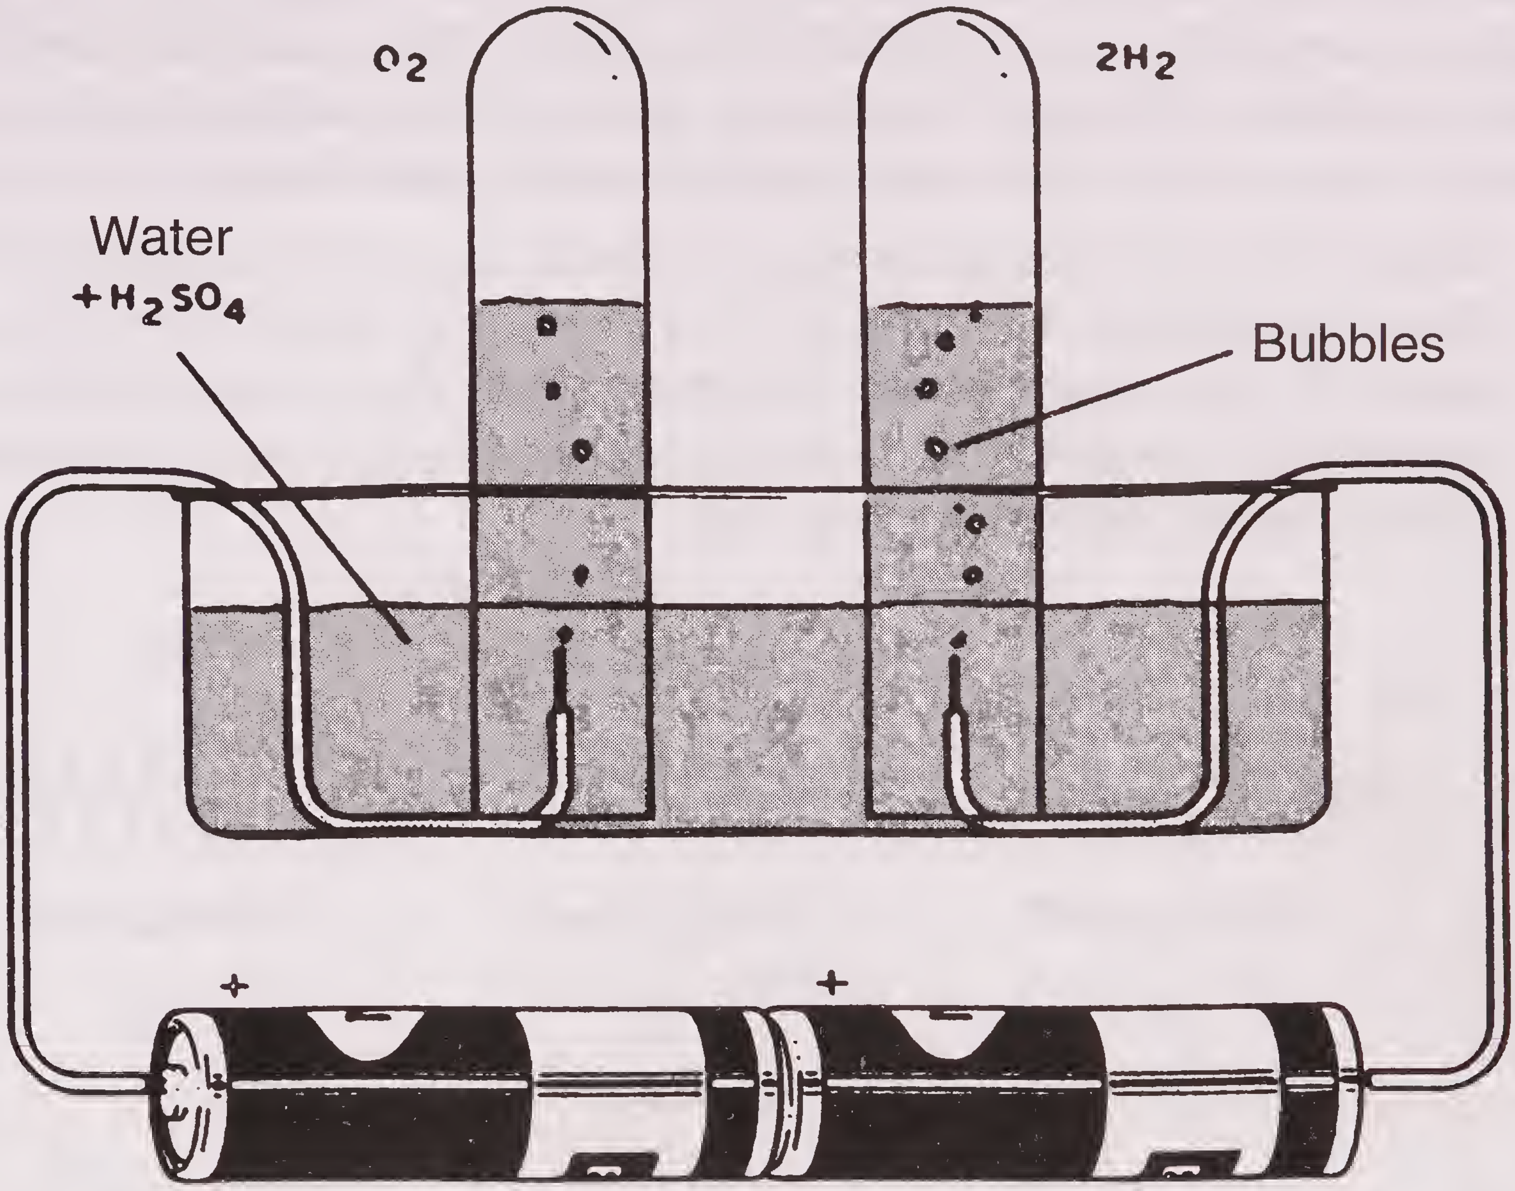
Chemical Effect

When passing through chemical solutions, the electric current can be the agent that causes chemical reactions. The best known of them is decomposition of water and its elements (oxygen and hydrogen) called electrolysis. It can be done with an electric current made with a simple experiment (Figure 17).

Some electronic devices such as electrolytic capacitors and cells when charging are examples of devices that use this effect.

Physiologic Effect

Electric current, when flowing through a living body, can act on that body. For example, in humans electric current can excite the nervous sys-



Cells

Figure 17

tem. It can cause a little itching sensation when the current flow is very low or severe shocks and burns if the current flow is high. This effect is used in some applications for nerve stimulators and other medical applications.

f) Series and Parallel

In an electric circuit one power supply can be used to power many elements. Even in a simple circuit several elements are used. The manner in which these elements are wired determines how the current flows, how the voltages are divided, and how the heat is produced by each element. In electrical applications the analysis of the circuits is generally simple when few elements are used.

Otherwise, in electronics the circuits used to be very complex, with hundreds or even thousands components. Knowing the way in which the components are wired is fundamental to find failures or to calculate component values. Any electrician must know the differences in the way the various components are wired to be able to make a correct analysis of their operation. Although the circuits can be formed of hundreds or thousands components, there are only two ways to wire them:

1. Series—Two or more elements of a circuit are wired in series if they are placed as shown in Figure 18. The current in all the elements of this circuit (in our case, resistors) is the same. The voltage across each element is proportional to its resistance. The components with the larger resistance will dissipate more heat.

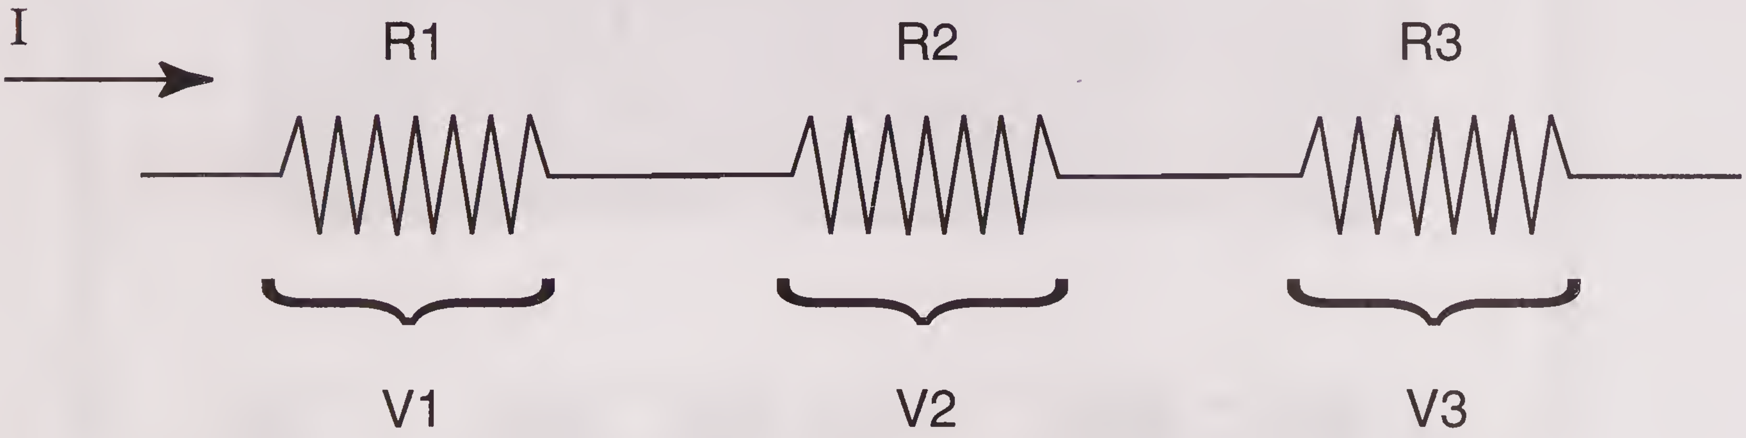


Figure 18

2. Parallel—The components of a circuit (in our example lamps) are wired in parallel when placed as shown in Figure 19. The voltages applied to all the components are the same, and the element presenting the lower resistance dissipates more heat as the current in this element is also the higher.

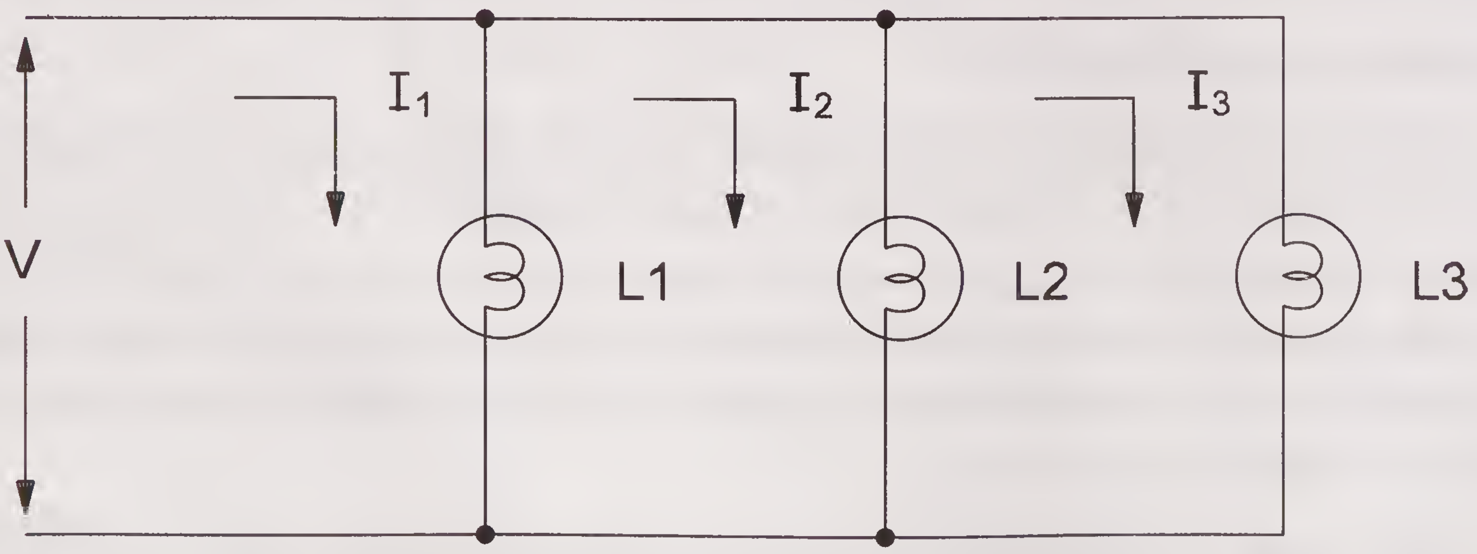

Figure 19

When working with electronic circuits, the electrician can find many types of components and, they can be combined in complex associations where some devices are in parallel and others are in series. So, series-parallel associations are common (Figure 20).

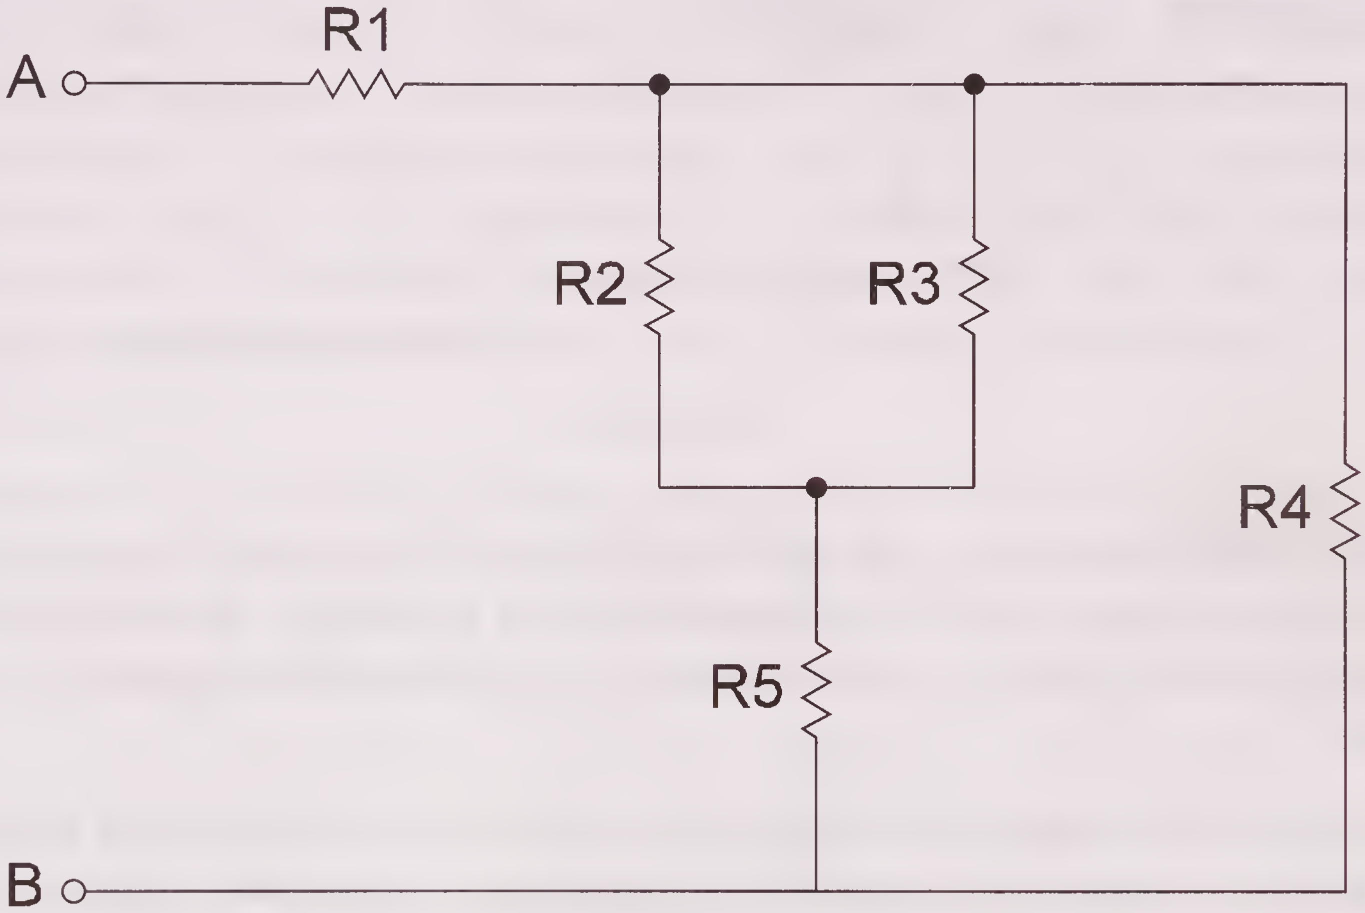

Figure 20

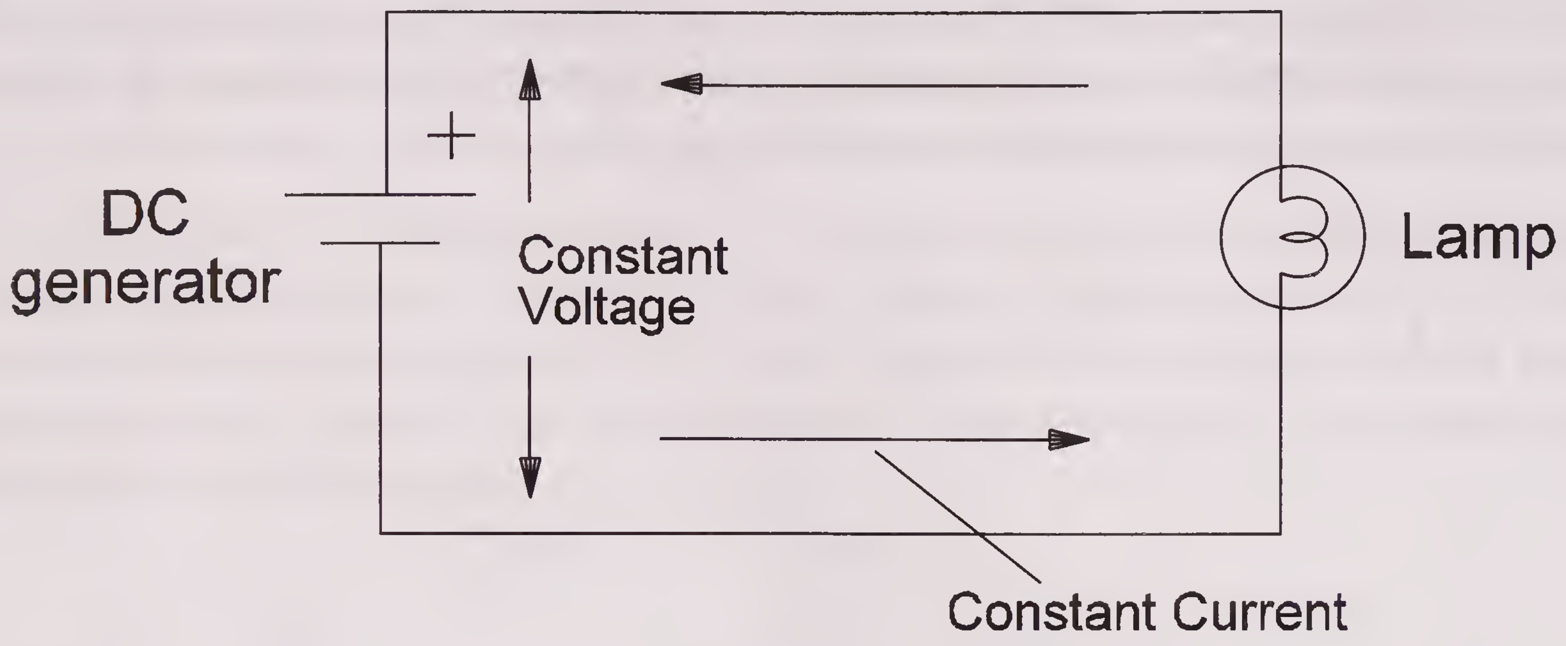
The electrician can analyze one of these configurations taking into consideration which components are in series and which are in parallel. For readers who want to learn more about this topic, a specific electronics course in calculus of equivalence resistance associations is recommended.

g) AC and DC

In basic examples used to show how an electric circuit works, we supposed energy sources or generators with special characteristics. In the poles of these generators we found a constant voltage meaning that when a constant resistance circuit was wired to them, the current flow was established in one direction with a constant value.

This circuit operates with a DC or direct current generator and the current through all its elements is referred to as DC (Figure 21).



DC
generator
+
Constant
Voltage
Lamp
Constant Current

Figure 21

Through this circuit, the electrons can move only in one direction, transporting energy from the generator to a device or load. Cells, batteries, and dynamos are DC generators as the voltage found in their poles is constant.

On the other hand, the electrician who works with electric installations knows that the electricity supplied to buildings is not DC, but AC or alternating current.

+
–
+

Figure 22

What is the difference and what does it mean? It is not necessary to have a constant flux of charges or constant current flow through a device to transport energy to it. Figure 22 shows a generator that changes the voltage in its terminals at high speed.

One moment pole A is positive and B is negative. The electrons are pumped through the device being used as load (a lamp, for example) releasing their energy and heating the filament. The lamp glows. An instant later, the poles of A and B are inverted. The electrons are now pumped in the opposite direction but must pass through the filament of the lamp again releasing energy. The lamp continues to glow. If the generator continues to change its poles, the electrons are pumped forward and backward through the circuit.

Observe that in this process, the charges move only a microscopic distance in one direction, then reverse motion so the charge retraces its path. The action is repeated continually so that the actual average movement of the charges is zero. But, a current flows because the charges are in motion. This is enough to cause an oscillating movement of the electrons in the circuit and to transfer energy from the generator to the load (any device that can absorb energy). This kind of current moving forward and backward is alternating current (AC).

The curious fact to be observed is, although the electrons move only a few centimeters each second, the force that pumps the electrons acts as a wave that moves near the speed of the light through the wires. In domestic installations the AC energy found in outlet jacks changes its poles 120 times by second, or 60 times in a second a pole is positive and 60 times is negative. We say that the frequency of the AC power line is 60 hertz (60 Hz). This is standard in most countries, but in some it is 50 Hz.

The alternating current found in the AC power line has a special waveform of variation represented by a curve shown in Figure 23.

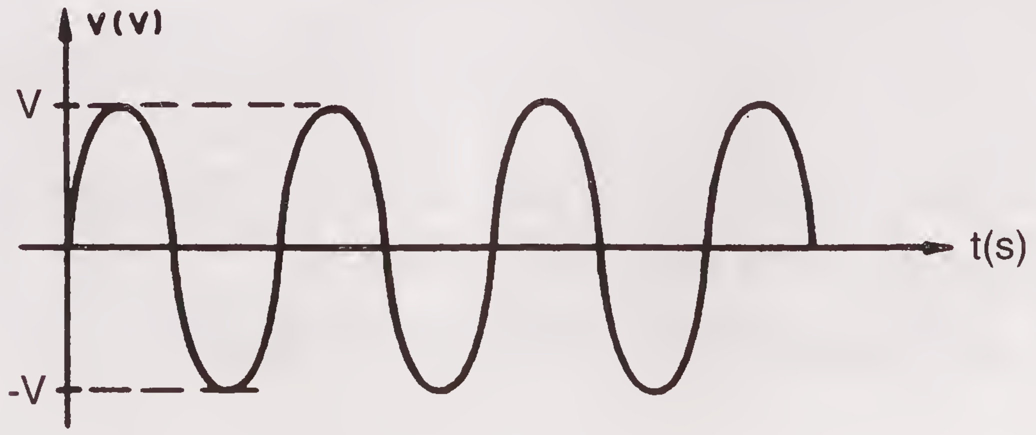

Figure 23

This is a the curve of a trigonometric function called sine and it shows that the voltage across of the poles of an AC generator changes slowly from the positive to the negative passing across the zero point, pumping the electrons forward and backward through a circuit.

When working with electronics, the electrician can find both DC circuits and AC circuits. The circuits powered from batteries or cells are DC circuits. The stages of these circuits are powered from DC sources but they can have some parts where AC currents are found. In general, AC currents ranging from low to high frequencies found in these circuits are called signals. They are used to transport some kind of information like sounds or images.

For the circuits powered from AC power, there are three situations to take into consideration:

1. Some use only AC in their circuits such as the ones used to control AC appliances (motors, lamps, etc).
2. Some use AC in the input but convert it to DC and then DC is used in almost all the internal circuits.
3. Some can use both AC and DC depending on the stage. And, in many stages we can find 60 Hz AC currents and signals ranging from a few hertz to hundreds or thousands of megahertz.

This means that the electrician working with electronic equipment must be prepared to find both AC and DC voltages independent of the used power supply.

h) Sound and Electromagnetic Waves

Many electronic circuits are designed to operate with sounds or electromagnetic waves (radio waves). Telephones, wireless alarms, electronic doorbells, and remote control systems are examples of electronic devices that work with sounds and/or electromagnetic waves.

When working with these devices it is important for the electrician to know something more about the "vibrations." Of course, many electric devices such as doorbells, lamps, and buzzers also work with light and sound, but in a more simple way than many electronic devices.

First of all, we must separate the two kinds of vibrations:

1. Sounds

When a metal bar is struck the vibrations produce disturbances in the surrounding air. These disturbances are caused by compression and decompression waves that propagate through the air in all directions, as shown in Figure 24.

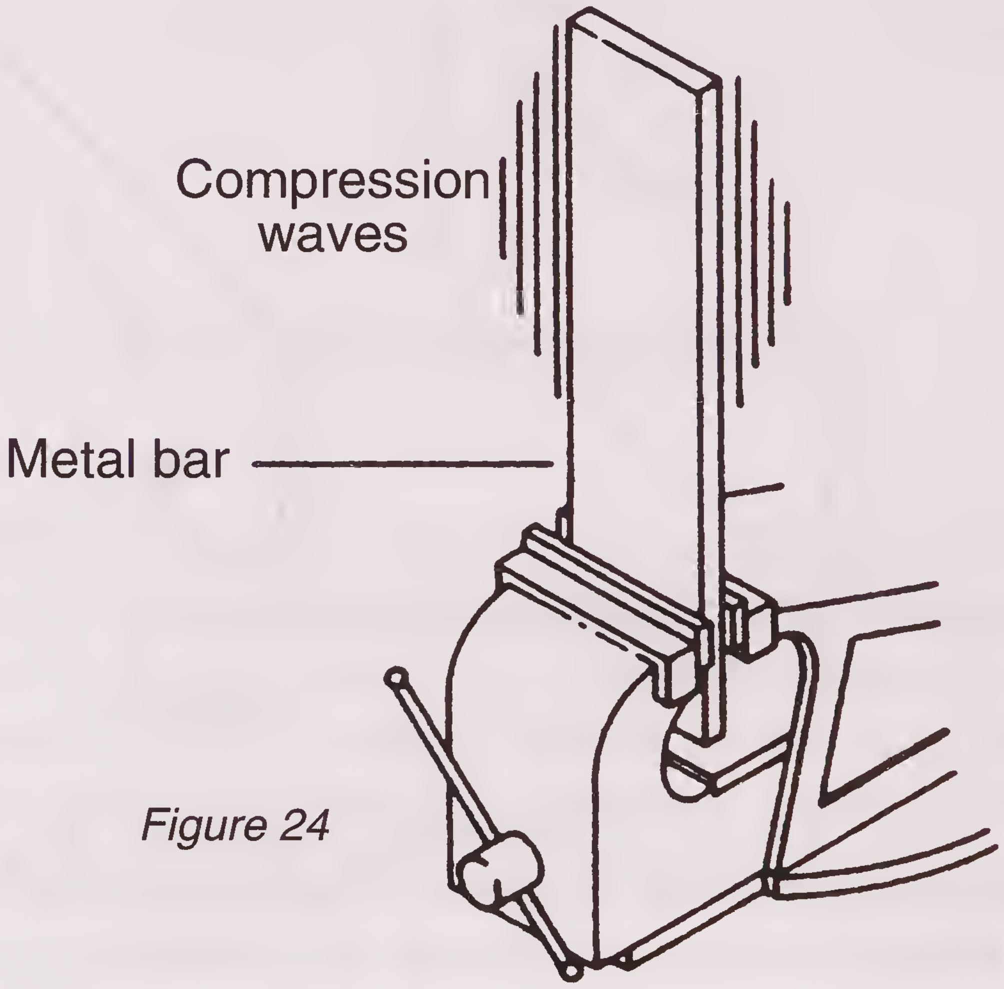

Figure 24

When reaching our ears these waves give us the sensation of sound. But, to be heard as sounds the disturbances or waves must have some special characteristics. First, the human ear can only perceive vibrations inside a limited range of frequencies or "speed" of vibrations. We can hear only the vibrations in the range of about 16 to 18,000 Hertz (vibrations per second). For example, if the bar vibrates at 30,000 Hz it produces sounds that are beyond the audible limit—ultrasonic vibrations. Many animals (dogs, bats, and dolphins) can hear ultrasonic sounds.

Another important characteristic of the sounds is that the human ear can differentiate them by their frequency. Low-frequency sounds, between 16 and 500 Hz, are perceived as bass. High-frequency sounds are perceived as treble. Our ears are sensitive enough to differentiate two sounds if their frequencies are separated of 1/16 of their value. It is because of this that we can differentiate two adjacent musical notes by the number of vibrations or frequency.

Also important is the way the metal bar is put into vibration. The natural way of vibration for a "perfect body" like a tuning fork is the one that produces a sine sound wave as shown in Figure 25.

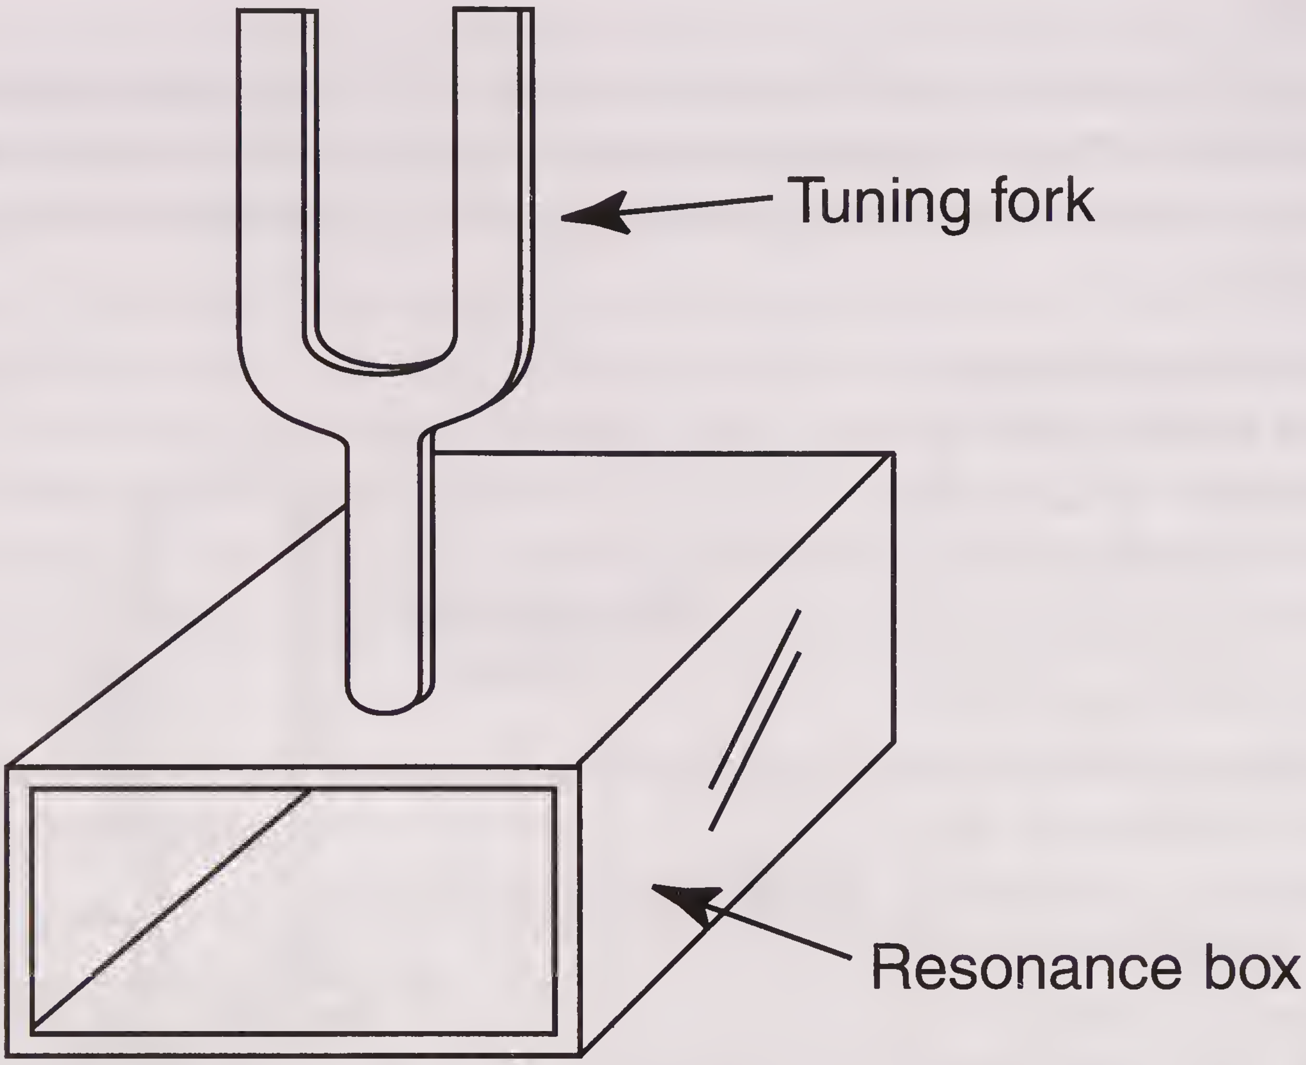

Figure 25

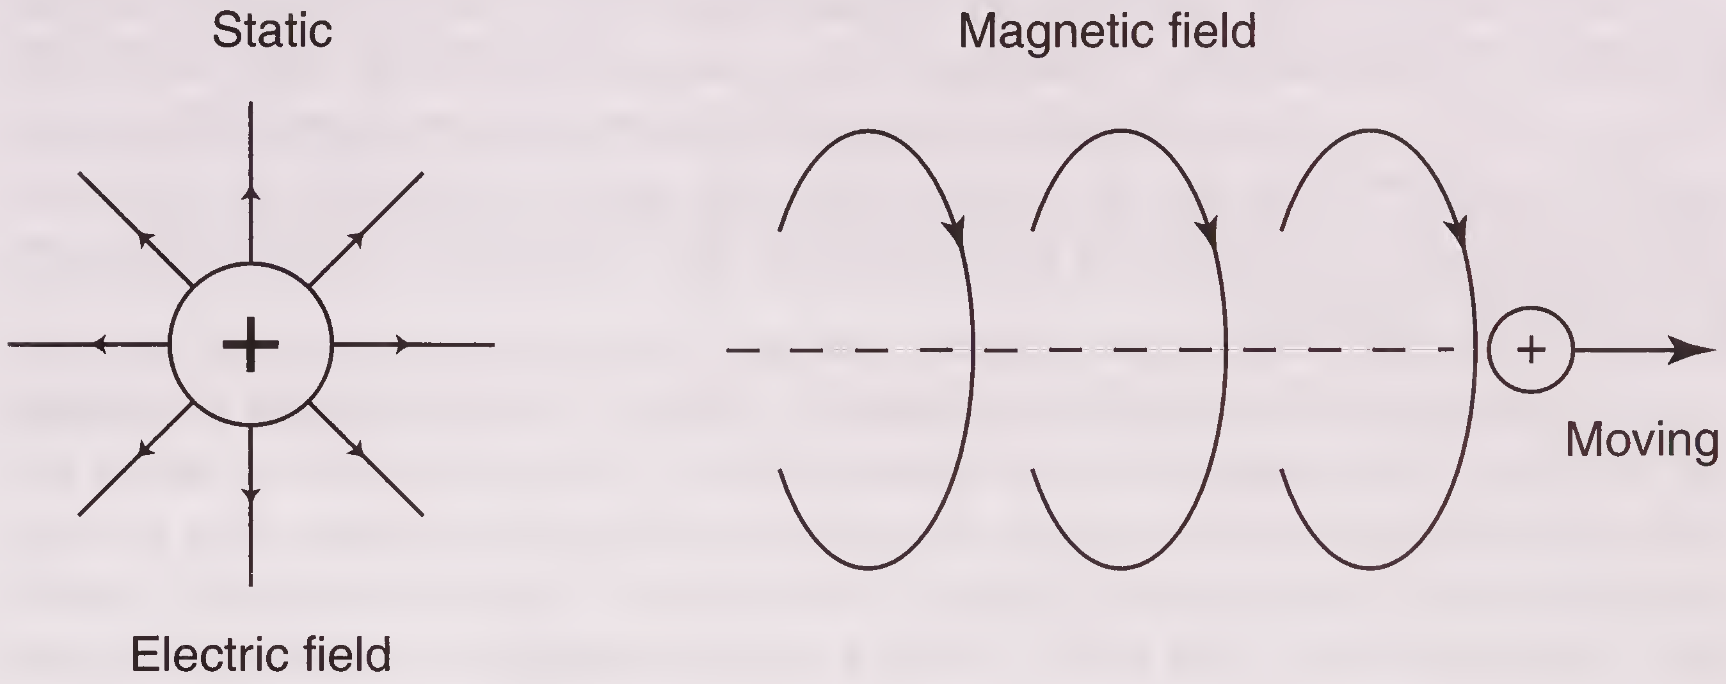
But, if the vibrations are produced by "imperfect bodies" or bodies with special formats such as musical instruments that have resonance boxes or special sizes and formats, the waveform can be different. The different waveforms give the sound a characteristic referred to as timbre or color. Timbre allows us to differentiate between the same tone or musical note produced by a violin and a piano; they have the same frequency but different timbre.

Sounds need a material to support their propagation. What this means is that they can't propagate in a vacuum. In the air, the speed of a sound wave is about 340 m/s.

2. Radio or Electromagnetic Waves

It was in 1865 that the physicist and astronomer James Clerk Maxwell published a theory explaining the existence of electromagnetic fields or electromagnetic waves.

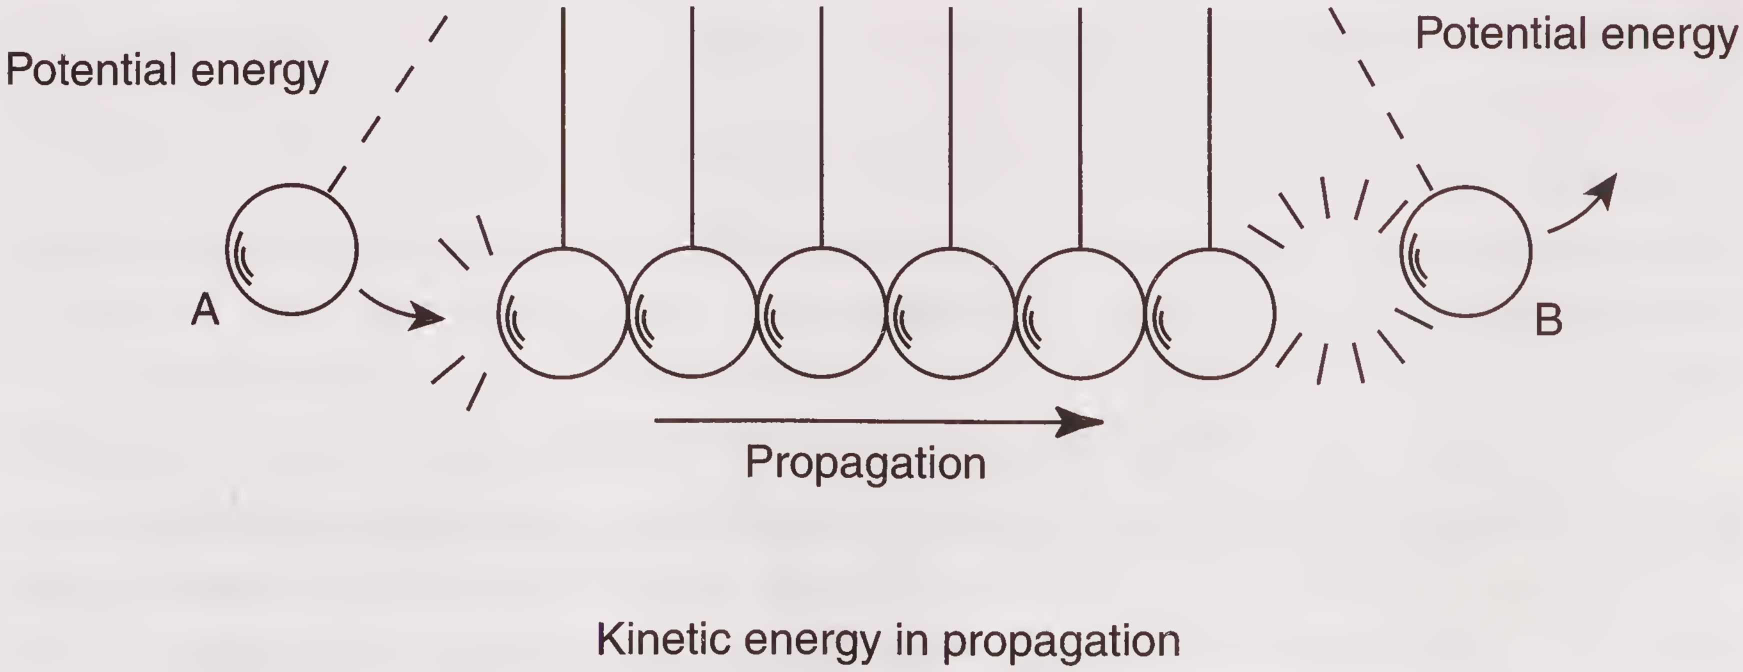
To explain this, begin with the idea that a standard electric charge is surrounded by an electric field and a moving electric charge is surrounded by a magnetic field as shown in Figure 26.



Static
Electric field
Magnetic field
Moving

Figure 26

From this, a simple imaginary experiment can be done to show Maxwell's theory using a row of swinging metal balls (often sold as desk-top toys) as shown in Figure 27. If metal balls are placed end to end in a row and then one end is struck by another moving ball, as shown in (a), the motion of the striking ball is transmitted through entire row. There is little loss as the motion is passed to the ball at the other end of the row as shown in (b).



Potential energy
Potential energy
A
B
Propagation
Kinetic energy in propagation

Figure 27

Maxwell showed with this process that a detectable time delay exists between the departure of energy from a source (striking ball) and that energy's arrival to the last ball, during the interval the energy exists in the moving medium (the row of metal balls). He also concluded that the energy exists half in the form of the motion of the medium and half in the form of an elastic reliance.

In the case of an oscillating electric charge, the two forms of energy are stored in the magnetic and electric fields, correspondent to what we call potential and kinetic energy. So, when a charge oscillates, the energy is transferred to surrounding space in the form of electromagnetic waves that combine in the two fields. These electromagnetic waves can travel through space with the speed of light or 300,000 km/s (as we will see, light is an electromagnetic wave).

Electromagnetic waves are present in our world in many forms. Because electromagnetic waves can be produced in any frequency from zero to infinity, they are represented by a continuum or spectrum as shown in Figure 28.

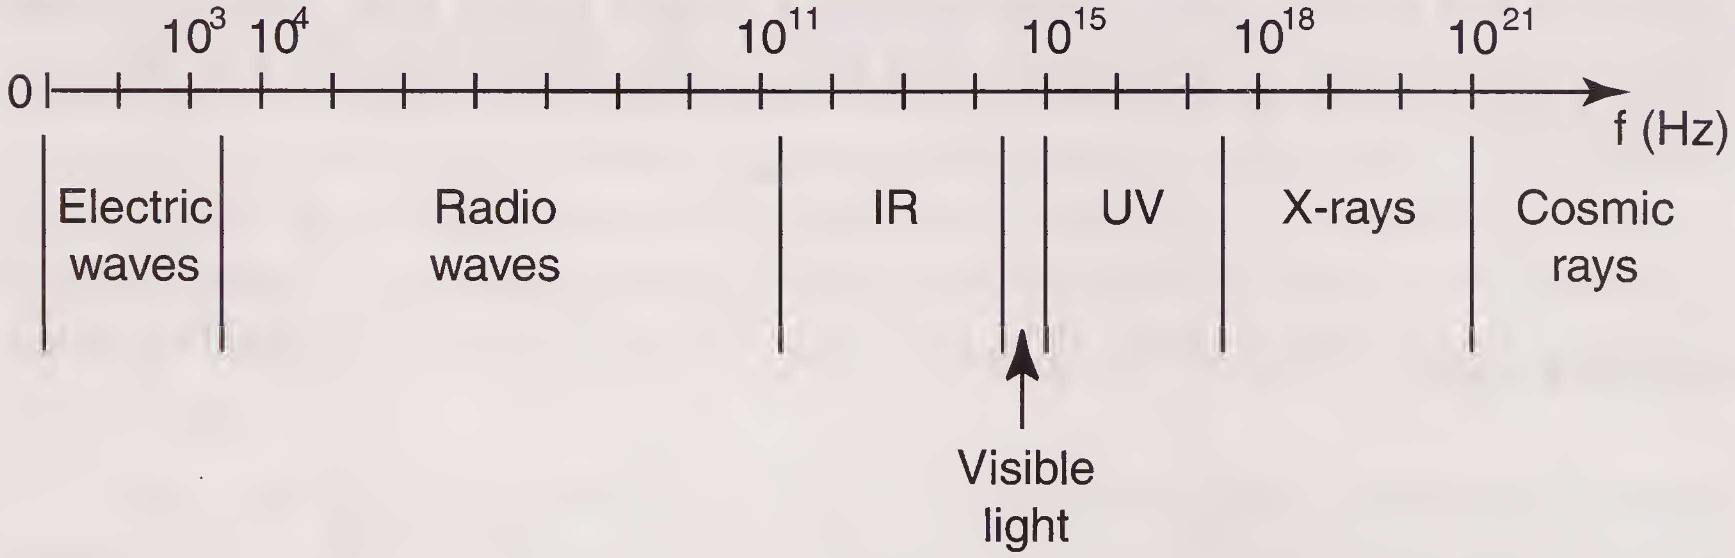


Figure 28

The lower part of the diagram is where radio waves used in broadcasting are found, as well as telecommunications, radar, cellular telephones, TV, remote controls, etc. A little further up is the IR or Infrared part of the spectrum. This corresponds to heat waves. Radiation in this part of the spectrum is due to thermal agitation of an object's atoms. The next segment consists of visible light with the colors, followed by UV waves (ultraviolet radiation). At the upper end of the spectrum are X-rays, gamma rays, and cosmic rays with very high frequency and energy. For the electrician who wants to work with electronics, the most important parts are those corresponding to radio waves, infrared, and visible light.

Two important quantities are associated with electromagnetic waves—wavelength and frequency. Any electromagnetic wave can be represented by sine curves corresponding to the electric and the magnetic fields as shown in Figure 29.

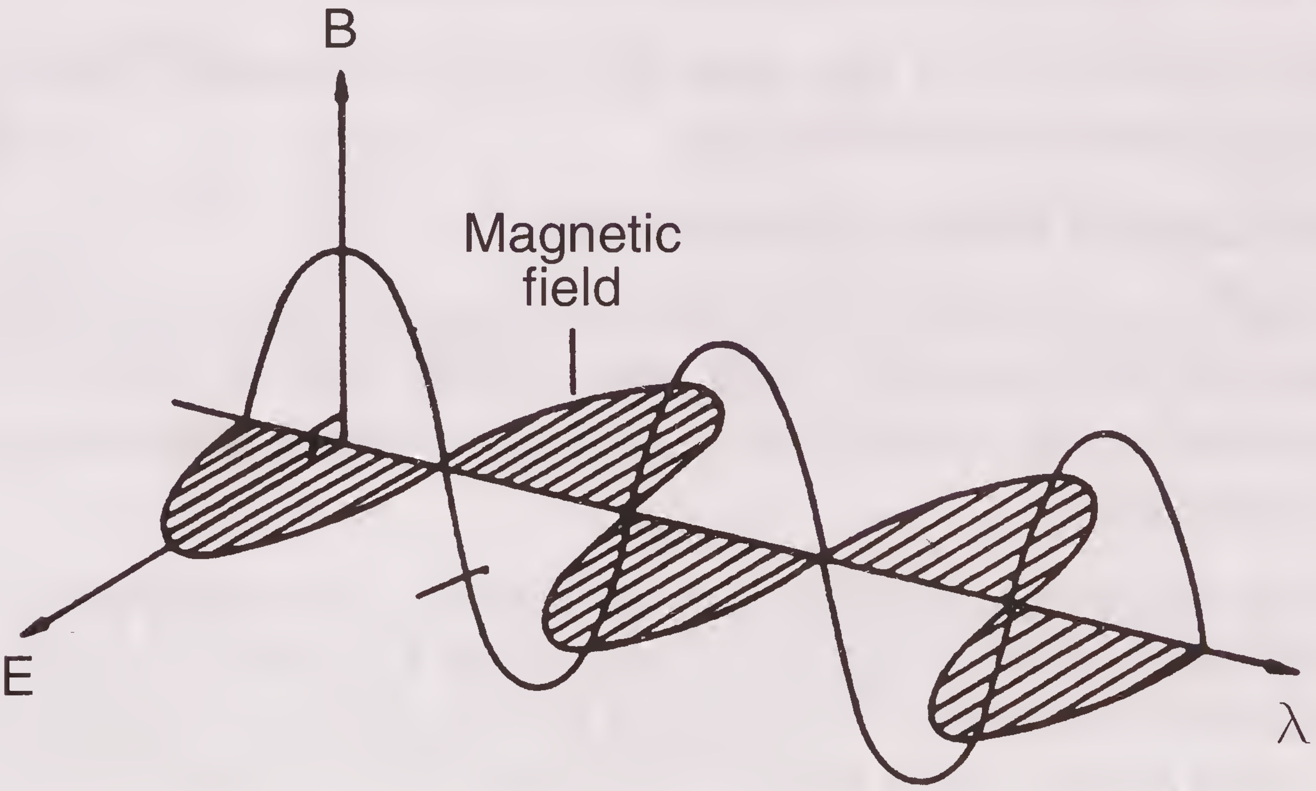

Figure 29

The frequency is the number of waves produced in each second and is measured in hertz (Hz). As high frequencies are common in electronic circuits, the use of the prefixes kilo (k), mega (M), giga (G), and tera (T) are common. When starting from the source, the distance traveled during one cycle can be defined as the wavelength (λ). This distance depends on the speed of the electromagnetic wave that, in a vacuum, is 300,000,000 m/s (or 300,000 km/s). So, to calculate the wavelength of an electromagnetic wave, divide 300,000,000 by the frequency in hertz.

If, for example, the wavelength of a 100 MHz (100,000,000 Hz) signal of an FM radio broadcast station is:

λ= 300,000,000/100,000,000 = 3 meters

Knowing the wavelength of a radio wave is very important since it determines the characteristic of the antenna used to transmit or receive it.

The sizes of the elements of any radio antenna depend on the wavelength of the signal it is designed to use.

The fundamentals of electricity are the same that command electronic circuit operations. In electronic circuits, AC and DC currents pass through components and use all the common effects as you most likely studied before. Light, heat, magnetic fields, motion, images, and sounds are generated by devices that operate based on principles found in any electric devices or are explained by the physics principles.

For the electrician, the next step is to know what tools must be used when working with electronic circuits.

i) Printed Circuit Board and Solder

The small components used in electronic equipment can't stand alone without any physical support. They need some kind of support to keep them fixed while at the same time providing an electrical connection with the rest of the circuit.

Opening any piece of electronic equipment, the electrician will find that the electronic components are mounted on a special board of fiber or another insulating material. This support or chassis for the components is called a printed circuit board (PCB). The board, as shown in Figure 30, is made of an insulating material where copper strips are printed on one or both sides.

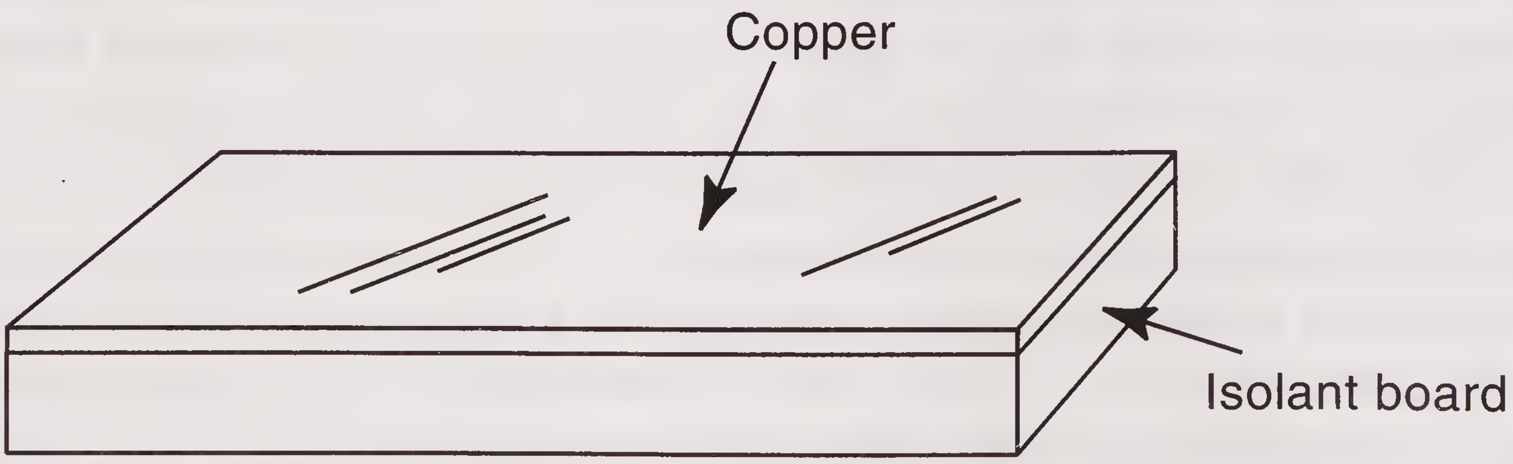

Figure 30

The strips act as wires, conducting the currents from one component to another. The pattern of the strips is determined by the function of the circuit. All the strips are planned before the manufacturing process to provide the necessary connections between components in the desired function. This means that a printed circuit board produced to receive components that form a radio can't be used to mount TV circuits or any other equipment.

As shown in Figure 31, the small components are soldered onto the board so their terminals make contact with the copper strips.

Figure 32

Removing and reinstalling components on a printed circuit board is a delicate operation that an electrician who wants to work with electronics, to repair and mount circuits, must know. Special techniques are required for this work because the components are so small and extremely sensitive to heat. The solder used in electronics is an alloy formed of 60 percent tin and 40 percent lead with some rosin. It is common to call this kind of solder transistor solder, radio-TV solder, or 60-40 solder.

When heated to about 273 degrees Celsius, the solder melts and involves the terminal of the component which fixes it to the board, while at the same time providing electric contact with the copper strips or other components. When working on component mounting or replacement, an electrician will need some solder and a soldering iron. The solder can be bought in small quantities as shown in Figure 33.

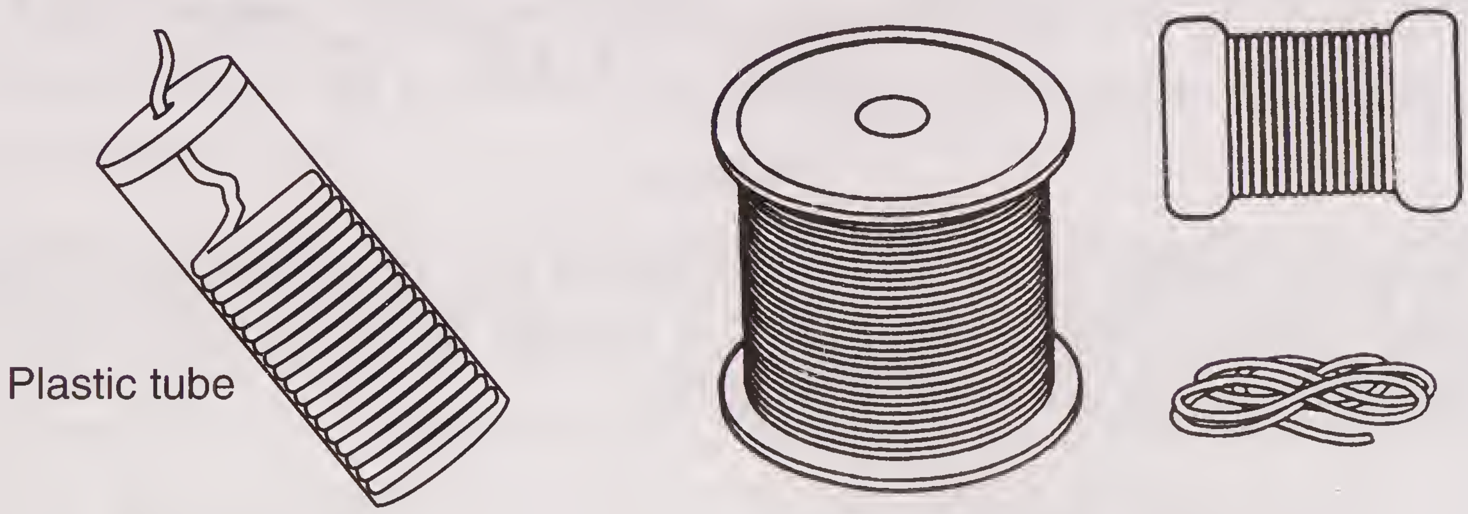

Figure 33

A soldering iron is shown in Figure 34.

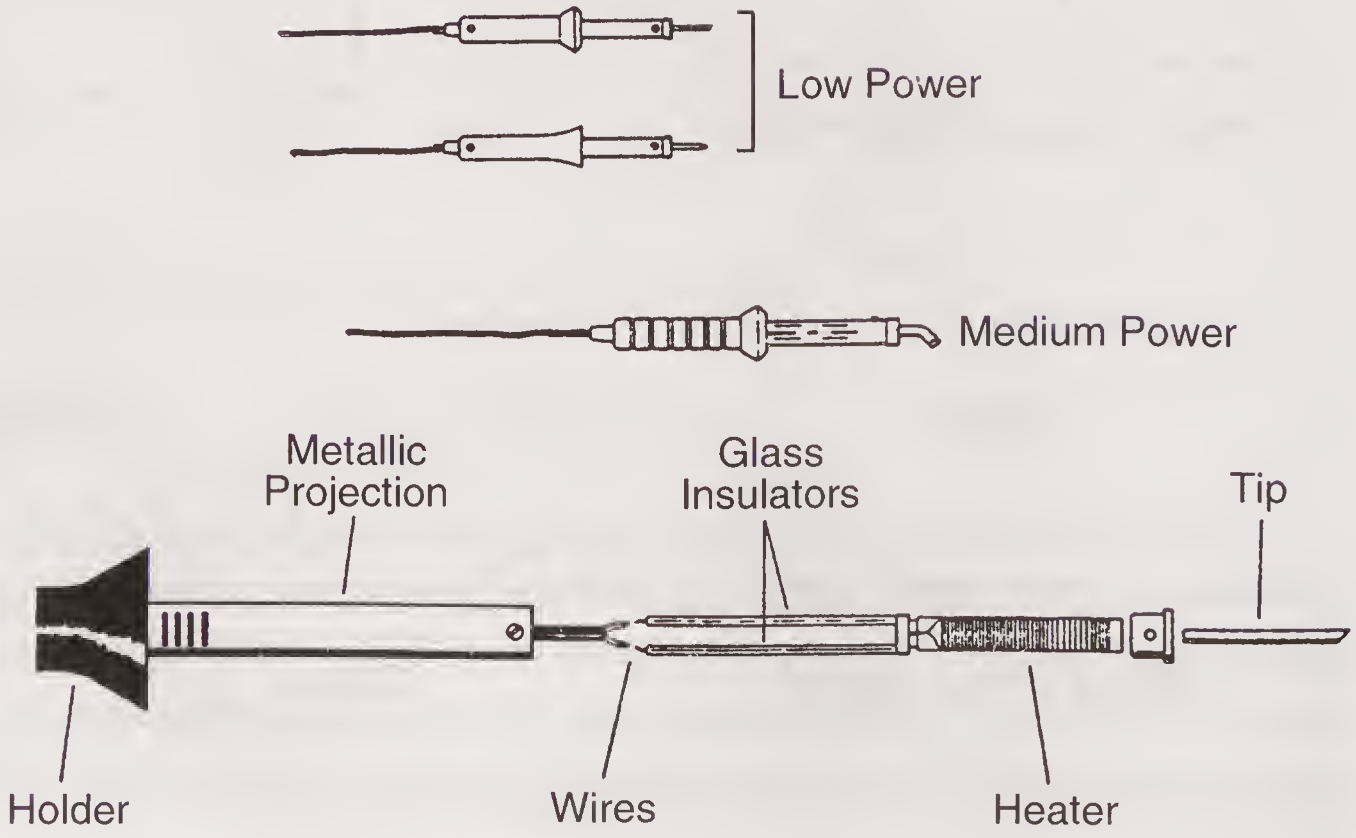

Figure 34

A 25- to 40-watt soldering iron with a shiny tip is recommended when working with small electronic components found in circuits. Of course, the electrician can also have a heavy-duty soldering iron to remove or place larger components like those found in some electric and electronic applications. Radio Shack has soldering irons suitable for this task as well as the next task:

- Dual Wattage Pencil Iron, 15 to 30 W (Radio Shack 64-2060)
- 15 W Pencil (Radio Shack 64-2052)
- 25 W Pencil (Radio Shack 64-2072)

Soldering is a simple operation and many electricians are familiar with this kind of work. But, electronic devices are very special and care should be taken when soldering to avoid damaging them. Many electronic devices are easily damaged by excess heat or the incorrect soldering procedure. The basic procedures to solder electronic components (remove or install on a PCB) are as follows:

- Plug in the soldering iron and heat for at least five minutes. This is long enough to bring the tip to the correct temperature for good soldering operation.
- Touch the soldering iron to the work area, allow a very short time for the connection to heat up, and then touch the solder to the connection, not the iron, as shown in Figure 35.

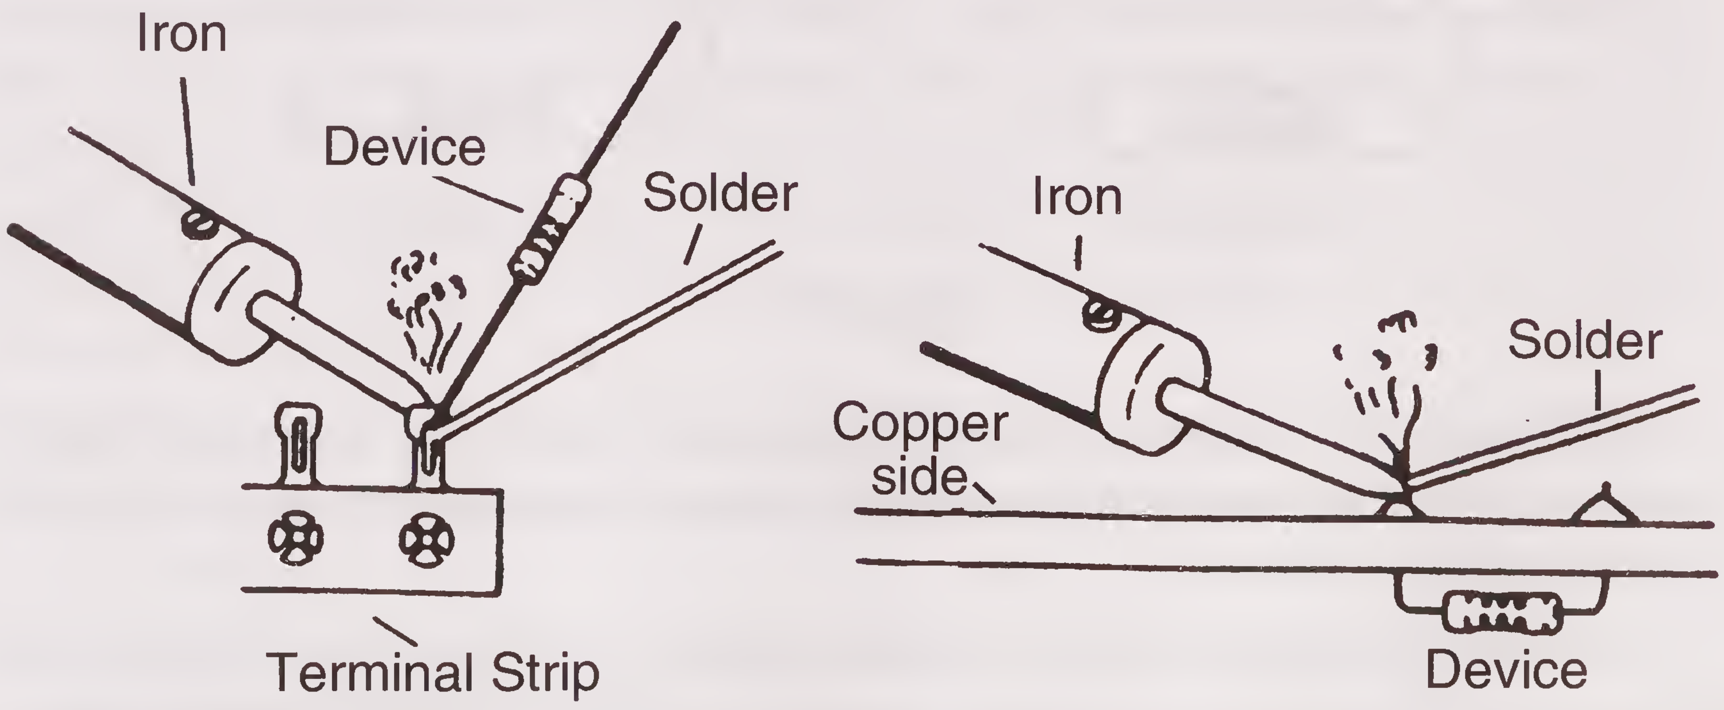

Figure 35

- You will notice that when the solder melts it penetrates every part of the solder joint.
- Remove the iron and do not move the joint until it has had time to cool. It is easy to see when the joint is cool. A peculiar haze will pass over the hot metal after which, the joint is cool enough and strong enough to withstand movement.

Figure 36 shows a perfect solder joint and some solder joints with problems. One of the principal causes of problems in electronic equipment is "cool solder." The solder seems to involve the component, but no electric contact is established because the joint was not heated enough to penetrate the metal creating an isolated layer of moisture or oxide to form between them.

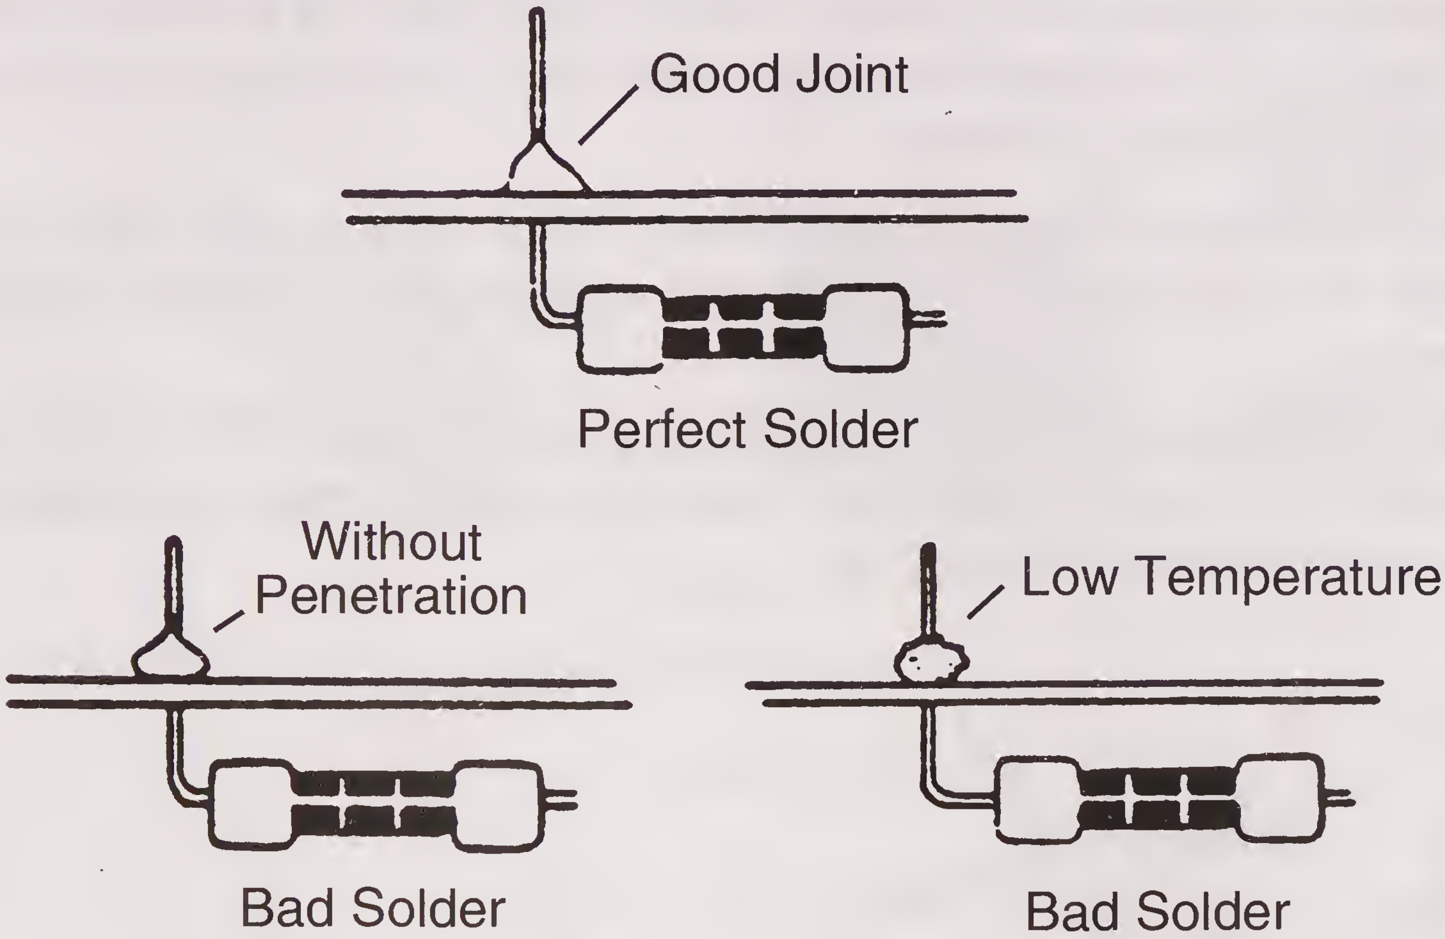

Figure 36

Although the use of the soldering gun, such as the one shown in Figure 37, is not forbidden, there are many cases in electronic works in which it is not recommended.

This type of soldering tool has its resistive tip heated by a strong current coming from the low-voltage winding of a transformer. When working with sensitive components such as integrated circuits, transistors, and others during the soldering operation, this current can be enough to burn them.

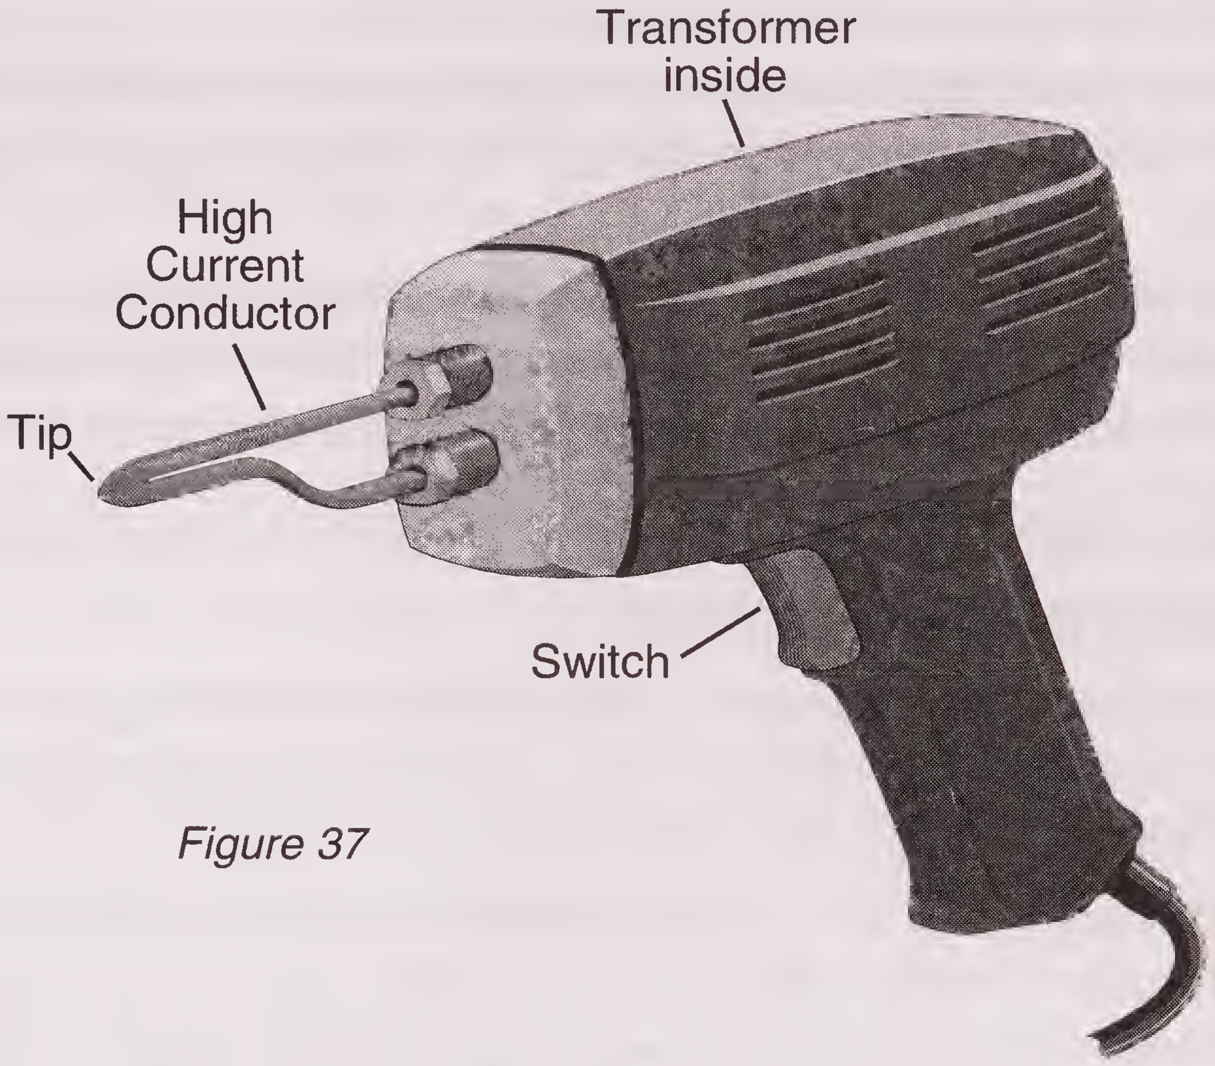

Figure 37

j) Other Tools

The soldering iron isn't the only special tool needed by electricians who intend to work with electronic circuits.

When working with electronic parts, many of the tools used in electric installations or automotive electricity are suitable. On the other hand, many electronic components are very small and delicate and need special tools and care. The use of improper tools when working with these components is often the cause of damage. If an electrician intends to work with electronic circuits, some special tools are needed. I suggest having at least some of these tools:

- Cutting pliers or diagonals (often called dykes) in sizes from 4 to 6 inches.
- Chain-nose or needle-nosed pliers with very narrow tips in sizes from 4 to 5 inches.
- Two or more screwdrivers sized between 2 and 8 inches. (Seven-piece set: Radio Shack 64-1823).
- Crimping tools—stripper and cutter for 10 to 22 wire gauges (Radio Shack 64-2129).

- Precision tool set (10 to 16 tools) with small screwdrivers of hex, common, and Phillips types (Radio Shack 64-1948).
- Soldering and desoldering accessories such as a desoldering bulb (Radio Shack 64-2086) and a soldering iron holder/cleaner (Radio Shack 64-2078).
- Extra hands to hold the work in the form of a mini-vise with vacuum base (Radio Shack 64-2094) or a Project Holder (Radio Shack 64-2093).
- Mini hand drill (five-piece hand drill, Radio Shack 64-1779).

Many other tools can be found in electronic and tool catalogs.

k) Diagrams and Symbols

As in the case of electric installations in buildings or automotive installations, schematic diagrams are used to represent the way the many parts of equipment are interconnected.

There are many differences between an electric diagram and an electronic diagram. These differences start with the symbols used to represent components and end with the way they are connected. These differences are one of the problems to be solved by an electrician wanting to know something about electronics. He needs to be acquainted with new symbols since there are many electronics components represented by symbols that the electrician doesn't know. Learning the symbols used to represent each component and what they do in a circuit are the next steps in this book.

Let's begin with the schematic diagrams.

Figure 38 is a diagram of a simple piece of electronic equipment: a DC power supply similar to those used to power small calculators, CD players, and other appliances from the AC power line.

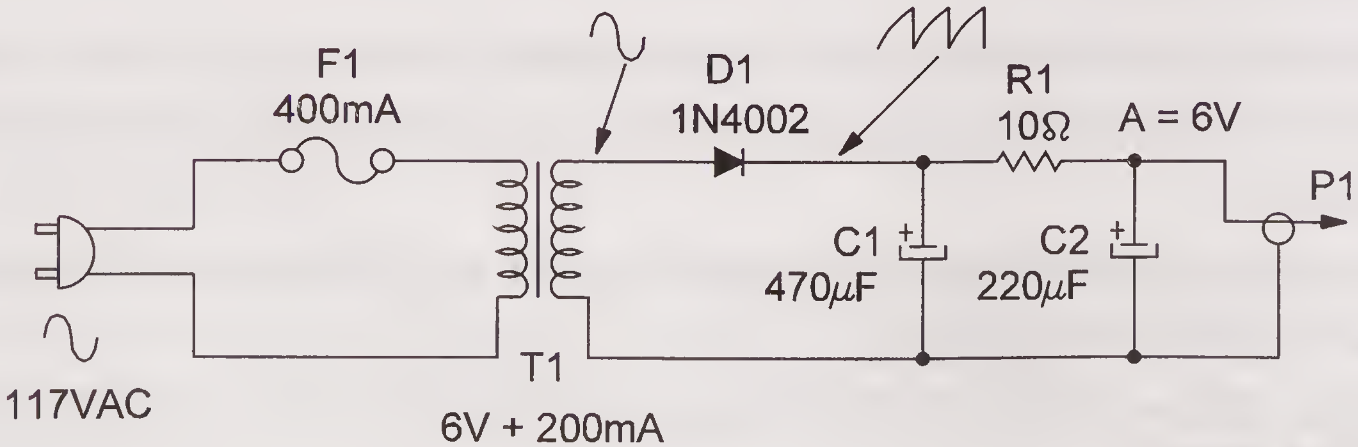

Figure 38

This schematic diagram represents all components by their symbols, and in many cases, the identification, values, and other important information are given. At the side of the symbol of each component is the identification number. This is important since it can help the technician find the component on the PCB or inside the equipment.

For example, all the resistors are identified by the letter R followed by the number of the device in the equipment. This means that many resistors can be found in a device identified by R1, R2, R3, etc. Capacitors are usually noted by the use of the letter C. The capacitors of a circuit are numbered starting from C1, C2, C3, etc. Transistors can be identified by the letters Q, T, or TR. They can be represented as Q1, T1, or TR1.

In many cases, a second number can identify the “block” or a “stage” in which the component is placed. So, the resistors of the first stage can begin at R101 and the resistors in the second stage from R201. Near the identification and the symbol we can also find the value or type of the component.

Resistors have the value of resistance to the side, such as R1, 1000 ohms or 1k. If it is a transistor, you might find 2N3906, meaning that when used, the transistor must be replaced with a 2N3906. The usual identification number for transistors begins with a 2N, but many manufacturers have started using letters signifying their names such as TIP (Texas Instrument) and MPS or MM (Motorola). There is also a European code that uses the letters BC or BD in the identification of devices, and a Japanese configuration that uses the letters 2SB, 2SC, or 2SD to indicate transistors.

Depending on the circuit, other important information can be found in the schematic diagram. For example, the voltage at different points in the circuit can be found.

In the example presented, it is indicated that, between A and the ground (normally taken by reference or 0 V), the measurement is 6 V when a multimeter is used to take the voltage (Figure 39).

Another important piece of information found in a diagram is the waveform of the signal present in a point.

As we said, electronic circuits don’t operate only with DC voltages but also with AC voltages in a large range of frequencies and waveforms. These AC voltages or signals are not only sine signals, but can have several

waveforms and amplitudes. Oscilloscopes are used to observe waveforms of a signal in a circuit. Figure 40 shows a common oscilloscope used on electronic workbenches for troubleshooting and diagnostics.

Gain

Figure 40

By observing the waveform of a signal at a point in a circuit a technician can determine what is wrong. The oscilloscope is one of the most powerful tools in the electronic lab. In the schematic diagram example there is the indication of a waveform at point B.

Also found on a schematic are procedures for installation, diagnostics, equivalence, etc. Diagrams for many types of equipment can be found with their manuals, but this is not common. A solution for the electrician who has problems with a piece of equipment and needs the schematic diagram is to purchase one. Sams Photofact is the most important supplier of schematic diagrams for commercial electronic equipment. You can access the company's Web site at www.samswebsite.com.

Section 2

Electronic Components

The parts found in electronic equipment are very different from the ones the electrician finds in electric installations of buildings and cars. Knowing how these electronic components work, how they are used, and how to read and interpret their specifications is an important item to everyone who intends to be an electronic technician. It is also very important to know how these parts can be tested.

So, as a brief introduction of electronics to the electrician, the principal electronic components are described. These are found in some equipment for use in domestic installations and also the automobile. From this description, the electrician will be able to recognize these components when working with electronic equipment. This knowledge is also very important as a starting point for a basic course in electronics.

Wires

Wiring material is used to connect the circuit parts, devices, equipment, etc., electrically. There are various types of wiring material for use in electronic applications. The wires used in electronic equipment have some differences from the ones found in electric installations. The current flow, in general, is lower in electronic appliances, which need thinner wires, but some devices use special wires. Basically the electrician will find three types of wires in electronic work:

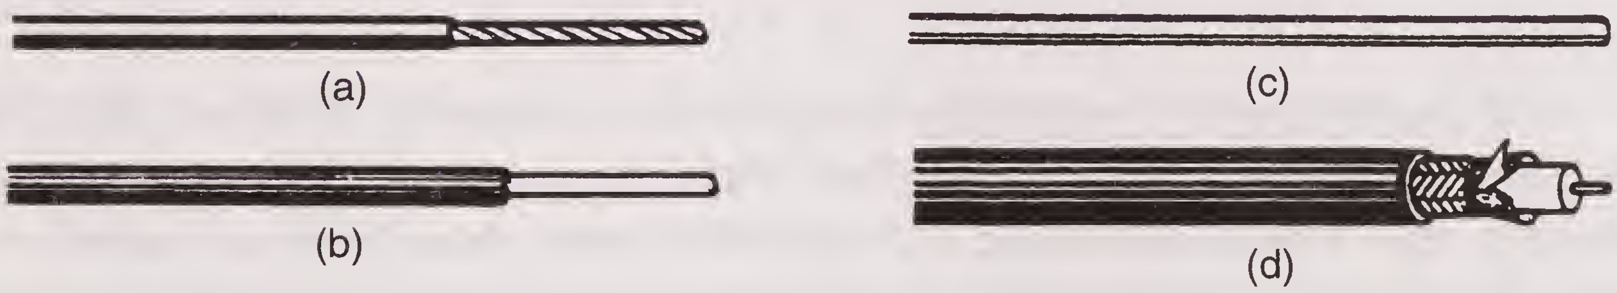
A. Cable—formed by a core of several copper conductors and covered by plastic insulation.

B. Rigid—formed by a core with only one conductor covered by plastic insulation.

C. Bare—formed by a copper conductor without cover (insulation).

D. Screened and Coaxial—formed by a core with one or more plastic covered conductors. These conductors are enveloped by a copper screen. Over the entire cable there is a plastic cover.

The plastic-covered wires can be found in several forms including single wires, twisted wires, flat cable, etc. Figure 41 shows some types of wire used in common wiring of electronic circuits and parts.



(a) (b) (c) (d)

Figure 41

AWG (American Wire Gauge) is a special type of enameled wire that is used in some electronic (and also electric) components such as coils, relays, solenoids, motors, magnetic sensors, loudspeakers, earphones, and many others. AWG is a standard U.S. set of nonferrous wire conductor sizes. The gauge is referring to the diameter. This standard is mostly applied to copper household wiring and telephone wiring. AWG is sometimes known as Brown and Sharpe (B&S) Wire Gauge, also.

AWG enameled wire is formed by a rigid copper wire insulated by a cover of enamel. The diameter of the wire determines the amount of current it can conduct. The diameter of a wire can be expressed in millimeters, mils, or by an AWG number. The higher the AWG number of a wire, the smaller the diameter. Table 1-2 shows the characteristics of the AWG wires used in electronics.

AWG No.	Dia.	Cross Sec. (mm²)	Resistance (ohms/km)
0000	11.86	107.2	0.158
000	10.40	85.3	0.197
00	9.226	67.43	0.252

Table 1-2
Standard annealed copper wire (AWG & B&S)

Fuses

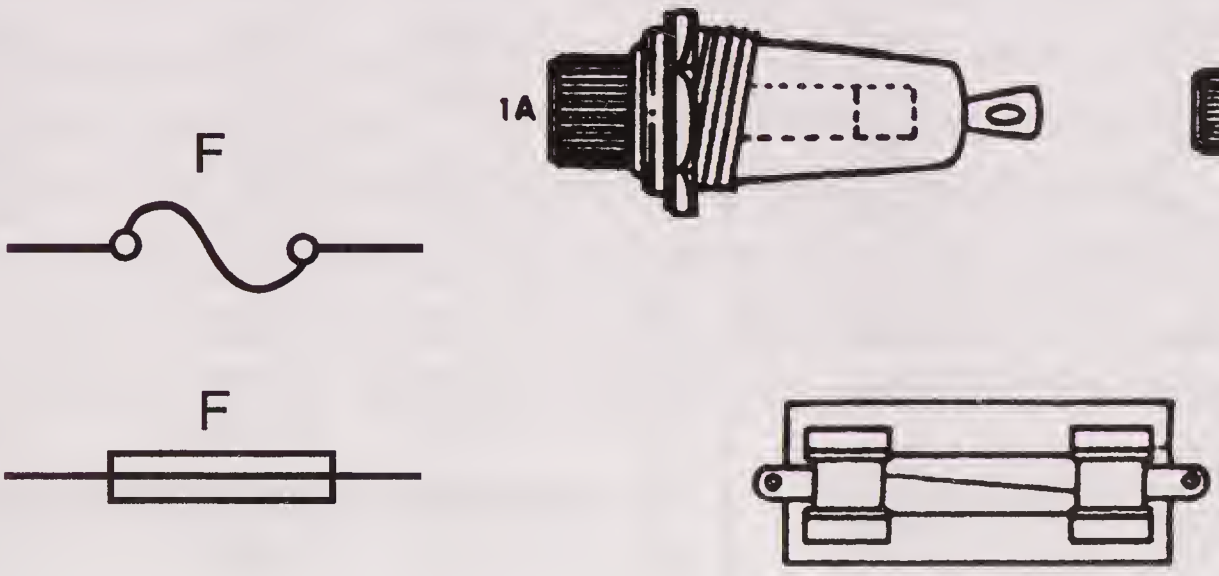
Fuses are the protection elements of a circuit.

The whole purpose of a fuse is to switch off the current in the circuit before anything other than the fuse can be harmed when a problem occurs. They operate based on the old principle of a chain being only as strong as the weakest link. It is easy to see that the best way to protect everything else was to make one link deliberately weakest so it would fail first.

The name fuse comes from fusible link, as suggested by the previous analogy. A fuse is designed to conduct its rated current and act as a conductor. When the current increases beyond the rated value the fuse melts, acting as an SPST switch and opening the circuit.

Symbols and types

Figure 42 shows the symbols used in electronics diagrams to represent a fuse and also the types of common fuses found in electronic equipment. These fuses are basically formed by a piece of wire in which thickness is the determining factor of the melting current.



Examples

Figure 42

Where they are found and how they are used

The fuse is wired in series with the device or circuit to be protected as shown in Figure 43. It is usual in some electronic equipment to have several fuses, each one protecting one stage or part in such a manner that if one stage fails and the corresponding fuse melts, the other stages can continue their normal operation unless they are interdependent.

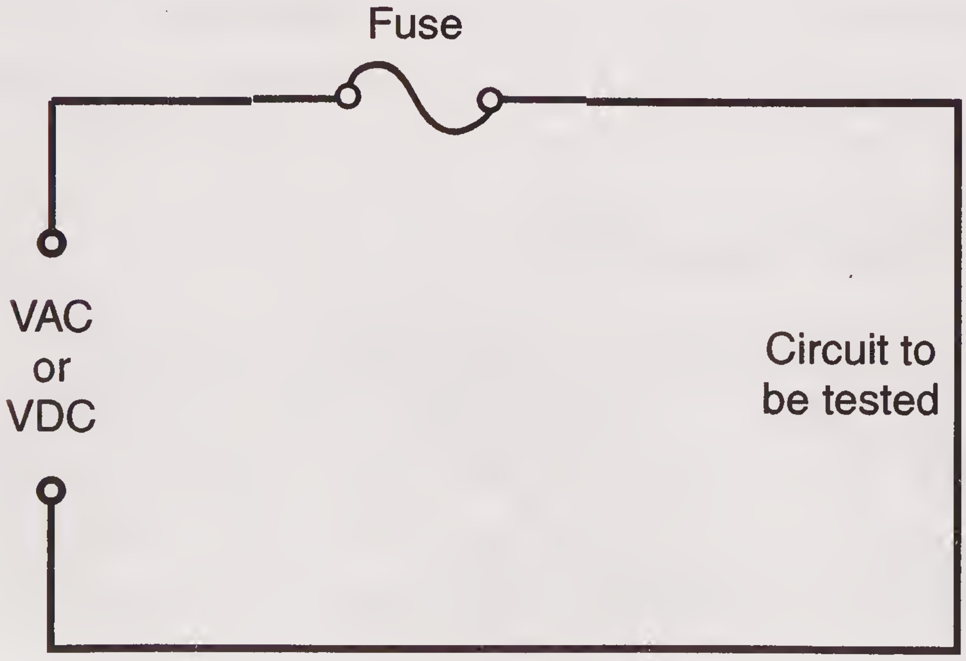


Figure 43

Specifications

The most important specification of a fuse is the melting current or the current that causes the fuse to burn. This nominal current can be specified in miliamperes or amperes according to the value and application.

When replacing a fuse, never use a unit with current specification larger than the original. The specification of current must be the same. If a larger fuse is used and a failure occurs in the circuit, increasing the current to a dangerous value, the fuse may not be the first component to burn out. It may be some component of the circuit or possibly many of them that will burn.

Other specifications of a fuse to consider are how fast it burns when problems occur and the highest operation voltage. In some electronic circuits the fuse is a small piece of bare wire placed between two terminals. The wire gauge is chosen to melt with the desired current.

How to Test a Fuse

A good fuse must present a low electric resistance. To know if a fuse is in good condition, test its continuity—whether it can conduct the electric current. A high resistance means a burned fuse (open circuit). A good fuse measures a resistance near zero when tested. A multimeter can be used for this task.

Switches

In electronic appliances the electrician will find many types of switches. As in any other electrical application, the switches are used to control the current flow throughout the circuits or parts of them.

The difference between the switches used in common electric installations and cars is not important. In electronic equipment the switches, in many cases, are used to control many currents at the same time. The design also depends the applications.

Symbols and Types

Figure 44 shows the symbols and types of the main types of switches found in electronic circuits. The symbol indicates what the switch makes. For instance, (a) shows an SPST (Single-Pole Single-Throw), which is a switch that controls the current flow in only one circuit (single-pole). As the name suggests, this switch controls one circuit turning the current on and off.

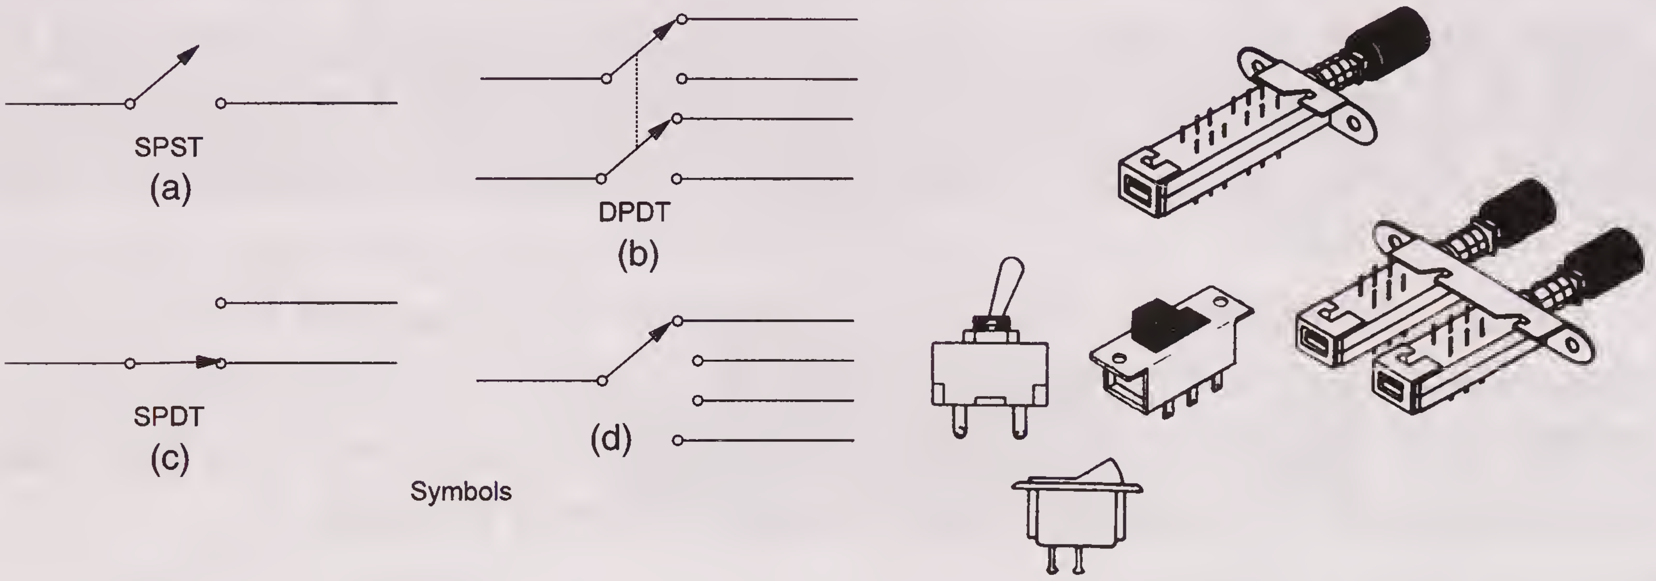

Figure 44

A DPDT (Double-Pole Double-Throw) is shown in (b). This switch can control the current in two independent circuits (double-pole) transferring it to one or another circuit (double throw). The switches also are different in the way they are operated. A circuit can have slide switches (b), toggle switches (c), and rotary switches (d).

Some special switches are also shown in Figure 44, such as thumbwheel types, pushbuttons, and subminiatures that are suitable for installation in PCBs (Printed Circuit Boards), etc.

Where they are found

Switches are found in any application where current must be controlled. Every piece of electronic equipment needs at least one switch for its operation—the on/off switch.

Specifications

The switches are identified by the number of poles, the number of positions, the maximum operating voltage, and current.

The poles and positions are indicated by symbols or letters. These are the main types:

SPST—Single-Pole Single-Throw
SPDT—Single-Pole Double-Throw
DPDT—Double-Pole Double-Throw

Maximum Operating Current and Voltage

The maximum operating current is indicated in amperes (A). Never use a switch in a circuit with a current larger than the maximum recommended. The contacts can heat causing problems. The maximum voltage is indicated in volts (V).

How to Test

An open switch must present a very high resistance (near infinite) and when closed a very low resistance (near zero). To test a switch, take a simple continuity measurement using a multimeter in the lowest resistance scale. It is important, in some cases, to make a visual inspection: a switch with contact problems due to excess current can present some visible signs such as deformations or dark areas in the contact.

Cells and Batteries

Cells are primary chemical energy sources for much electronic equipment. The cell is basically formed by two different metals immersed in some kind of chemical substance. The cells used to power electronic equipment can be found in a large collection of types, shapes, and sizes. The type, size, and shape are determined by the energy requirements of the application, the length of time the battery must source energy, and the overall size of the equipment to be powered. Many types of technology are used by the manufacturers to provide all the batteries found in electronic equipment. The technology involved is with the materials used inside the cell and its form as they are installed.

The most common cell is the carbon-zinc dry cell or Leclanché cell that is found in many battery sizes (button, AA, AAA, C, and D). This cell consists of one electrode of carbon and one of zinc with an electrolyte of ammonium chloride. Actually, the carbon electrode is composed of a mixture of manganese dioxide, carbon, and solid ammonium chloride. Most of the energy produced by this cell comes from decomposition of the manganese dioxide.

A variation of this type of cell is the alkaline cell. In the alkaline-manganese cell the chemical reaction is the same as in the carbon-zinc cell, but it takes place in an alkaline medium rather than the acid mixture used in the carbon-zinc cell. This kind of cell can provide up to twice the current output with a much longer shelf life.

These common cells are not rechargeable as they operate based in a nonreversible chemical reaction, thus the name primary cells. On the other hand, rechargeable or storage cells are called secondary cells—such as the ni-cad (nickel-cadmium) types.

These cells can be recharged by a current flowing in the reverse direction than the current source flows when they are in operation. Special devices, such as the one shown in Figure 45, are used to source this current.

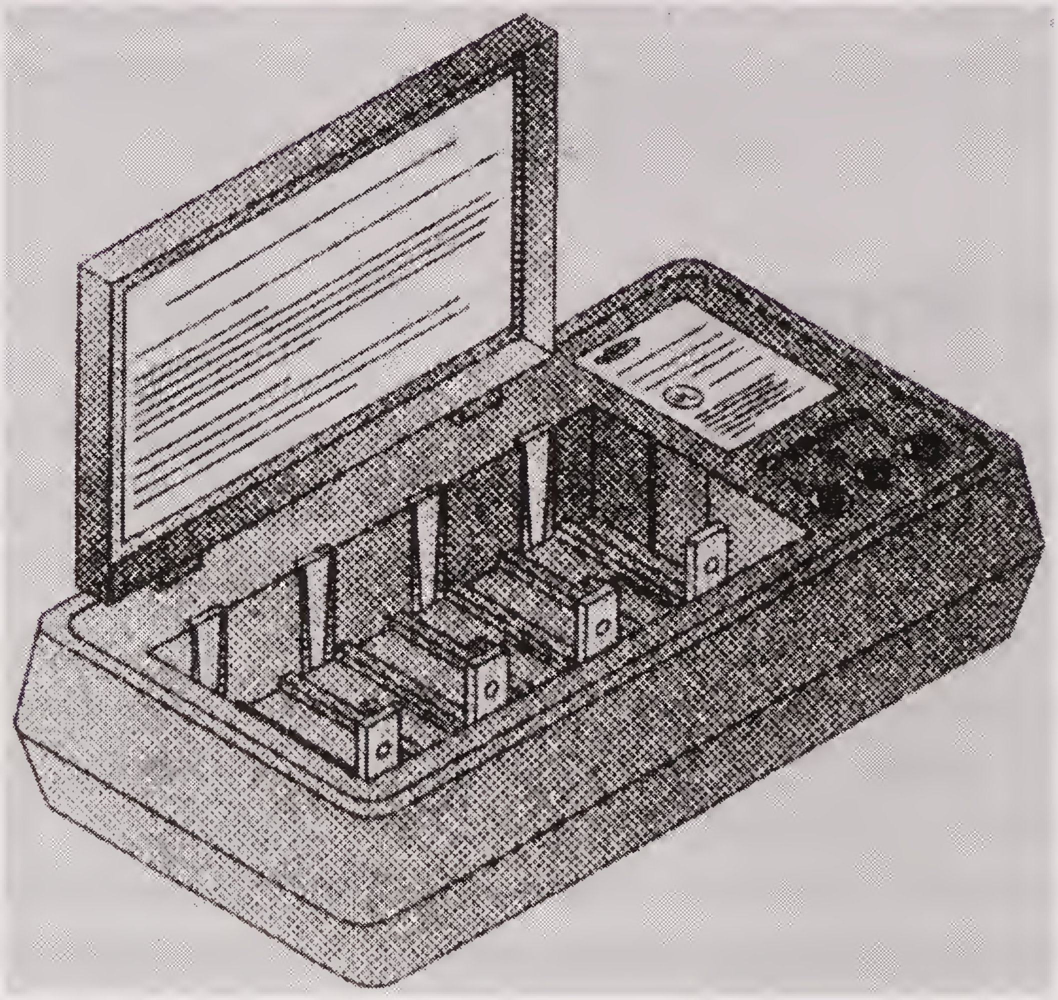

Figure 45

Common cells source voltages between 1.2 V and 1.5 V.

When many cells are associated in series we call the association a battery. The most common type of battery found in electronic applications is the 9 V battery. It is formed by the association of 6 single 1.5 V flat cells.

Symbol and Types

Figure 46 shows the most common types of cells and batteries found in electronic applications. Each type can be found in dry, alkaline, ni-cad, and some other versions based on the application.

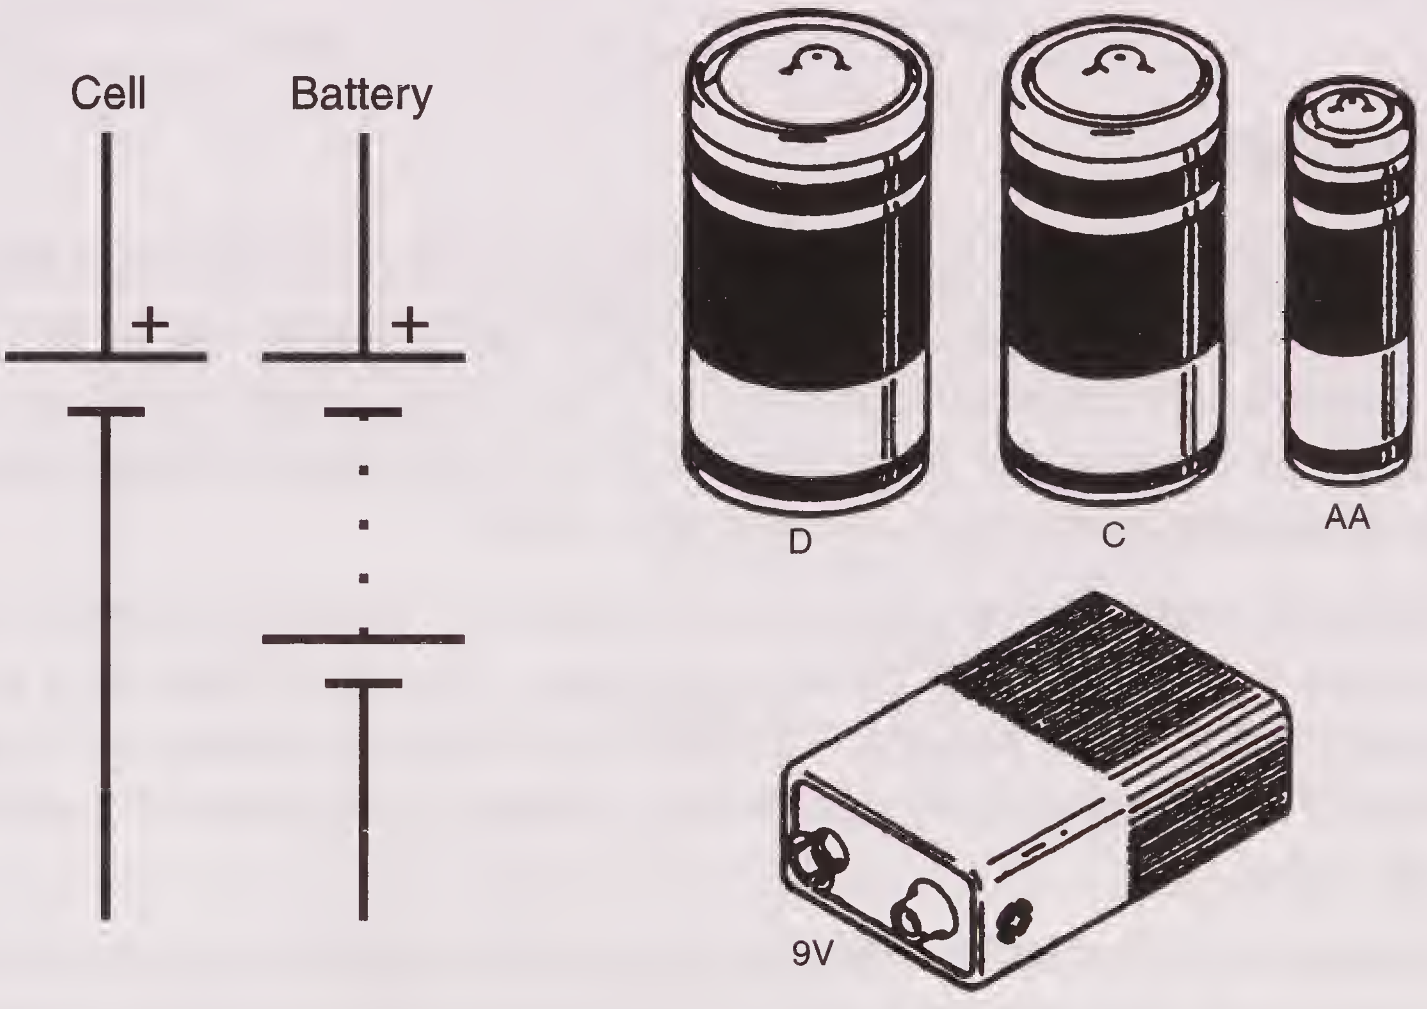

Figure 46

Specifications

A. The first and principal specification of a cell or battery is the type and size. Standard designations are groups of letters to indicate the format and size (AA, A, C, D, etc.).

B. The second specification, voltage, can be omitted because it is included in the type.

C. Depending on the application it is important to know how many hours the battery can source a determined amount of energy to a device. This is indicated by the battery or cell Ah or mAh (amperes x hour or milliamperes x hour). For example, a battery with a 100 mAh specification can source 10 mA of current to a circuit during 10 hours or 1 mA during 100 hours.

Testing

Many battery testers are available in specialized stores. But, a simple multimeter can also be used to make this test. Many of them have a battery test function. The measure of the voltage of a cell is not a conclusive way to test a battery or cell.

Resistors

The presence of resistance in an electric circuit is not desirable. Only when electric power must be transformed into heat such as in air heaters, water heaters, and electric showers, are elements present with an electric resistance to the current flow used. Forcing passage through those elements allows the current flow to produce heat.

Devices that add resistance to a circuit can be used to limit or reduce the current flow or to step down a voltage—two functions that are very important in electronic circuits. To add an amount of resistance to a circuit or reduce the flow of electric current by a circuit, components called resistors are used.

The common resistor or fixed resistor is a component made from some conducting material the size, shape, and conductivity of which are arranged to determine the amount of electrical resistance needed. The amount of resistance is measured in ohms (Ω).

Inside electronic equipment are resistors of many types and sizes with resistance values ranging from less than 1 ohm to many million ohms. The resistors are classified into fixed or variable resistors. Let's look at fixed resistors, also called resistors.

Resistors are found in many sizes and shapes according to the amount of resistance they present, some special performance feature they must have, and the amount of heat generated when working.

Symbols and Types

Figure 47 shows the symbols used to represent a resistor and the types of resistors commonly found in electronic circuits. The symbol shown in (a) was adopted by the American system of symbols. In European equipment the schematics or circuit drawings represent the resistor as shown in (b).

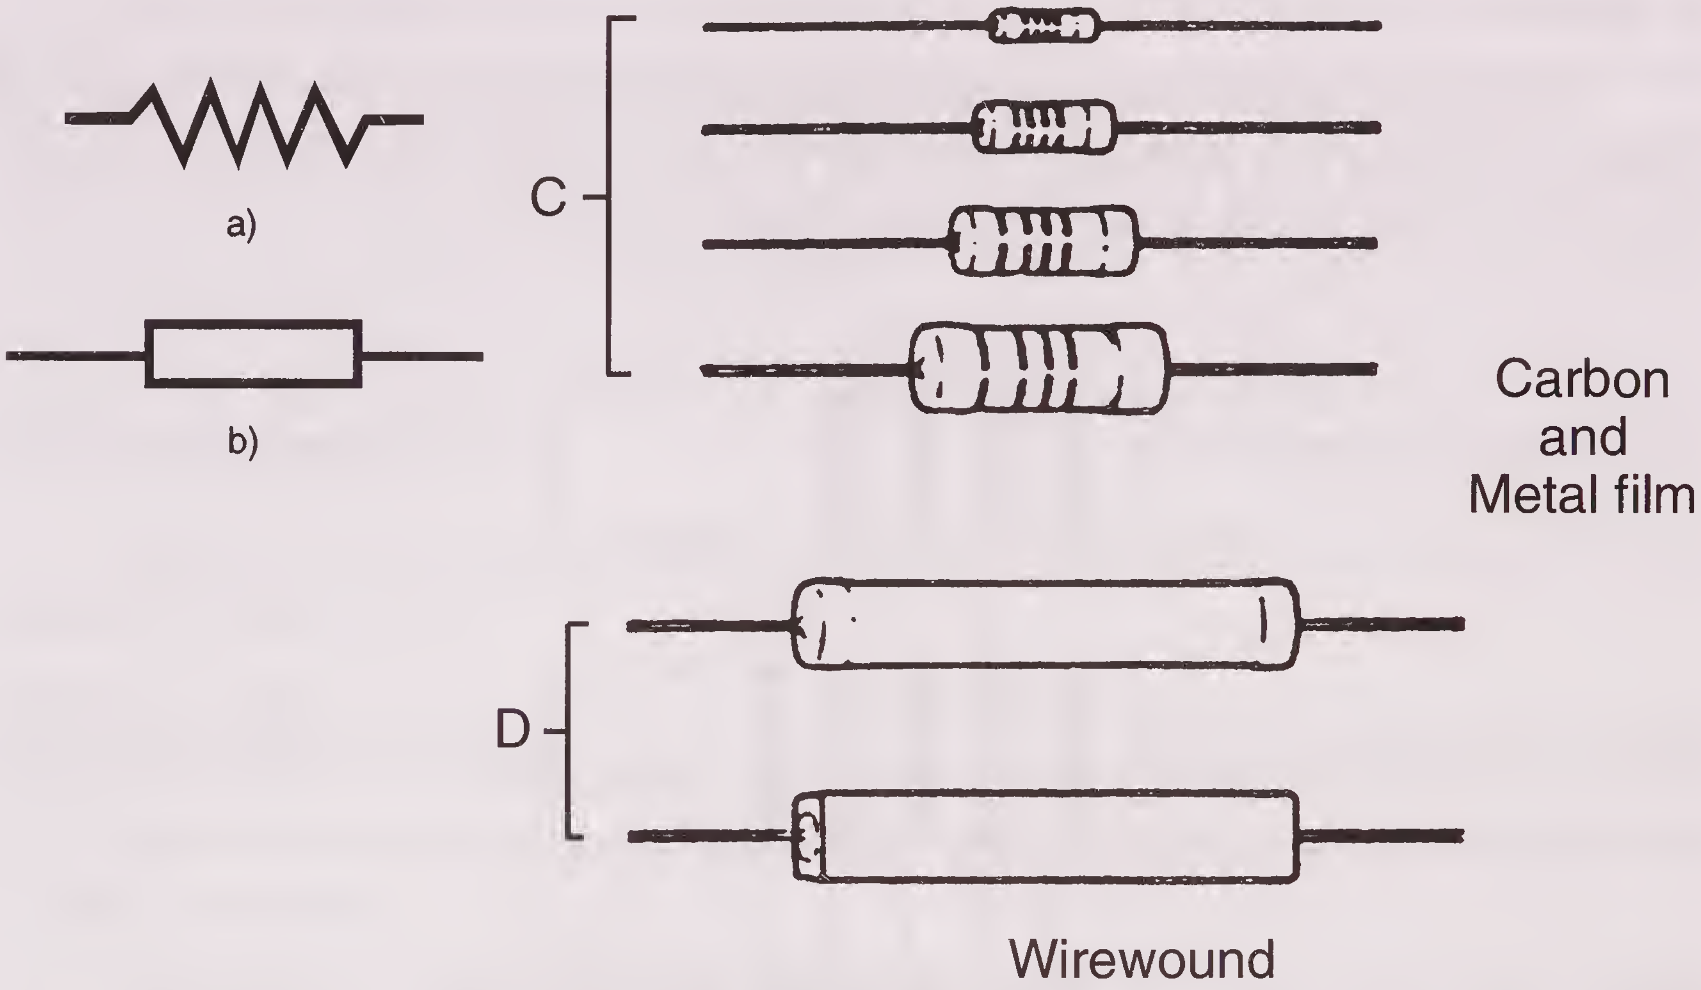

Figure 47

The most commonly used resistors are carbon composition and carbon film types, as shown in Figure 47 (c) where the resistive element is a thin layer of carbon strips deposited onto a ceramic rod. Another type is the metal film resistor or film resistor, with the same external aspect as the carbon type. In this type, metal is evaporated onto ceramic rods forming a thin film. These resistors are cheap and can be easily fabricated in a large range of values. They are intended for applications in low-power or small-current circuits. The disadvantage of carbon resistors is that they are noisy.

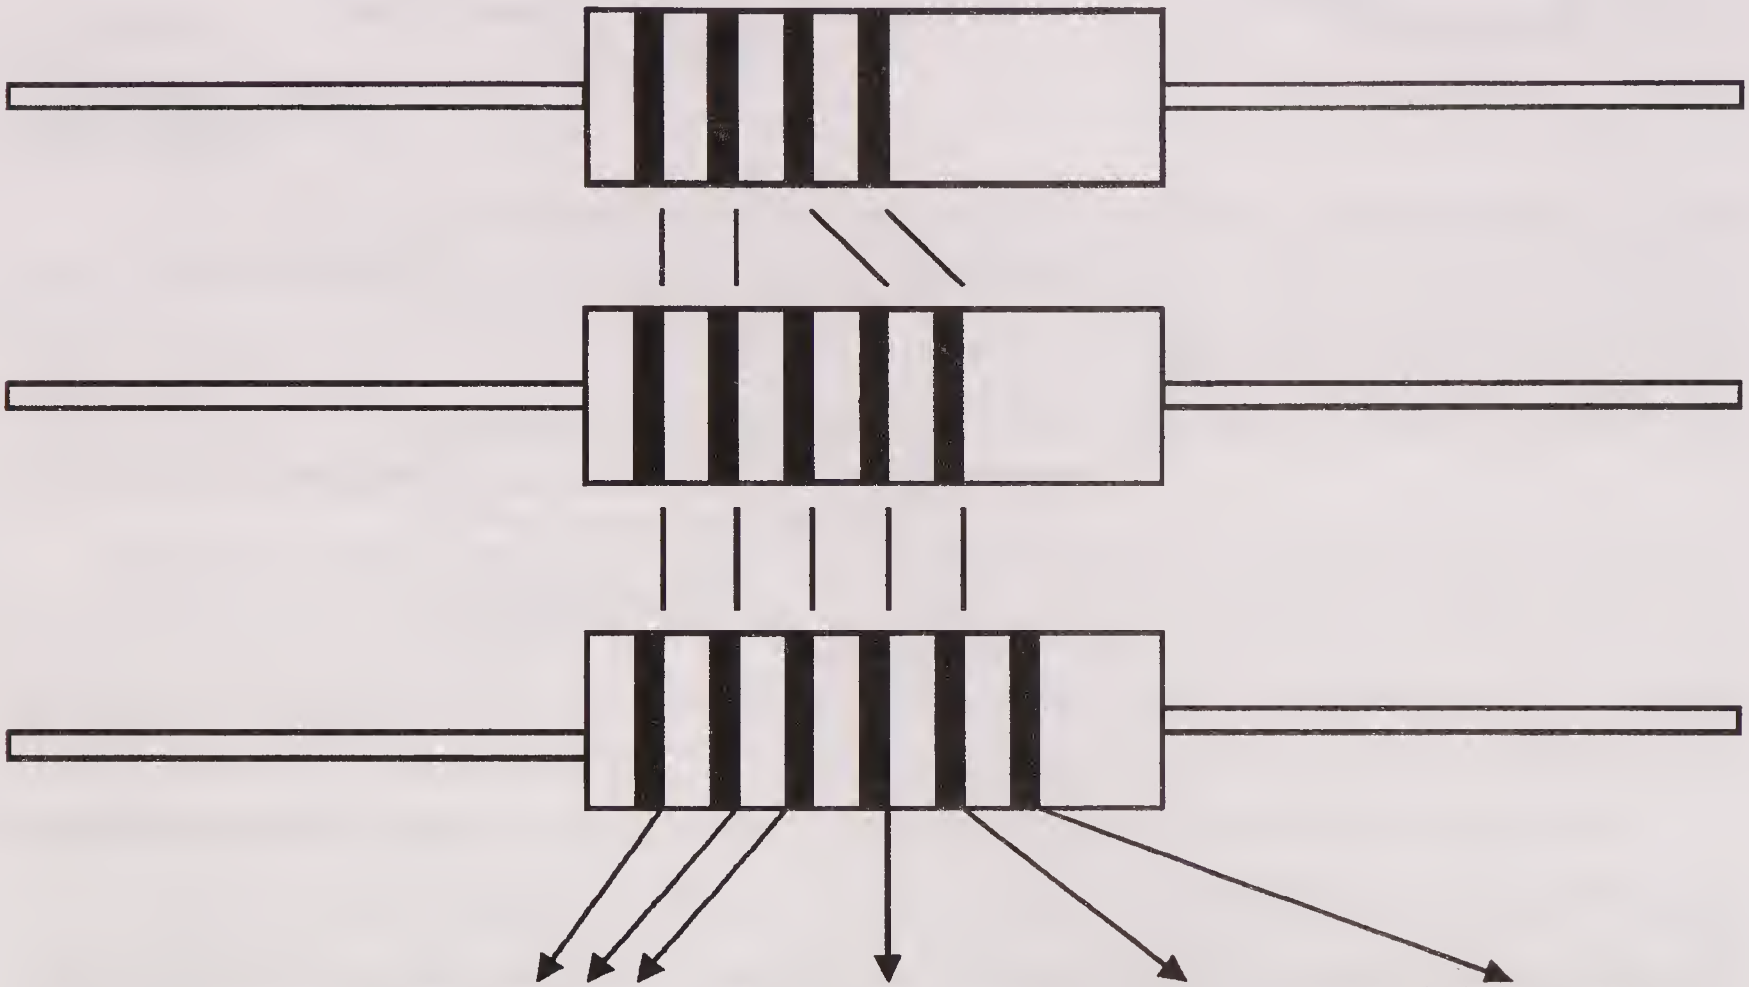
When desiring resistors that can operate with large currents, the wirewound type shown in Figure 47 (d) is preferred. Those resistors are formed by turns of metal wires (alloys such as nickel, chromium, iron, silver, etc.) onto a ceramic rod. The material, gauge, and number of turns determine the amount of resistance, the size, and how much heat they can handle.

Specifications

When replacing or testing any electronic device it is necessary to know its specifications. The main specifications for resistors are:

A. Value

The value is the amount of resistance in ohms (Ω) of a resistor. In large-size types the resistance can be found on the body of the device, the same as in the wirewound resistors (See Figure 47).



COLOR	Significant Figures	Multiplier	Tolerance	Temperature Coefficient ppm/°C
Black	0	1	-	-
Brown	1	10	1%	100
Red	2	100	2%	50
Orange	3	1,000	-	15
Yellow	4	10,000	-	25
Green	5	100,000	0.5%	-
Blue	6	1,000,000	0.25%	10
Violet	7	10,000,000	0.1%	5
Gray	8	100,000,000	0.05%	-
White	9	1.000.000.000	-	1
Gold	-	0.1	5%	-
Silver	-	0.01	10%	-

Table 1-3 Color Code for Resistors

But, in smaller types such as carbon and metal film types as well as SMDs, there isn't enough space to display the resistance value. In this case, and also to make the manufacturing process a bit easier, a color code is used. Color bands or stripes are printed on the resistor body. Accordingly, the position in the equipment is part of the meaning of a band. Combining the two, the resistance value of any resistor can be found. In addition to the value in ohms, the color bands also indicate the tolerance of the component.

Table 1-3 indicates how the value and tolerance of a resistor is read using the color code.

Notes on Table 1-3

1. If the resistor is a three-band type, the tolerance can be assumed as 20%
2. If the resistor is a three- or four-band type the temperature coefficient is not indicated.

Example—A resistor has colored bands in this sequence: red, violet, orange, and silver. (Read the colored bands from the end to the center.) Bands 1 and 2 form the number 27. Band 3 indicates that we must multiply this value by 1,000. The resistance is 27,000 ohms. Band 4 indicates that the tolerance is 10%.

B. Dissipation

The size and the material the resistor is made of determines how much heat it can produce without burning. Based on the application the resistors are to be used for, resistors must be chosen in different sizes or dissipation capacities.

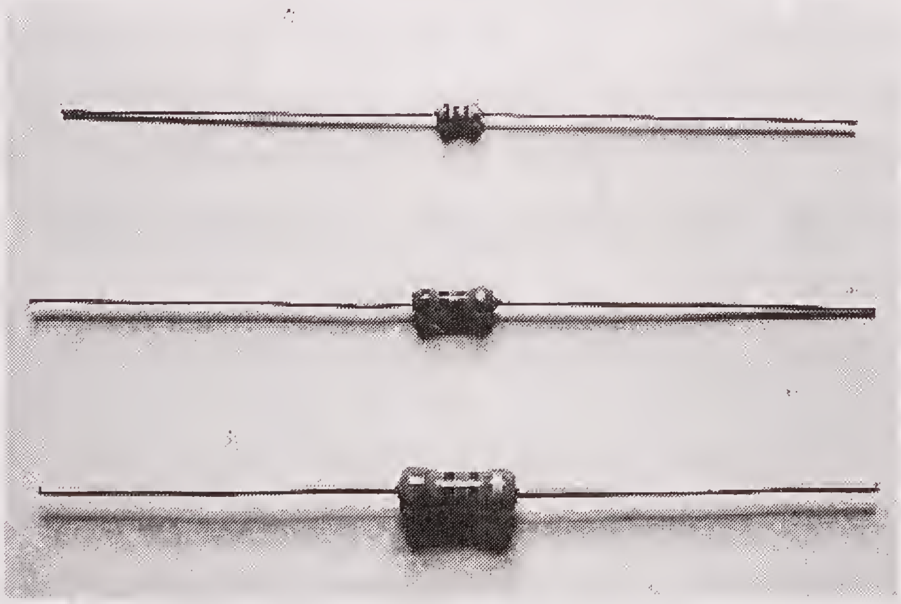


Figure 48

The dissipation or power rate of a resistor is specified in watts (W). Small resistors (metal film or carbon) have dissipation in the range between 1/8 and 2 W. Wirewound types can be found in dissipation starting from 1 or 2 W to more than 200 W. Figure 48 shows the differences in size between carbon resistors according to their dissipation.

(Figure 48) Carbon resistors with different dissipations are shown. From the smaller to the greater the dissipations are 1/8, ¼, and 1/2 W.

C. Tolerance

It is impossible to manufacture a resistor with an exact value of resistance. This is not necessary as the electronic circuits are designed to operate within a certain band of value of components and voltages. The difference between the value specified for a component and the real value or measured value is called tolerance.

Resistors can be found in tolerance ranges from 1 percent to 20 percent. This means that a resistor indicated as 1000 ohms/10 percent unit can really present resistances between 900 and 1100 ohms. As a consequence, it is not necessary make resistors with all values between 900 and 1100 ohms, as the 1000 ohms resistor covers that range. So, the electrician will be surprised when observing that the resistors are found in few common values, according to their tolerances. The basic values are determined by a commercial series of values.

20% SERIES OR E-6	10% SERIES OR E-12
10	10
	12
15	15
	18
22	22
	27
33	33
	39
47	47
	56
68	68
	82
100	100

Table 1-4

Table 1-4 shows that resistors of 47 ohms, 470 ohms, 4700 ohms, 47,000, 470,000 x 20 percent and many other values in multiples of 10 can be found, but not 39 ohms, 390, or 3,900 ohms x 20 percent. These values are found only in 10 percent resistors. In the same manner, you'll never find a 3.4 ohms, 34 ohms, 340 ohms, etc., resistor with 10 or 20 percent tolerance because it doesn't exist.

Where Resistors are Used

The resistors are the most common of the electronic components. They are used in all applications where a current must be limited or a voltage steps down.

In electronic circuits the main application for resistors is in bias or stepping down a voltage. Many elements of a circuit must operate with voltages lower than supplied by the power supply. This means that resistors must be used to step down the voltage to the desired value. These resistors are called bias resistors.

Testing

When heated by excess current, the resistors can open or burn. Although a dark area in the body of the component is an evident sign that it is damaged, in some cases the component doesn't present any other visible signs of problems.

Resistors are tested using the multimeter (VOM). Desolder one terminal of the component and take it off of the printed circuit board or out of the circuit and measure the resistance. Don't measure it while still in the circuit because the multimeter can indicate the resistance of the circuit, not that of the component.

Figure 49 shows how to do this test.

Remember to consider the tolerance when reading the value displayed by the multimeter and comparing it with the value displayed by the component. When replacing a resistor use a unit of the same type and same value. The dissipation, in some cases, can be higher if enough space is available for its placement.

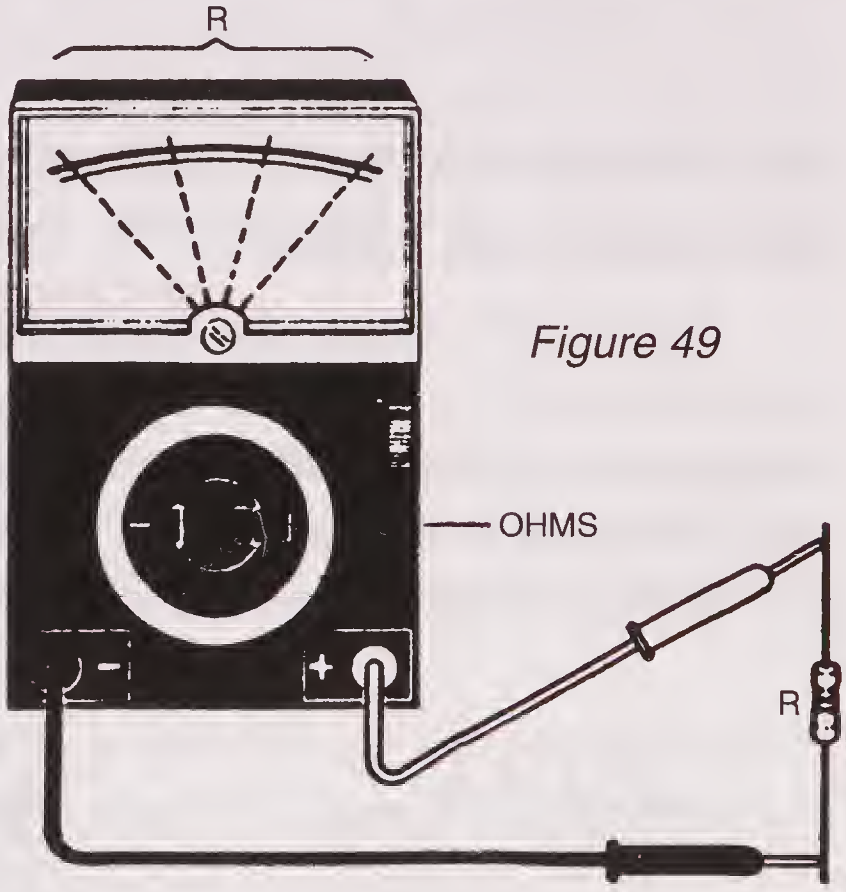

Figure 49

Variable Resistors

In many applications something in a circuit can be controlled or adjusted by changing a resistance. You can increase the volume of an amplifier or the brightness of a lamp by altering the current in a circuit. The common way to alter currents and voltages in circuit is altering a resistance placed in the circuit for this task. The principal component that can be used to make this happen is the variable resistor. The electrician will find variable resistors in a large number of functions in electric and electronic appliances.

As the name indicates, a variable resistor is a device presenting a resistance that can be changed. Variable resistors are found in different sizes and aspects. There are two types. One allows the resistance value to be changed easily and often, like the volume or tone adjustment of an audio amplifier. The other is the semifixed resistor that ordinarily doesn't change the resistance value. It is used to adjust the operational condition of the electronic circuit.

Basically, variable resistors are formed by a resistive material (metal or carbon) with a cursor sliding onto it. When the resistance between the cursor and any corner of the resistive material changes normally, between 0 and a determined value of resistance, it is called nominal resistance. So in a 1000 ohms variable resistor, the resistance between the cursor and any of the corners can assume values between 0 and 1000 ohms.

Symbols and Types

Figure 50 shows the symbols and types of the two basic types of variable resistors. In (a), a trimmer potentiometer or adjustable potentiometer is shown. This small variable resistor is used to adjust the operational condition of a circuit one time. They are found inside the equipment. Size and form of mounting can change according to the application.

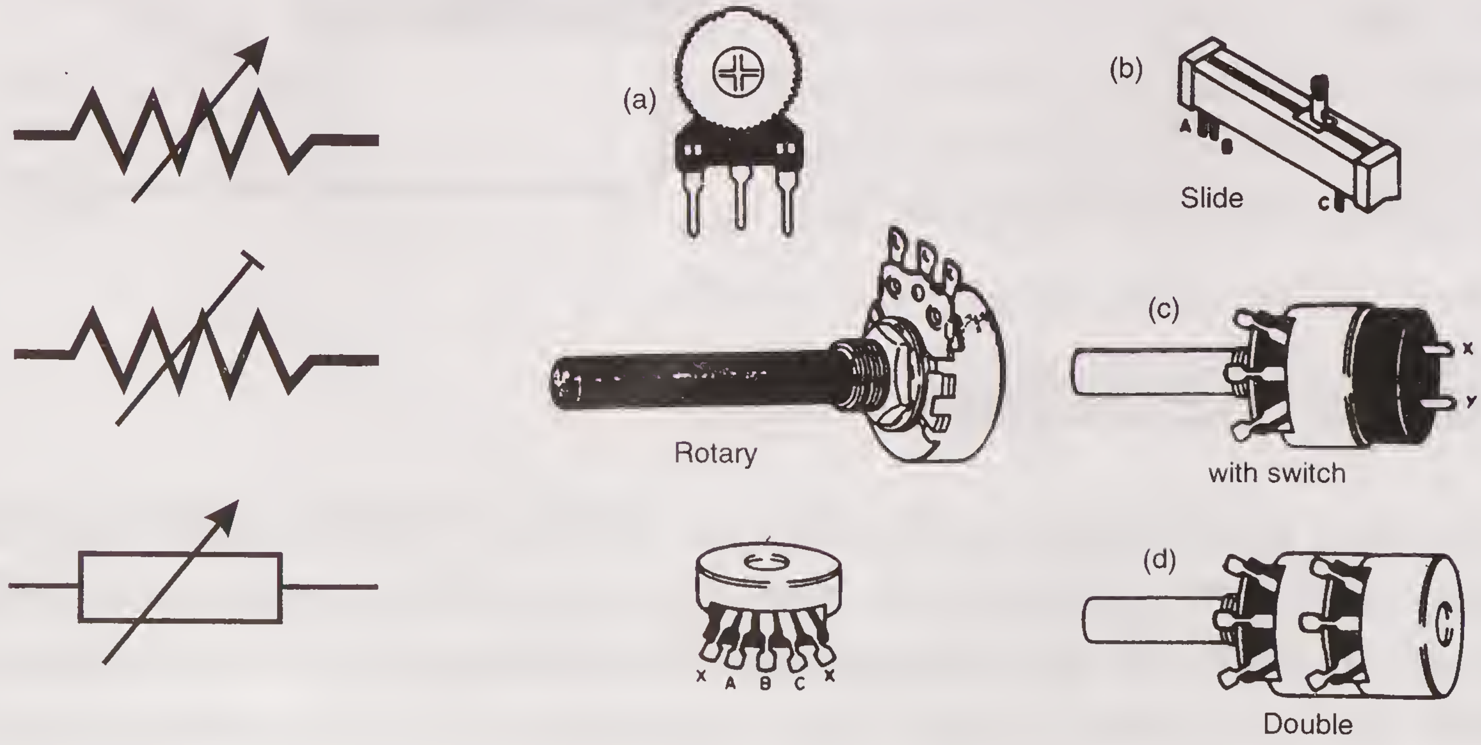

Figure 50

In (b) are potentiometers (slide and rotary) that are used to control many functions of equipment. The slide potentiometers are common in audio equipment and the rotary types are found in TV, radio, dimmers, etc. Many potentiometers are double (d) as those used to control the volume in both channels of a stereo amplifier. Others (c) can include switches to turn on and off an appliance.

Specifications

A. Value or nominal resistance

The most important specification in a variable resistor (potentiometer or trimmer potentiometer) is the nominal resistance. This resistance is indicated in ohms (Ω) and represents the maximum value of resistance assumed by the component. For example, a trimmer potentiometer preset with 10,000 ohms or 10kΩ can be adjusted to any resistance between 0 and 10,000 ohms.

B. Variation of resistance

In some applications the way the resistance changes when the potentiometer is adjusted is important. There are basically two types of variation of resistance curves: linear and logarithmic.

Where they are found

The electrician can find trimmer potentiometers and potentiometers in many types of electronic equipment. In every application where a function of a circuit must be adjusted or controlled by changing current in a circuit, a variable resistor can be used.

An example of a common use is in a dimmer where the amount of current in a circuit determining the brightness of a lamp is controlled by a potentiometer. Timers also use a potentiometer to adjust the time.

Testing and replacing

Trimmer potentiometers and potentiometers can burn or present many functional problems. One of the problems is the cursor contact can fail. Another common problem is caused by noise generated when the cursor slides on the resistive element. This occurs mainly in audio equipment. This problem is the cause of the scratching noise produced when the volume control of a radio or amplifier is adjusted.

A basic test can be done with a multimeter to measure the resistance of the resistive element (between the extreme terminals in potentiometers). Another test is done by sliding the cursor and listening to hear if noise is produced (if a multimeter doesn't indicate abrupt jumps in the resistance change).

Incandescent Lamps

Small incandescent lamps or bulbs are used in electronic equipment as panel indicators, flashlights, or even as active elements of a circuit. The nonlinear characteristic of the filament (voltage vs. current) makes incandescent lamps ideal for use as a current regulator in some applications.

Incandescent lamps are formed by a tungsten filament placed inside a glass enclosure where the oxygen is removed. When the electric current heats the filament to a very high temperature, it produces light. The metal of the filament doesn't burn because there is no oxygen to be a source of a combustion chemical reaction.

Electronic equipment usually uses small incandescent lamps rated for low voltage in the range between 1.5 and 12 V. This is an important difference from the lamps found in electric applications that are primarily used to illumination purposes and are powered directly from the AC power-line voltage.

Symbols and Types

Figure 51a shows the symbols used to represent small incandescent lamps. In (a), the American symbol is shown and in (b), the symbol found in some diagrams from European manufacturers is shown. Figure 51b illustrates the common types used as panel or instrument indicators and for other functions.

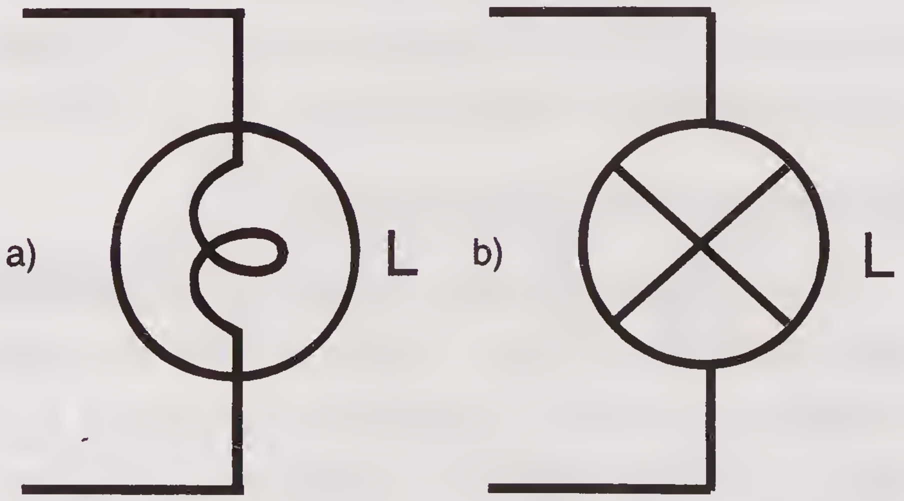

Figure 51a

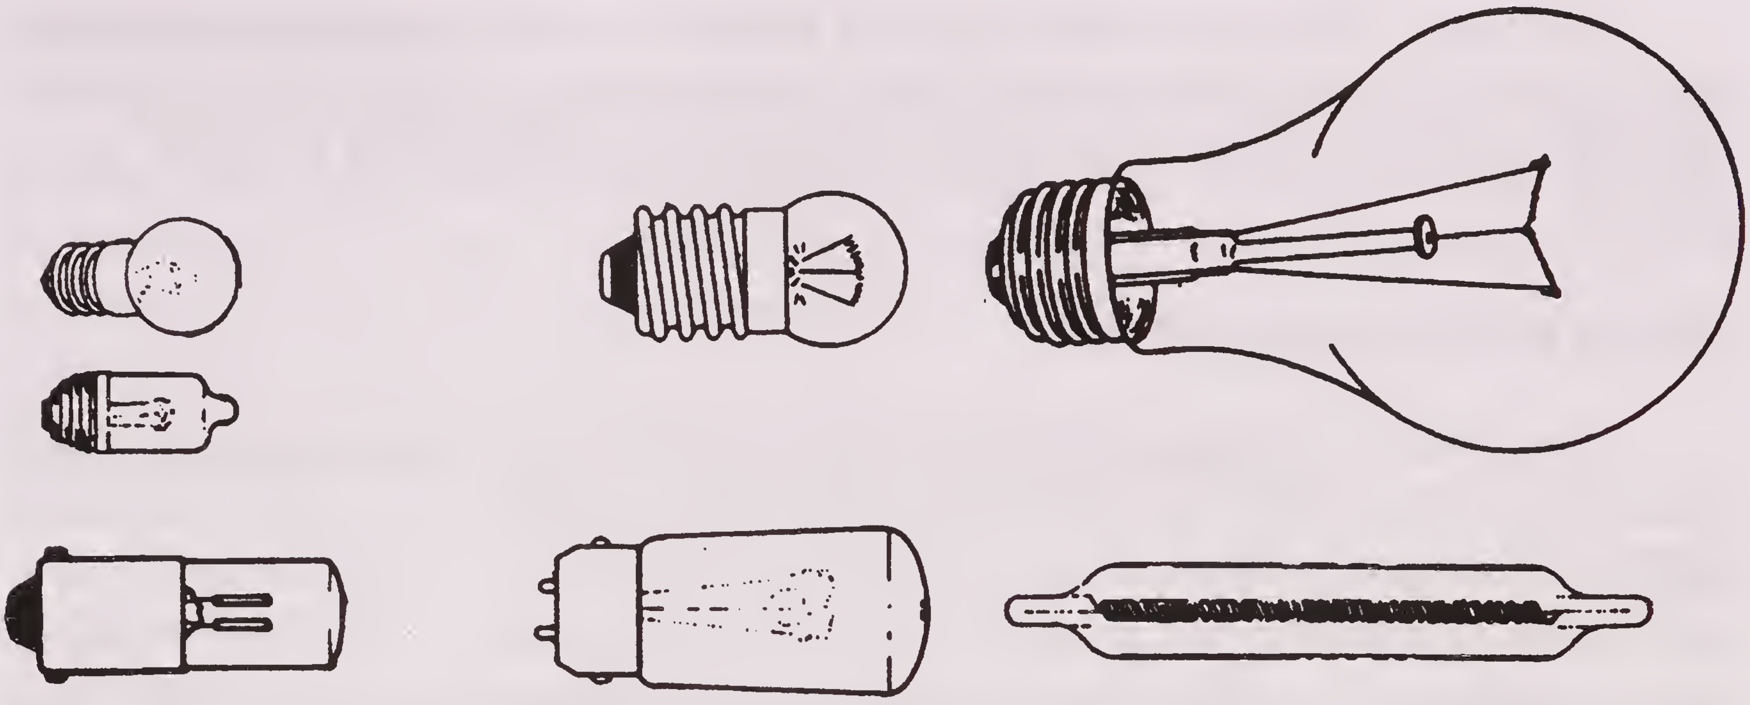

Figure 51b

Observe that the base of the lamp changes in format or size according to the application. The main types are the bayonet base, telephone slide, flange, and threaded.

Specifications

A. Nominal voltage

This is the operational voltage of the lamp. Common types are indicated to operate in the range between 1.5 and 12 V.

B. Nominal current

This is the current flowing through the filament when the nominal voltage is applied. Common types can be specified to operate with currents in the range between 0.01 A (10 mA) and 1 A.

C. Type number

Many catalogs indicate the type of a lamp by a part number giving tables where the electric and mechanical specifications are placed. Types such as "47" are popular. This is a lamp rated to 6.3 V x 150 mA using a bayonet base.

Where they are found

The incandescent lamps can be found basically in all applications where illumination of a panel, instrument, or control is needed. In many pieces of equipment, small incandescent lamps are placed inside the panel instruments.

Although LEDs are replacing the lamps in many applications, those with white light production capabilities are becoming popular. These lamps are used as replacements in antique equipment and some modern applications.

Testing and Replacement

The small incandescent lamps have low filament resistances (varying according to their voltage and current). If the filament burns up, the resistance becomes infinite. Using a multimeter, it is easy to see if an incandescent lamp is good or not good. When replacing a lamp, if the part number is not available, the electrician must know the voltage and current and take care to choose one with the same base format.

Neon Lamps

Neon lamps are used in many electronic circuits as indicators or important active elements because their electric characteristics (negative resistance) make them ideal as trigger devices in timing circuits or waveform generators. The common neon lamp is formed by a small glass bulb filled with neon gas. Two electrodes are placed inside without one touching the other. When the voltage across the gas increases reaching the triggering point (between 60 and 80 V), the gas ionizes and becomes a conductor. The electric resistance falls allowing the circulation of a current. With the ionization, the gas emits an orange light.

Symbols and Types

Figure 52 shows the symbol used to represent the neon lamp and types of this device.

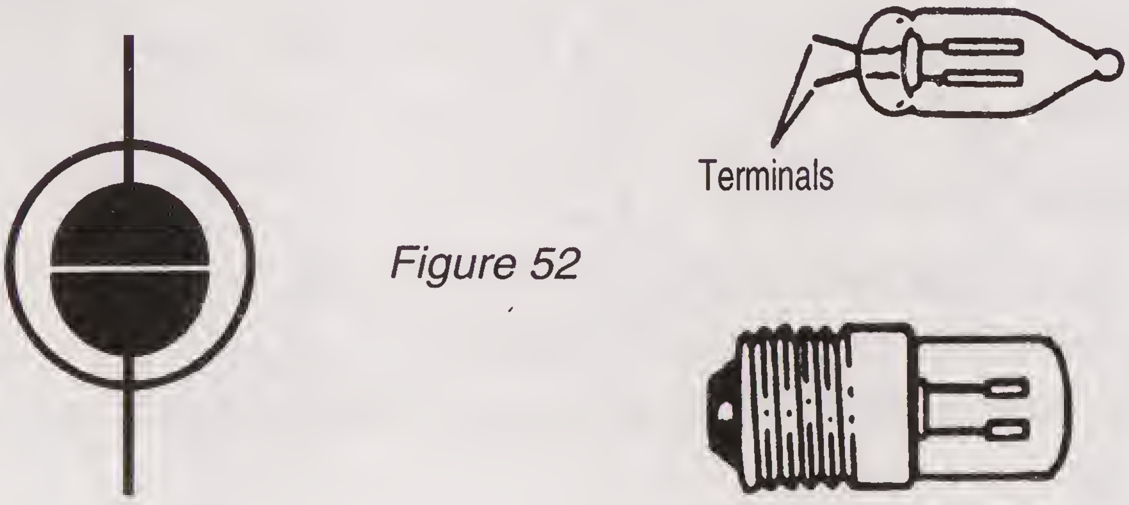

Figure 52

Specifications

The main specification of a neon lamp is the trigger voltage. Normally it is in the range between 60 and 80 volts. The manufacturers indicate neon lamps by a part number such as NE-2H or HE-51. Sometimes it is important to know the type of lamp and if it does or does not have a current-limiting resistor inside.

Where they are found and how they are used

Neon lamps can be used both as indicators and elements of an active circuit. As indicators, they can be found in the input of equipment monitoring the AC power line voltage as shown in Figure 53.

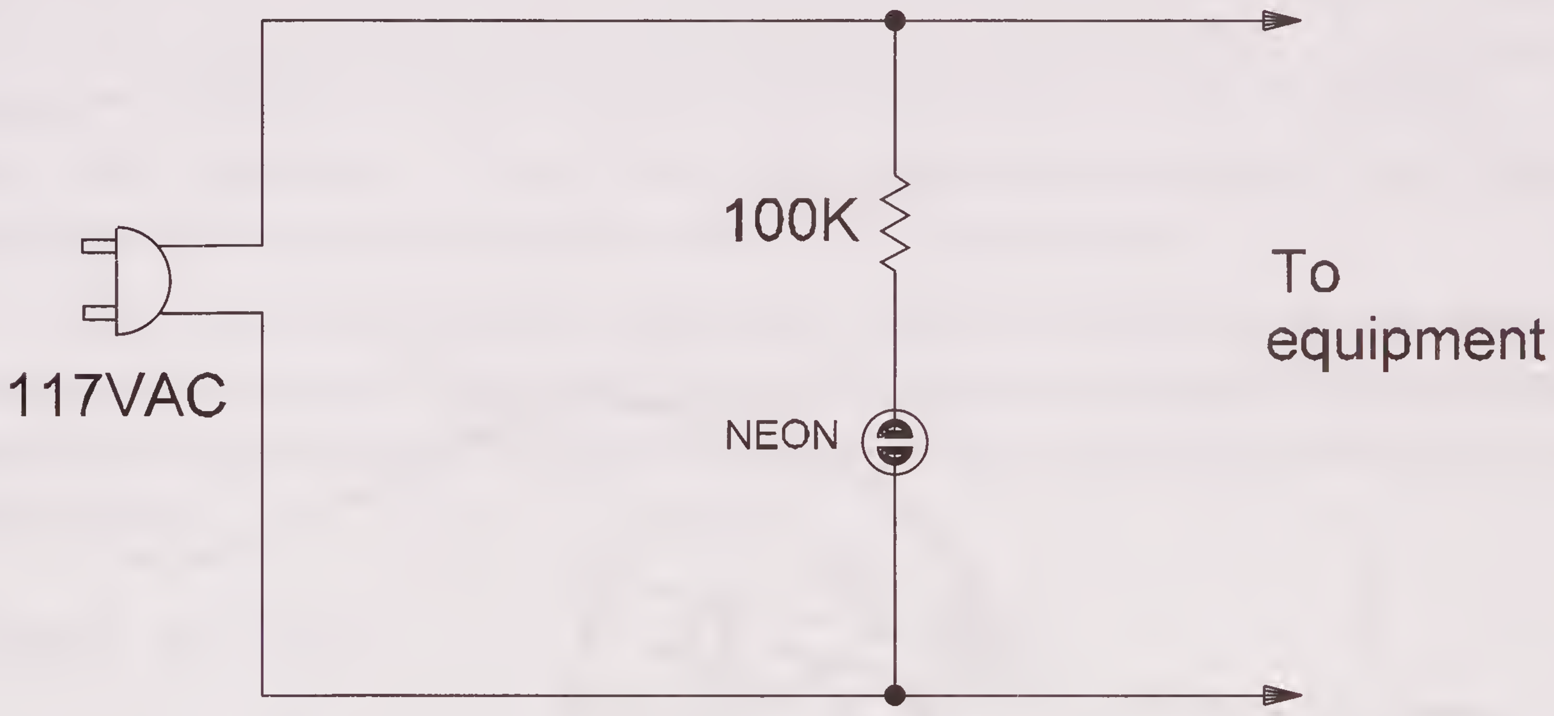

Figure 53

The electrician will find that in circuits like this, the lamp has a series current-limiting resistor (typically between 47k and 1M). Some types of lamps such as the NE-2 have this resistor inside for 120 V use. Others need an external resistor.

Another application is an oscillator for generating signals as in the configuration shown in Figure 54. Depending on C and R values, the circuit can generate sawtooth audio signals or make the lamp flash.

An interesting application of the neon lamp is as a phase indicator as shown in Figure 55. If placed in the phase terminal of an AC power line, the lamp will glow. The electrician will not feel any shock because the series resistor limits the current to a very low value, not enough to excite the nervous cells, giving a shock.

Figure 55

Testing

The simplest way to test a neon lamp is to plug it into the AC power line using a 220k ohms series resistor.

> ***WARNING:*** *Do NOT plug the lamp directly into the AC power line. Without the current limiting resistor it can explode!*

Light-Dependent Resistor or CdS Cells

Light-dependent resistors (LDR) or CdS cells or CdS elements are light-sensitive resistors presenting a resistance value that changes with the light. The resistance between the terminals of these components falls when the amount of light falling onto a sensitive surface increases. In the dark, the resistance is high and falls under the sunlight. The LDRs are used as light sensors in many electronic applications.

They are formed by a cadmium sulfide surface—the sensitive element of the device. This surface and its base are placed inside a transparent plastic enclosure. The size and the format of the device depend on the application.

Symbols and Type

Figure 56 shows the common symbols used to represent this component and Figure 57 shows what they look like.

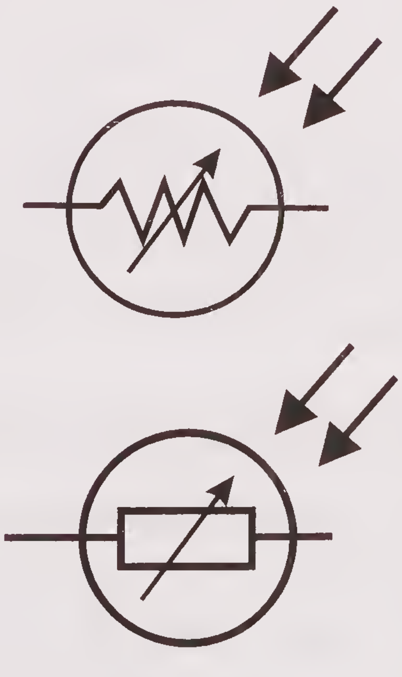

Figure 56

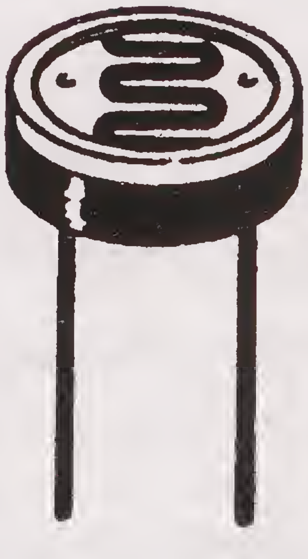

Figure 57

Specifications

The LDRs can by specified by the diameter (size) or by a manufacturer number. When replacing LDRs, types of the same size are normally interchangeable.

Where they are found

The electrician will find LDRs in many electric devices related to domestic applications. They are used as sensors in alarms, automatic lights, emergency lights, and many other circuits. In a typical application the LDR is placed in a way that it receives only the ambient light as shown in Figure 58.

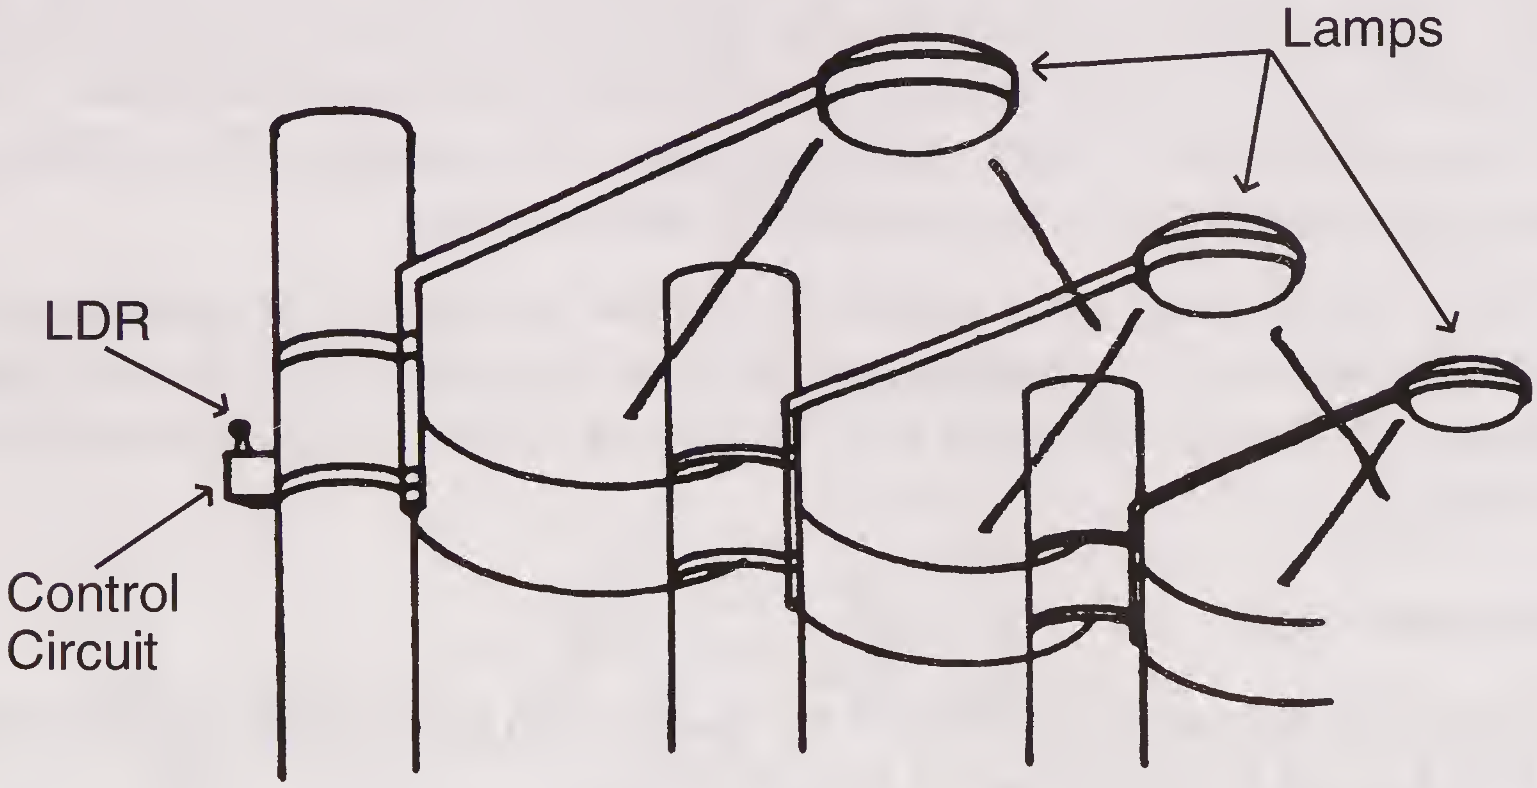

Figure 58

When the light falls at dusk, the LDR's resistance increases acting on the electronic circuit triggering a lamp. If the LDR receives the lamp's light a feedback process can interfere in the circuit. Oscillations and instabilities can be induced this way.

Although the LDRs are very sensitive devices, they are not fast enough for certain applications and can only be used to control simple circuits from slow light changes. When a fast action is needed, such as when reading bar codes or detecting fast changes of light, other devices are preferred like photodiodes and phototransistors.

In many applications the amount of light on the LDR or CdS cell can be increased with the use of a convergent lens. The use of a convergent lens, as shown in Figure 59, is important to help the device to detect light from smaller angles.

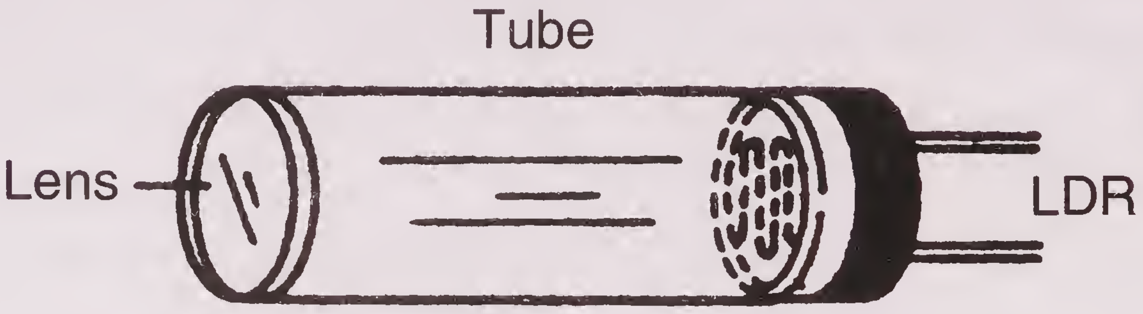

Figure 59

Testing

A simple multimeter (digital or analog) can be used to test any LDR. Put the multimeter on a resistance scale and plug the probes into the LDR. Passing your hand in front of it (to cut the ambient light falling in the sensitive surface) you'll observe the resistance changes in the multimeter's scale.

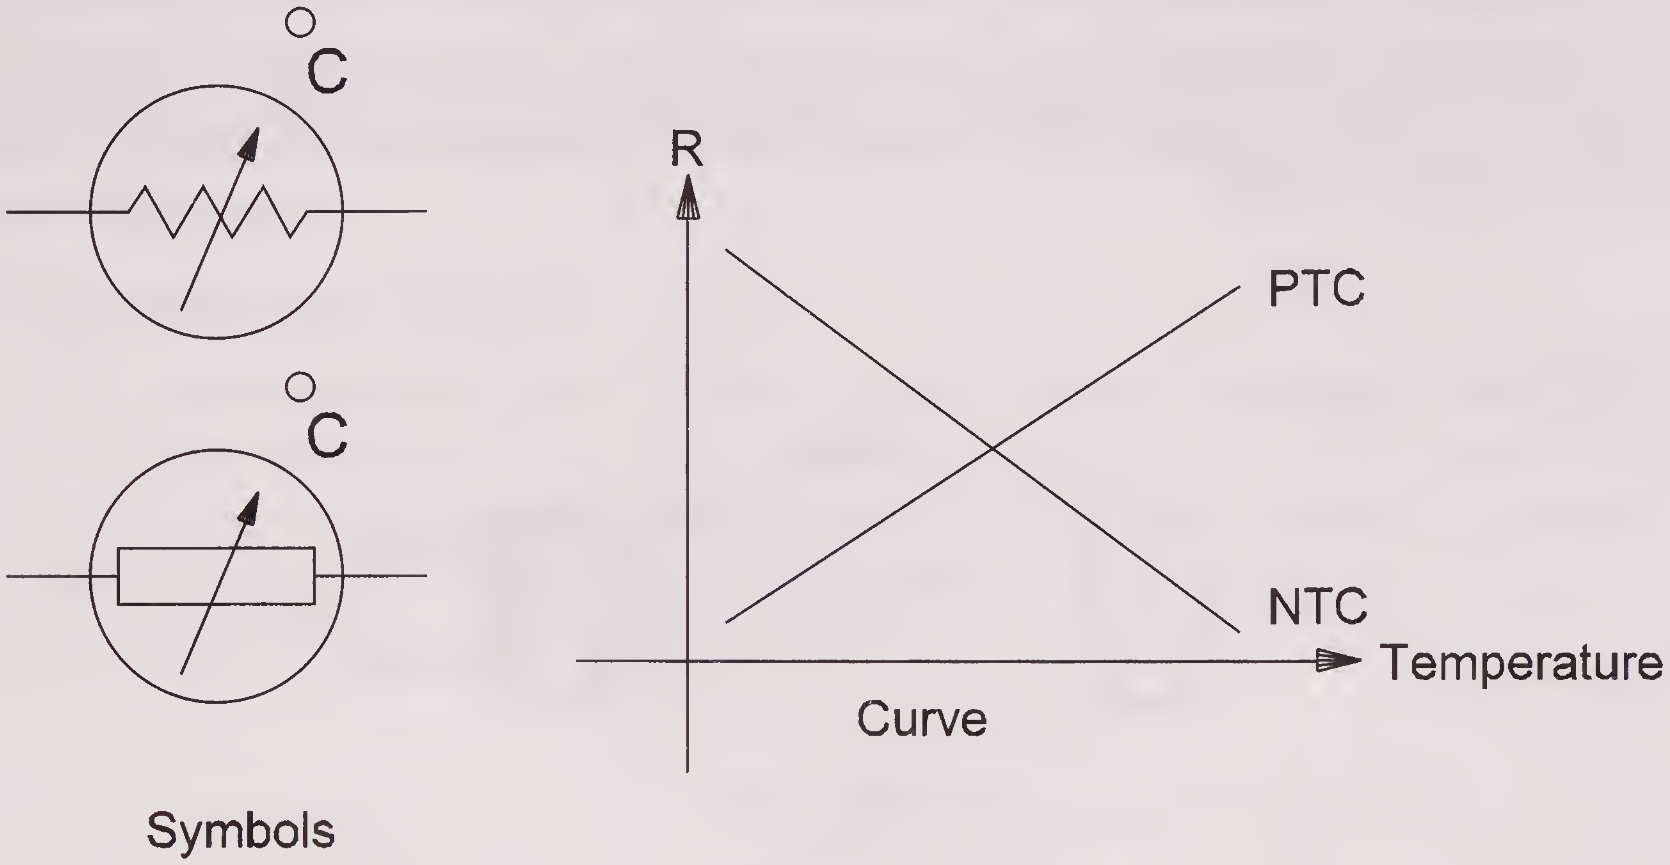
NTC/PTC

Negative Temperature Coefficient resistors (NTC) or Positive Temperature Coefficient (PTC) resistors (also called thermistors or thermally sensitive resistor) are components having a resistance that changes with their temperature. In the NTC the resistance falls when the temperature increases and in the PTC the resistance increases with the temperature.

They are formed by materials (alloys and mixtures) that have special thermal properties suitable to the task.

Symbols, Types, and Characteristic Curve

Figure 60 shows the symbols used to represent these components, types, and the characteristic curve.



Symbols

Curve

Figure 60

The size of the component determines how fast it is when altering its resistance during a temperature change. This is an important factor in some applications and is referred to as readiness. The format and size depend on the application.

Specifications

The NTCs and PTCs can both be specified by a manufacturer or part number and a nominal resistance, or a resistance in the ambient temperature (normally 20 degrees Celsius). Also refer to Figure 60 for the characteristic curve, a graphic representation of the changes of resistance with the temperature.

Where they are found

The electrician will find NTCs and PTCs in many electronic circuits used in electric installations or even in electronic appliances. Some fire alarms and ambient temperature controllers used with air conditioners, as well as many other devices, use one of these components as a sensor. They are installed in a place where the temperature can be detected. The signal is then sent to a remote device that acts on the element to be controlled (air conditioner, alarm, fan, relay, etc).

Testing

The NTCs and PTCs can burn or break. In this case, the resistance will increase and it can open the circuit. The simplest test consists of taking the resistance measurement using a common multimeter.

Moisture can alter the nominal resistance of high-resistance NTC or PTC inducing a circuit into a wrong operation. This is important to be considered if the NTC or PTC is used as a sensor and not protected from moisture or ambient action.

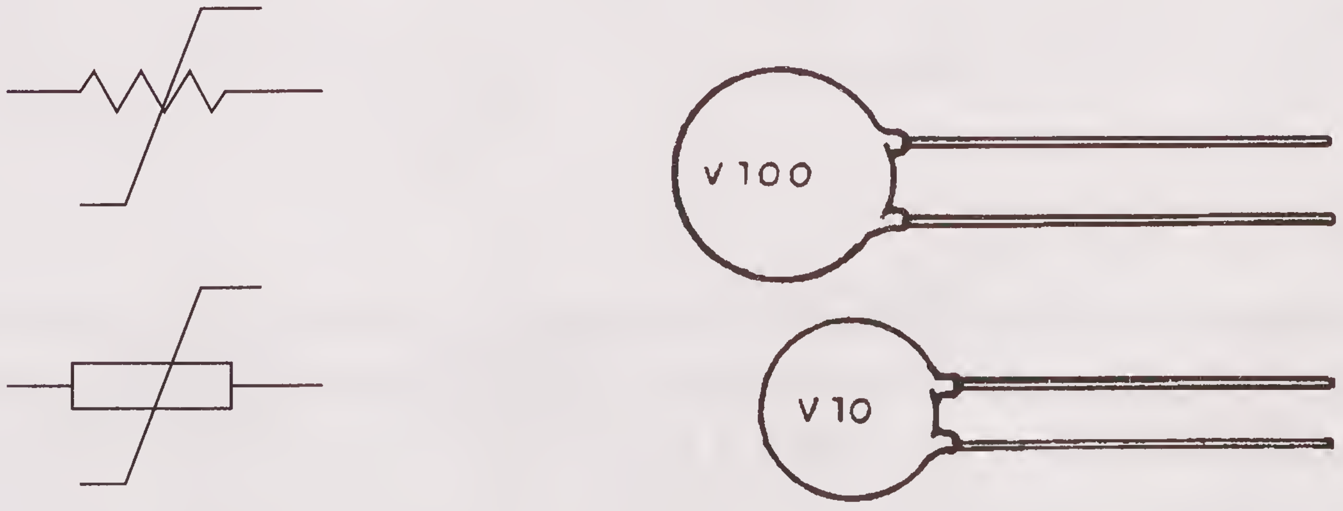
VDRs

Voltage Dependent Resistors (VDR) or Zinc-Oxide Varistors and Metal Oxide Varistors or Transient Surge Absorbers are devices having a resistance that changes with the applied voltage. They are nonlinear resistors and can be used in circuit protection and many other applications such as power supplies, microprocessor protection, surge protection for consumer and industrial electronics, and many other applications.

The VDR is a device that becomes a conductor when the voltage applied to it crosses a determined value.

Symbols and types

The symbols and examples of common VDRs are shown in Figure 61. The size of the VDR determines the amount of energy it can absorb when becoming conductor.



Symbols

Examples

Figure 61

Specifications

The main specification of a VDR is the breakdown voltage. It is the voltage at which the device becomes conductive, passing from a high-resistance state to a very low-resistance state. This component can be found with voltage specifications between 18 and 1800 volts.

Where they are found and how they are used

The electrician will find VDRs at the input of many electronic devices operating as a protective element. In fact, when voltage spikes appear in the AC power line, if their value is high enough to make the VDR conductive, the snap action of this component puts a short in the spike. So, the high voltage that could damage the equipment is shunted to the ground, or the energy of the spike absorbed by the VDR.

Computer outlet sockets with surge protection use this device as a main element in the protection circuit. Outlets for computers with surge protection such as the one shown in Figure 62 use VDRs as protection elements.

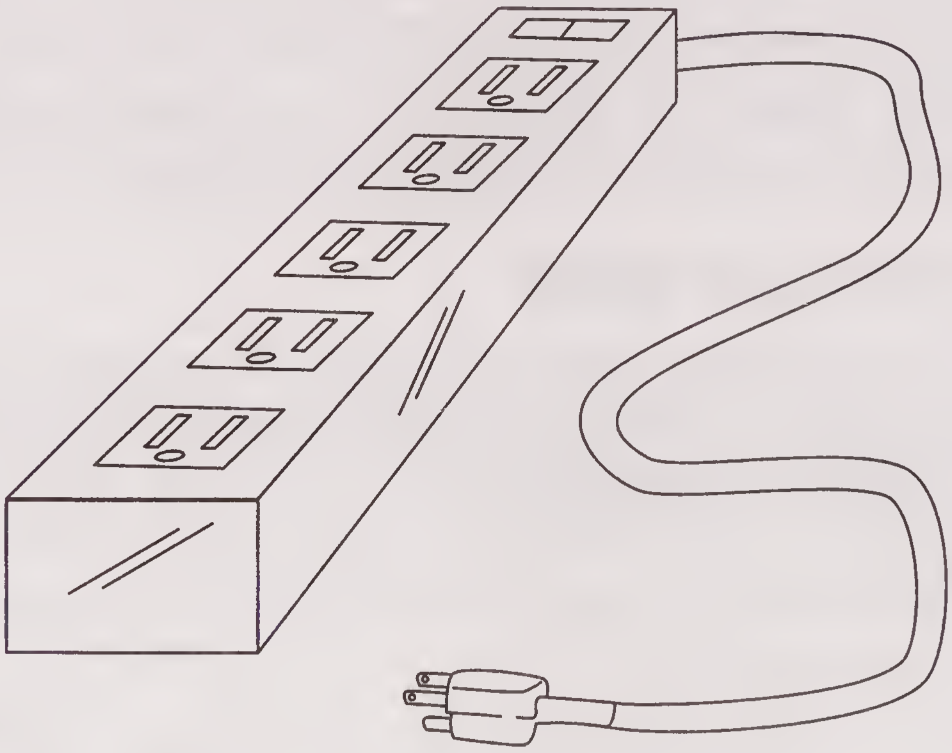


Figure 62

Testing

The effect of the absorption of the energy spikes coming from an AC power line or telephone line makes the VDR dissipate their energy as heat. This effect is cumulative, and after a lag in time of use, the VDR becomes conductive independently from the input voltage acting as a short. In this case, it must be replaced. The replacement type must have the same voltage as the original and be the same size.

The multimeter can be used for testing. A good VDR presents a high resistance above a predetermined hundred thousand ohms.

Capacitors

Capacitors have the function of storing up electrical energy. The basic capacitors are devices formed by a piece of insulating material between two pieces of conductive material. When DC voltage is applied to the capacitor, the electricity carried by the electric charge is stored up to each electrode. The capacitor energy lies in the electrical field formed between the pieces of metal or electrodes called plates. The insulator material is also referred to as dielectric. In electronic equipment, capacitors are used in many important functions. They can be found in many formats, sizes, and with different dielectric materials. The name of a capacitor is given by the material used as the dielectric. For example, a capacitor that uses ceramic as its dielectric is a ceramic capacitor, and a capacitor using mica as its dielectric is a mica capacitor.

Symbols and Types

The types of commonly used capacitors and the symbols used to represent them are shown in Figure 63.

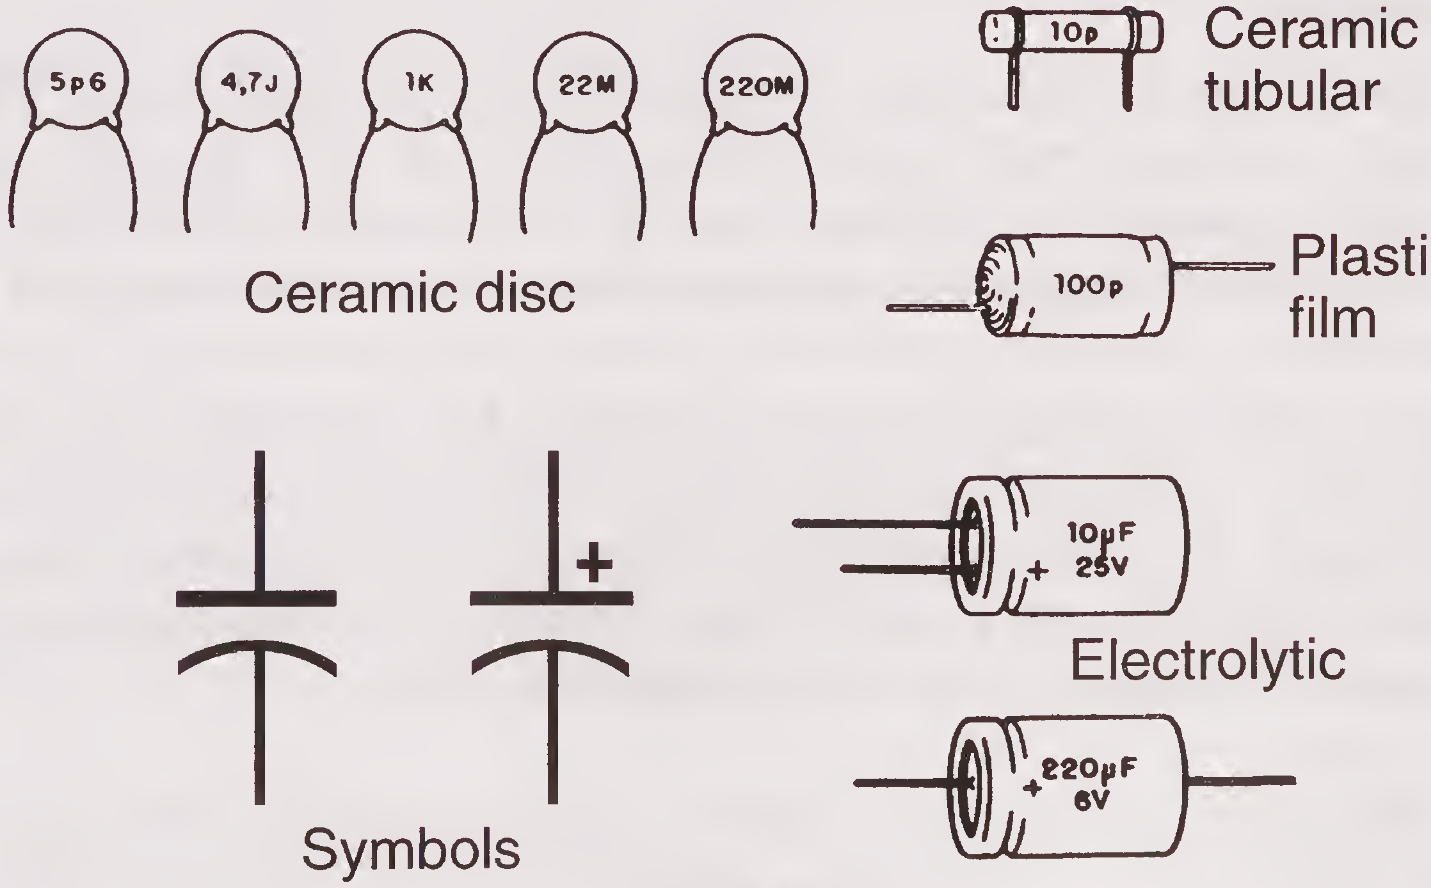

Figure 63

Some differences in representations are also found between diagrams as the European symbol used to represent capacitors is different than the American.

About the types, notice the differences in the manufacturing processes that result in tubular types (where the metal plates and dielectric form a coil) and the plate (where the dielectric is a planar piece).

The differences in types are very important as each capacitor has specific applications according to some electric properties of the material used and the format. For example, ceramic capacitors are suitable for high-frequency applications although polyester film is not. The plastic film capacitors such as polyester and polypropylene are used in low and medium frequency applications.

It is also important to know that electrolytic capacitors are polarized components. This means that they have definite positive and negative electrodes or plates. They can't be inverted when used in a circuit because this can cause the breakdown of the material used as dielectric conductor. In some cases, if a large current flows through the component during a fail, an explosion can occur.

Specifications

The electrician, when replacing a capacitor, must be aware of these specifications:

A. Capacitance

Capacitance is measured in farads. In normal applications the capacitances are very small when compared to this unit. So, the capacitances are expressed in multiples such as microfarads, nanofarads, and picofarads. Table 1-5 gives the conversion factor, the symbol, and the value of these units.

As in a resistor, some capacitors are too small to have the value printed on them. Some codes are used to express the capacitance of a capacitor. One of these is the "three-digit code." This code is formed by three numbers, or two numbers and a letter. If two numbers and a letter are used, it is easy to read the value as shown by these examples:

10n = 10 nF
47p = 47 pF
3.3n = 3.3 nF

Unit	Symbol	Value in Farads (F)
Microfarad	μF	0.000 001 = 10^{-6} F
Nanofarad	nF	0.000 000 001 = 10^{-9} F
Picofarad	pF	0.000 000 000 001= 10^{-12} F

Table 1-5

To convert	In	Multiply by:
Microfarads	Nanofarads	1,000
Microfarads	Picofarads	1,000,000
Nanofarads	Picofarads	1,000
Nanofarads	Microfarads	0.001
Picofarads	Microfarads	0.000 001
Picofarads	Nanofarads	0.001

If three numbers are used, the first two digits show the first and second figures of the capacitance and the third becomes a multiplier which determines how many zeros are to be added to the capacity as in these examples.

102 = 10 00 = 1000 pF

473 = 47 000 = 47 kpF or 47 nF (k = 1000)

Under 100 pF only two digits are displayed: 27 is 27 pF.

Figure 63, where many types of capacitors are shown, gives some samples with this kind of value indication.

Working Voltage

The capacitance of a capacitor depends on the distance between plates and the nature of the material used as a dielectric. The thicker the insulator in a capacitor, the greater its volume, but the smaller its capacitance. Otherwise, if the insulator is very thin, it can't isolate high voltages. Also, the physical construction of a capacitor is important to indicate the highest voltage that can be applied between plates. This is the maximum operating voltage, sometimes expressed as a WVDC (Working Voltage DC).

Types with working voltages in the range from very low voltages to more than 1kV are found in electronic equipment.

Type

The principal types of capacitors found in electronic circuits are:

- Electrolytic capacitors (Electrochemical type)

This type of capacitor uses aluminum as the electrode and a thin oxidization membrane as the dielectric. This layer is so thin that high capacitances can be achieved. But, since the layer is formed in an electrolytic process (thus the name), they are polarized. The pole is identified by a mark in the component (see Figure 64). Electrolytic capacitors have a pole indication that must be observed when installing them. Electrolytic capacitors are found in a capacitance range from 1 uF to more than 220,000 uF and are used in DC and low-frequency circuits.

- Tantalum capacitors

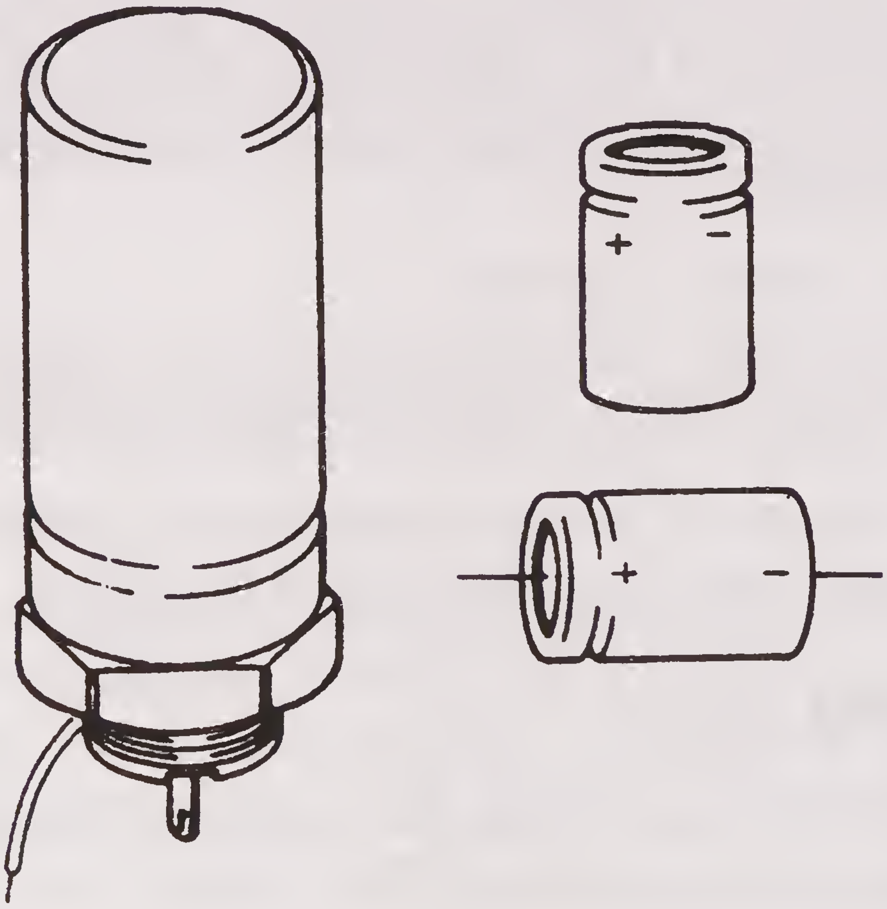

Figure 64

This is a special type of electrolytic capacitor using the material called tantalum for the electrode. Since tantalum oxide has greater dielectric constant when compared with aluminum, tantalum capacitors can be made with very large capacitances and small sizes. Even this capacitor there is polarity. It usually uses the symbol (+) to show the positive lead. Tantalum capacitors are found in a range of values starting from 0.1 uF.

- Ceramic capacitors

Special ceramics, such as titanium acid barium, are used as a dielectric in this kind of capacitor. The electric properties of the dielectric make this capacitor useful in high-frequency applications. The most common type is the disk style. The capacitance of ceramic capacitors is comparatively small. They are typically found in values between 1 pF and 470 nF.

- Polystyrene film capacitor

This capacitor is included in the family of the plastic film capacitors. A thin film of polystyrene is used as a dielectric in this capacitor. Since the plates and the dielectric form thin foils that are wound in a coil, the component presents some inductance. Because of this factor, this capacitor is not recommended for use in high-frequency circuits.

- Polyester film capacitor

Another type of plastic film capacitor is the polyester film capacitor. This kind of capacitor is recommended for high-frequency applications and can be found in a range from very low picofarads to 10 uF or more.

- Other capacitors

Other capacitors in this component family are polypropylene capacitors used in applications where low tolerances are needed, mica capacitors used in applications where high stability is needed, and metalized polyester film capacitors used in miniaturization applications.

In antique equipment other types such as oil/paper capacitors can be found. These capacitors use a paper infused in oil or dry paper as a dielectric. When restoring a piece of antique equipment where a damaged oil or paper capacitor is found, it can be replaced by an equivalent plastic film capacitor.

Where they are found

The electrician is familiar with capacitors since they are used with motors and in other electrical applications. However, the capacitors found in electronic equipment are found in a much larger assortment of types, values, and sizes as well as in every part.

Capacitors have special electric properties that make them very important to the performance of all electronic circuits. They can be used to measure time intervals, to perform calculus in computers, and to separate

AC signals from DC signals in audio and high-frequency circuits. They are also used as filters and for energy storage in many applications.

Testing

When connecting the probes of an analog meter to the terminal of an electrolytic capacitor (10 uF or greater) a current flow is registered by the needle's movement. This current flows while the electric charge is storing up. The current stops flowing when the charge finishes storing. The oscillating movement of a needle in a multimeter can be used to test an electrolytic capacitor. Use an intermediate resistance scale for this task.

Once charged, capacitors are like open circuits. When perfect, they can't let the current pass through them. This means that good capacitors have a very high resistance that can be measured with the aid of any common analog or digital multimeter. If a capacitor presents low resistances (under a hundred thousand ohms) we say that it presents losses or is shorted and must be replaced.

Variable Capacitors

In some applications a capacitance presented by a capacitor must be changed. This is the case in a radio receiver where the station tuned is determined by a capacitance of a resonant circuit. Every time we need to change the station the capacitance in that circuit must be altered. This task needs the aid of a special capacitor. The capacitor that can change the capacity is called a variable capacitor.

Like variable resistors, variable capacitors are found in several types. All of them are manufactured starting from the same principles: a moving plate can slide in front of a fixed plate with an insulator between them, or a moving plate can change the distance from a fixed plate also with a dielectric between them.

Two basic variable capacitor types are found in electronic applications: the trimmer, one that can be adjusted by a screwdriver, and the variable capacitor, or varicon, that is adjusted by a button placed in its axis.

Symbols and Views

Figure 65 gives the symbols used to represent variable capacitors and views of the most common types.

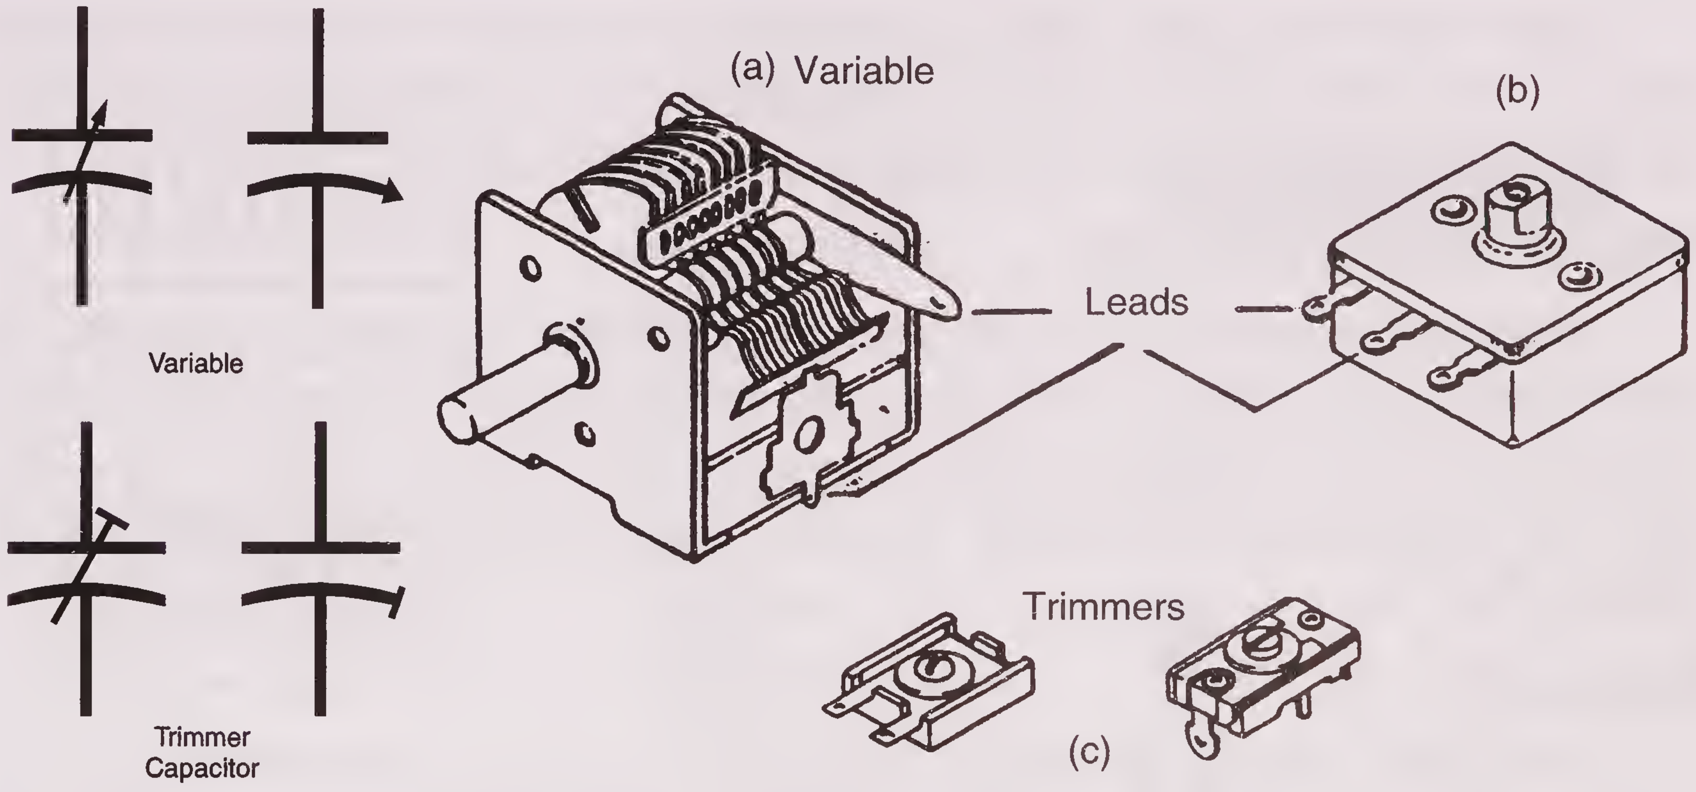

Figure 65

The variable capacitor shown in (a) is found in antique devices such as radios and tuners. The dielectric is the air gap between the moving plates and the fixed plates. In (b) are variable capacitors like those found in modern small transistor radios. In this type the dielectric is a polyester foil between the moving plates and the fixed plates.

The trimmer capacitors can be found with plastic, ceramic, and mica as the dielectric. Adjustment is made by a screw that moves one of the plates as shown in Figure 65 (c).

Specifications

Two main specifications are important when choosing variable or trimmer capacitors.

1. Capacitance

For variable capacitors, normally maximum capacitance is shown as nominal capacitance. Thus, a 120 pF capacitor is a capacitor that can change capacitance between a smaller value and 120 pF. However, even when totally open the capacitance isn't zero, which is normal, to indicate the minimum capacitance. For trimmer capacitors the capacitance range is given. For example, a 2-20 pF trimmer capacitor can be adjusted to present any value between 2 and 20 pF.

2. Type

Type indicates how many sections the capacitor has and of what material the dielectric is made. A two-section, air-dielectric capacitor with 365 pF sections is a type commonly found in old radios.

Where they are found

Variable capacitors are found in equipment operating with RF or radio signals like radios, remote control receivers and transmitters, wireless telephones, wireless communicators, and many others. They are used for adjustment or tuning circuits, placing them in a determined frequency.

Testing

The main problem of variable capacitors is shorts between plates. To test this, measure the resistance between the fixed and moving plates (the component must be disconnected from the circuit for this test). The resistance must be infinite in any position of the adjustment to indicate a good device.

Coils or Inductors

Coils, chokes, or inductors are components made of a certain number of turns of wire on a form. They are used to provide an inductance wherever it may be required. Inside the form is air (no core or air core) or some magnetic material such as ferrite (iron dust), iron, etc. The coils present opposition to current changes characterized by an electric quantity called inductance. The inductance is measured in henry (H) but, the fractions—millihenry (mH) and microhenry (μH)—are widely used in practical components. The number of turns and the gauge of wire determine the inductance of an inductor or coil.

Three major classes of coils or fixed inductors are available. They are the filter choke, audio frequency inductor, and the RF inductor or choke. (RF means radio frequency).

Symbols and types

Figure 66 shows some types of coils or inductors the electrician can find in electronic equipment.

Coil
Can
Basis
Air Core
Leads

Figure 66

The presence of a continuous line in the symbol indicates an iron core. The presence of an intermittent line in the symbol indicates a ferrite core. If the line is absent the coil is an air core type.

Adjustable coils can also be found in some applications. These coils have an adjustable core that can be slid or screwed in their form.

Specifications

A. Inductance

The inductance of a coil is expressed in henry (H) or its fractions. Low values in the range of microhenry are found in high-frequency applications. Values in the range of millihenry and henry are found in low-frequency circuits and as filter chokes.

B. Core

The nature of the core is an important specification for a coil. Low-frequency and DC coils (filters and audio) use iron cores. High-frequency coils use ferrite and air cores. It is also important to indicate the size and shape of the core. Ferrite toroids or rods are used for high-current chokes and RF applications. Pot cores are an example.

Where they are found

The lower the number of turns, the lower the inductance. Low-inductance coils are used in high-frequency circuits like tuned circuits, filters, etc. High-inductance coils are found in power supply filters, audio circuits, musical instruments, etc.

The use of large inductance coils in a circuit is not common. Because large inductance coils are heavy and expensive components, they are avoided in most projects. Circuits that can simulate inductance using other components are found in some applications.

Testing

The main problem of a coil is the interruption of the wire and the short caused by excess heat or mechanical problems. The test of coil continuity can be done using a multimeter on the lowest resistance scale. The resistance of a coil, depending on the number of turns and the wire used, should be in the range between 0 and 10,000 ohms. The test for a short is more difficult. Generally, a coil in short, when caused by excess current, presents burning signals such as dark spots and the smell of smoke.

Transformers

Transformers are components formed by two or more coils or inductors coupled so closely together that the magnetic field of one causes induction of current in the others. For the total coupling the coils are wound in a common form or core. When an alternating voltage is applied to one coil of a transformer (called the primary winding), this voltage induces alternating voltages in the other coils (secondary windings) depending on the ratio of turns of the two windings. For example, if a transformer has a primary winding with 200 turns and a secondary with 400 turns, and 110 VAC is applied to the primary, 220 VAC can be found in the secondary, as shown in Figure 67.

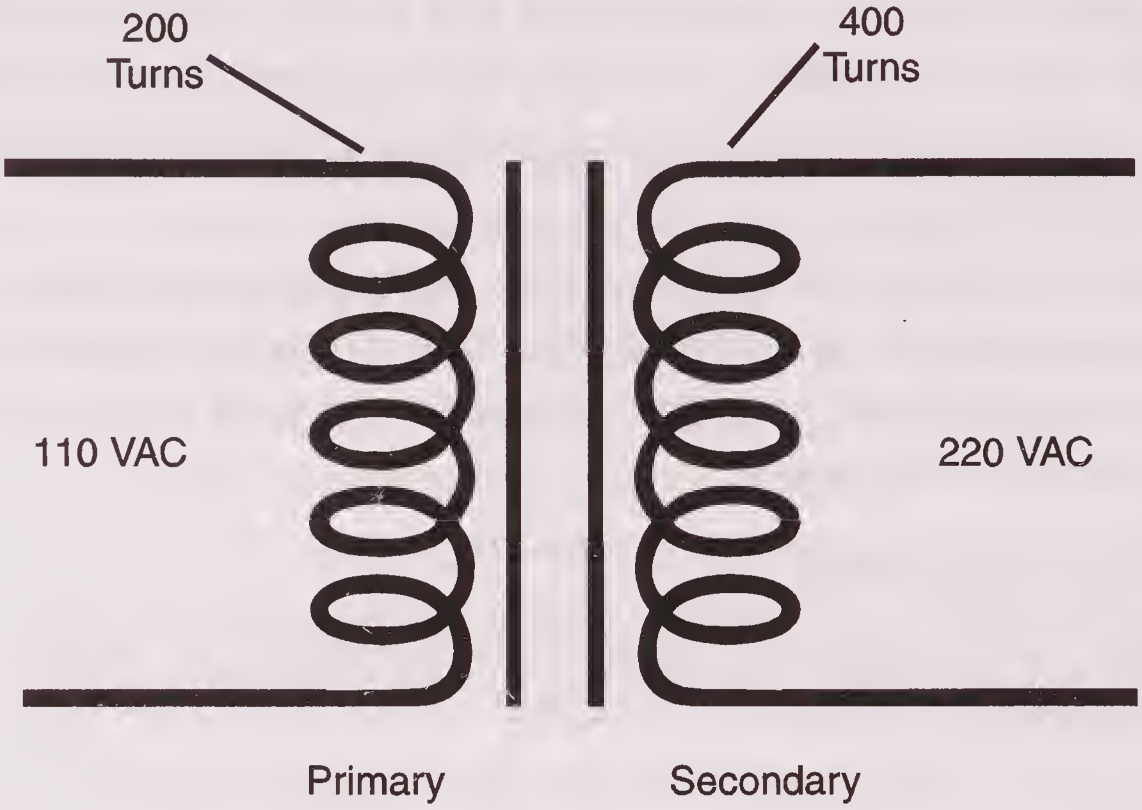

Figure 67

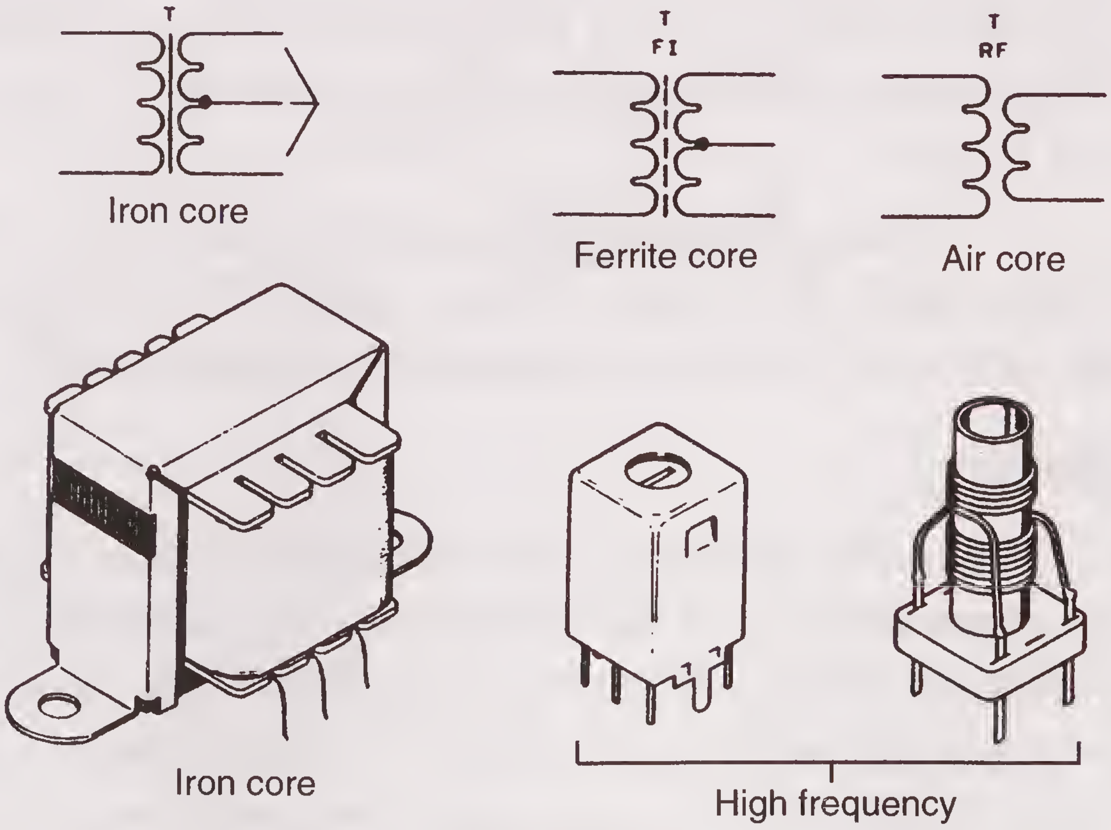
Transformers can be used to change voltages, currents, and impedances in an alternating-current circuit or high-frequency circuit. The transformers can be wound in forms with air cores, ferrite cores, or iron cores according to the application. Air and ferrite cores are used in high- and medium-frequency circuits and iron cores are used in medium- and low-frequency circuits.

Symbols and Types

Figure 68 shows the different symbols used to represent transformers and their types.

The presence of a material core (ferrite or iron) is represented by a continuous or intermittent line. If the line is absent it is an air core transformer.



Iron core

Iron core

High frequency

Figure 68

Specifications:

Audio and power supply transformers

- Input voltage or impedance—The primary winding or the input of a transformer is specified by the voltage such as the transformers found in power supplies. In transformers used as an impedance match in audio or other applications, the primary winding is specified by an impedance in ohms.
- The output voltage—The secondary winding of a power supply transformer is specified by the output voltage and current. For audio transformers the output impedance, and in some cases, also the output power, are given.

RF transformers

- Number of turns—In RF transformers the number of turns and the wire gauge are specified, mostly in circuits to be mounted.
- Core—The type of core and format is an important specification for high-frequency transformers.

Where they are found

The electrician will find transformers of many sizes and types in all electronic equipment. The most common types are the transformers used in the power supply of any equipment. The windings are isolated one from the other (the electric energy is transferred from one to the other by the magnetic field), so they are important as an insulation element in circuits. The presence of a transformer avoids shock hazards when touching parts of a circuit.

In audio and high-frequency circuits it is also possible to find transformers with air cores or ferrite cores. Computers and some audio amplifiers use toroid transformers in the power supply.

Testing

The simplest way to test a transformer is to check that the windings are not interrupted. This can be done using a common multimeter on the lowest resistance scale. RF transformers with few turns of wire must present very low resistances if they are good. Audio or power-supply transformers present higher resistances, in the range between low ohms and 10,000 ohms.

Important: the measured resistance of the winding of any transformer isn't its impedance but the ohmic resistance of the wire used to wind it.

Relays

Relays are electromagnetic switches. They are formed by an electromagnet coupled to switch contacts so that the switch is operated automatically when the electromagnet is energized. Applying a voltage to the electromagnet allows the devices wired to the switch to be controlled. Relays are important as they can be used to control high power loads from weak signals or currents. Another advantage in the use of relays is that the contacts are isolated from the control circuit, meaning a relay can be used to control a high-voltage circuit from a low-voltage circuit. The disadvantage is that the coupling between the coil and the contacts is mechanical, limiting the speed of response.

Figure 69 shows the basic construction of a relay as found in many electronic applications.

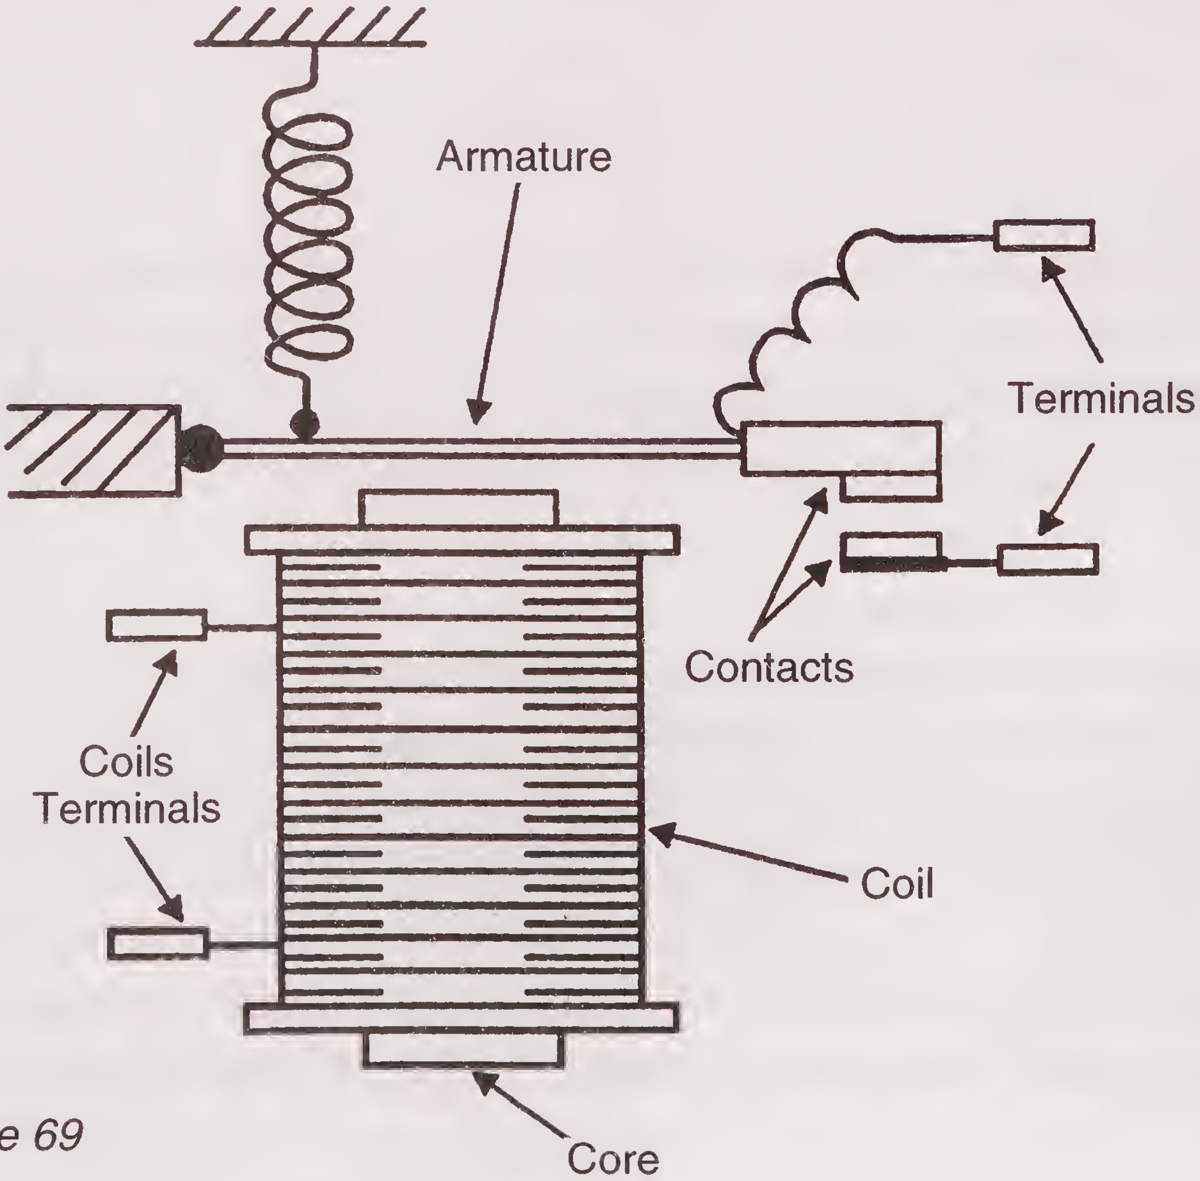

Figure 69

The coil is formed by hundreds or thousands of turns of thin, enameled wire. The contacts are designed to control high currents based on the final use of the device.

Symbols and Views

Figure 70 shows the symbols and views of the relays used in common electronic applications.

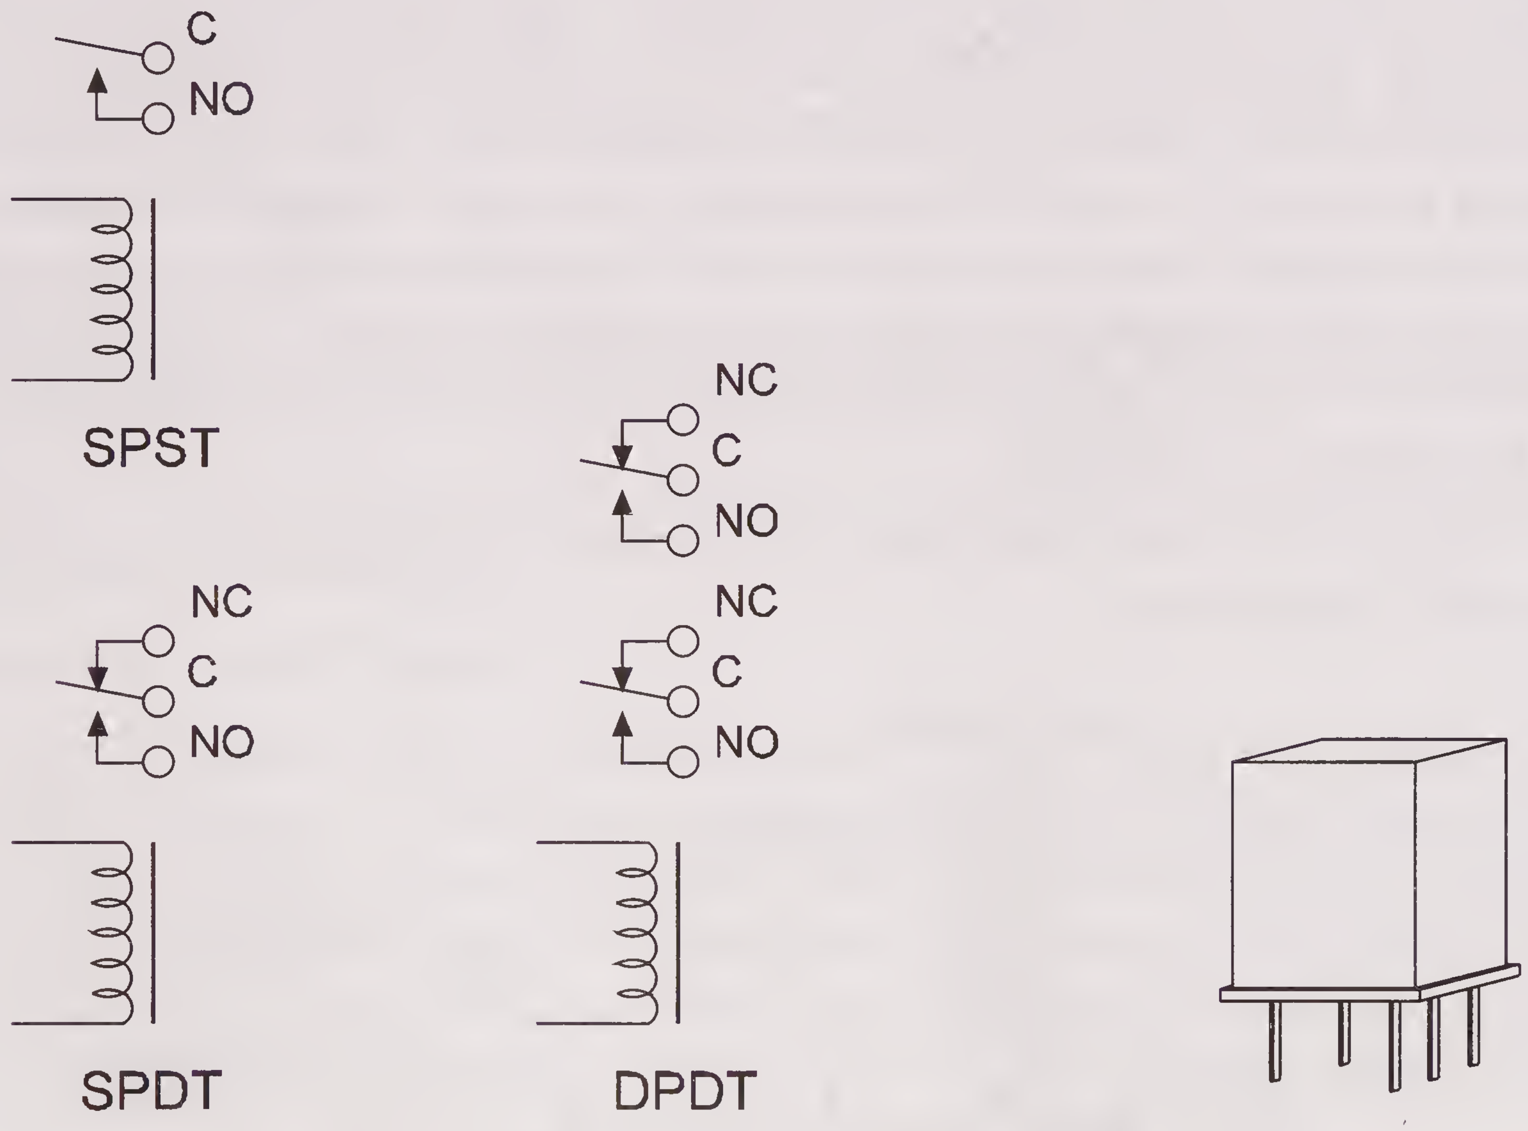

Figure 70

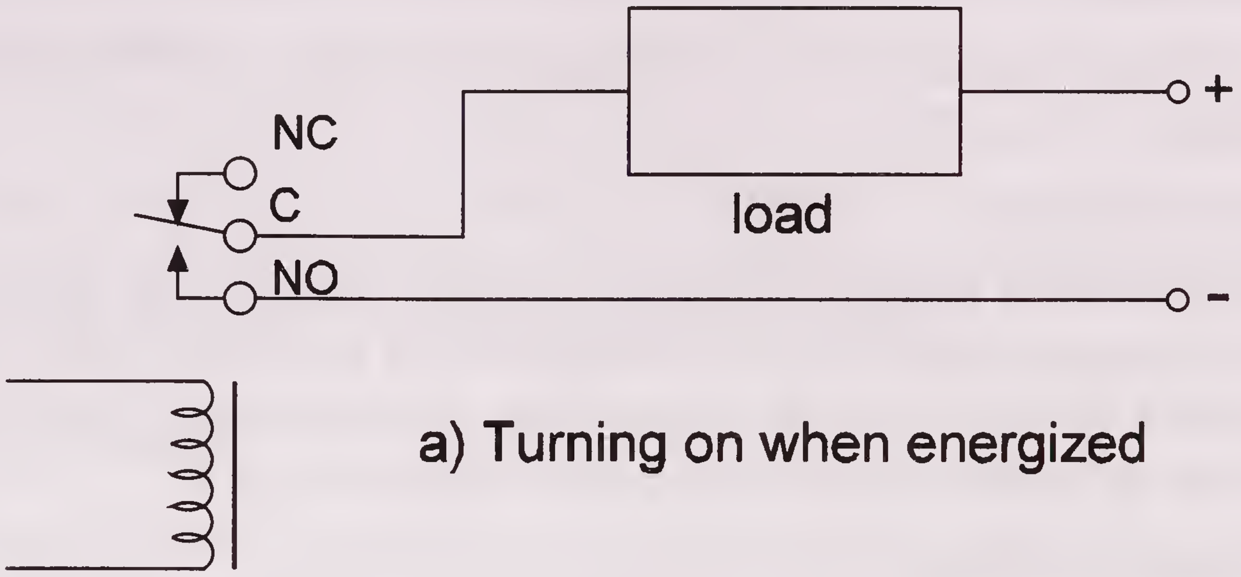
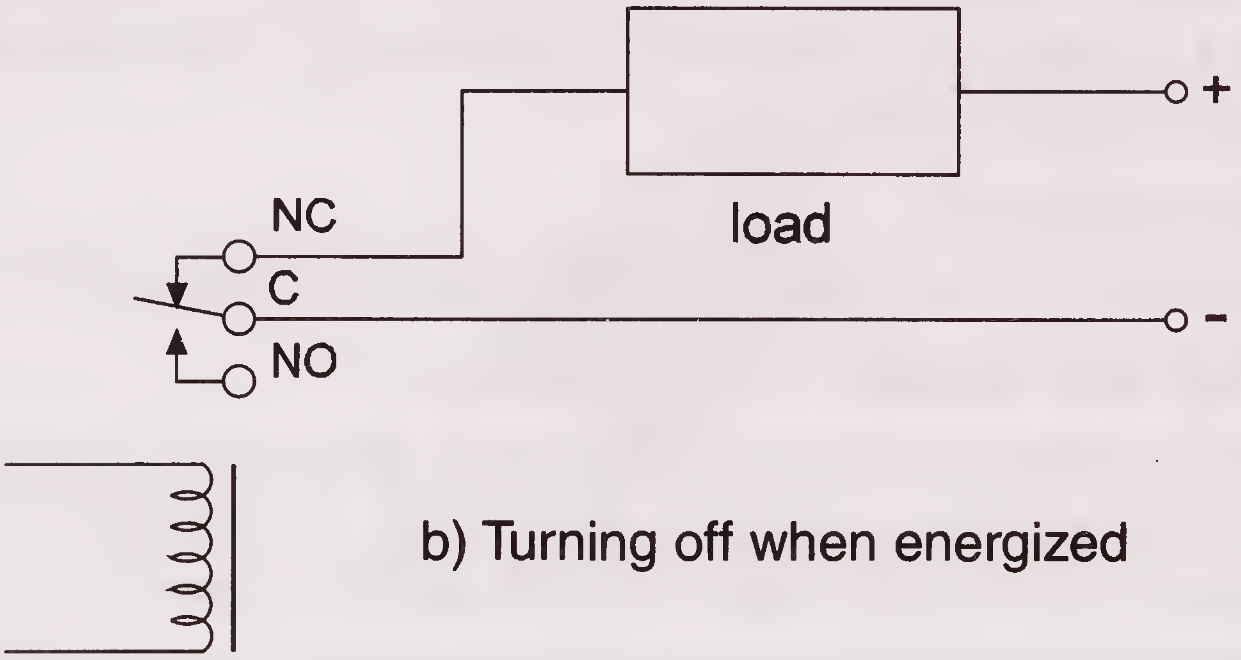
A relay can provide SPDT or DPDT depending on the contact placement. The numbers of contacts that can be controlled by the relay are shown in the symbols. Notice when the relay can have “normally open” contacts (NO) and “normally closed” contacts (NC). When controlling a load from the NO contacts, the load will be turned on when the relay’s coil is energized. Otherwise, if the NC contacts are used, the load will be turned off when the coil is energized. Figure 71 shows how these contacts should be used.



a) Turning on when energized



b) Turning off when energized

Figure 71

Figure 72 shows another important type of relay—the reed relay. This relay is formed by a coil involving a reed switch. The reed switch is formed by metal plates inside a glass enclosure that is filled with an inert gas. When a magnetic field acts on these plates, they touch one another, closing the circuit.

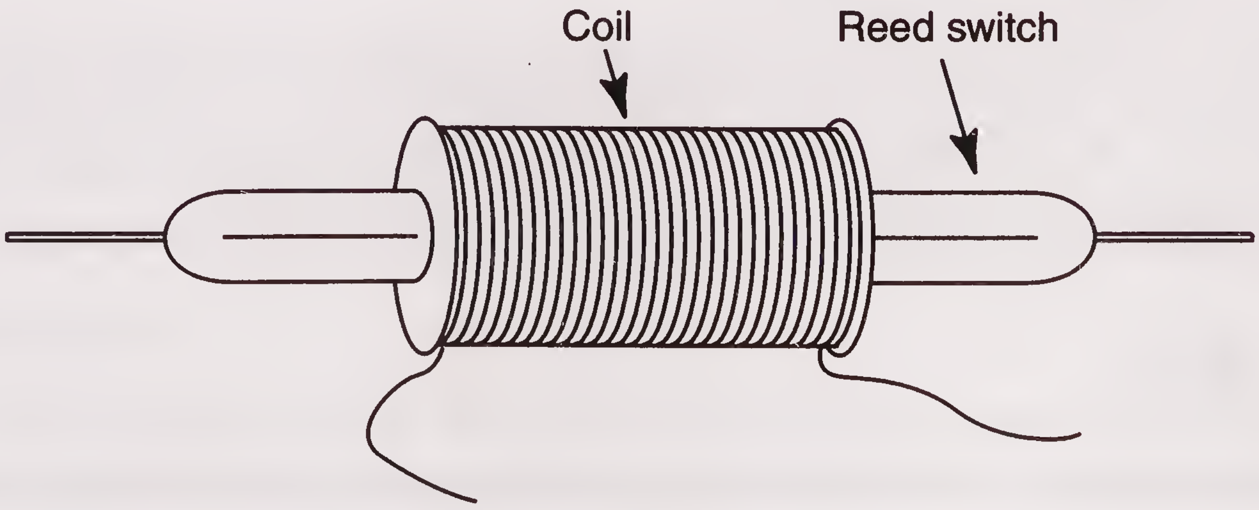


Figure 72

Specifications

When replacing a relay, the electrician must take care to observe these specifications:

A. Coil specifications

The current that turns a relay on is given by the coil specifications. The relay can be specified by the voltage to be applied to the coil in volts and the current, or by its ohmic resistance. For example a 12 V x 50 mA relay can also be indicated as a 240-ohm relay for 12 V.

B. Contact specification

This is the amount of current (and the voltage of the external circuit) that can be controlled by the relay.

C. Contact configuration

This is given by the number of contacts and their type—SPST or DPDT.

Where they are found

In electric circuits, the electrician usually finds relays controlling high electric currents such as in motors, lamps, etc. In electronic circuits it is most common to find small relays controlling small currents.

Small relays can be found in alarms controlling the siren, lamps, or other loads. In automatic doors, remote controls, and other applications, relays interface the control circuit with the controlled load.

Testing

Two kinds of tests can be done in a relay:

A. Coil: The state of the coil can be verified by a multimeter. A good coil presents resistances between some ohms and 10,000 ohms. This probe doesn't indicate a shorted coil.

B. Contacts: The contacts are tested by applying a voltage to the coil and measuring the resistance when they close. This resistance must be almost zero when tested with a common multimeter.

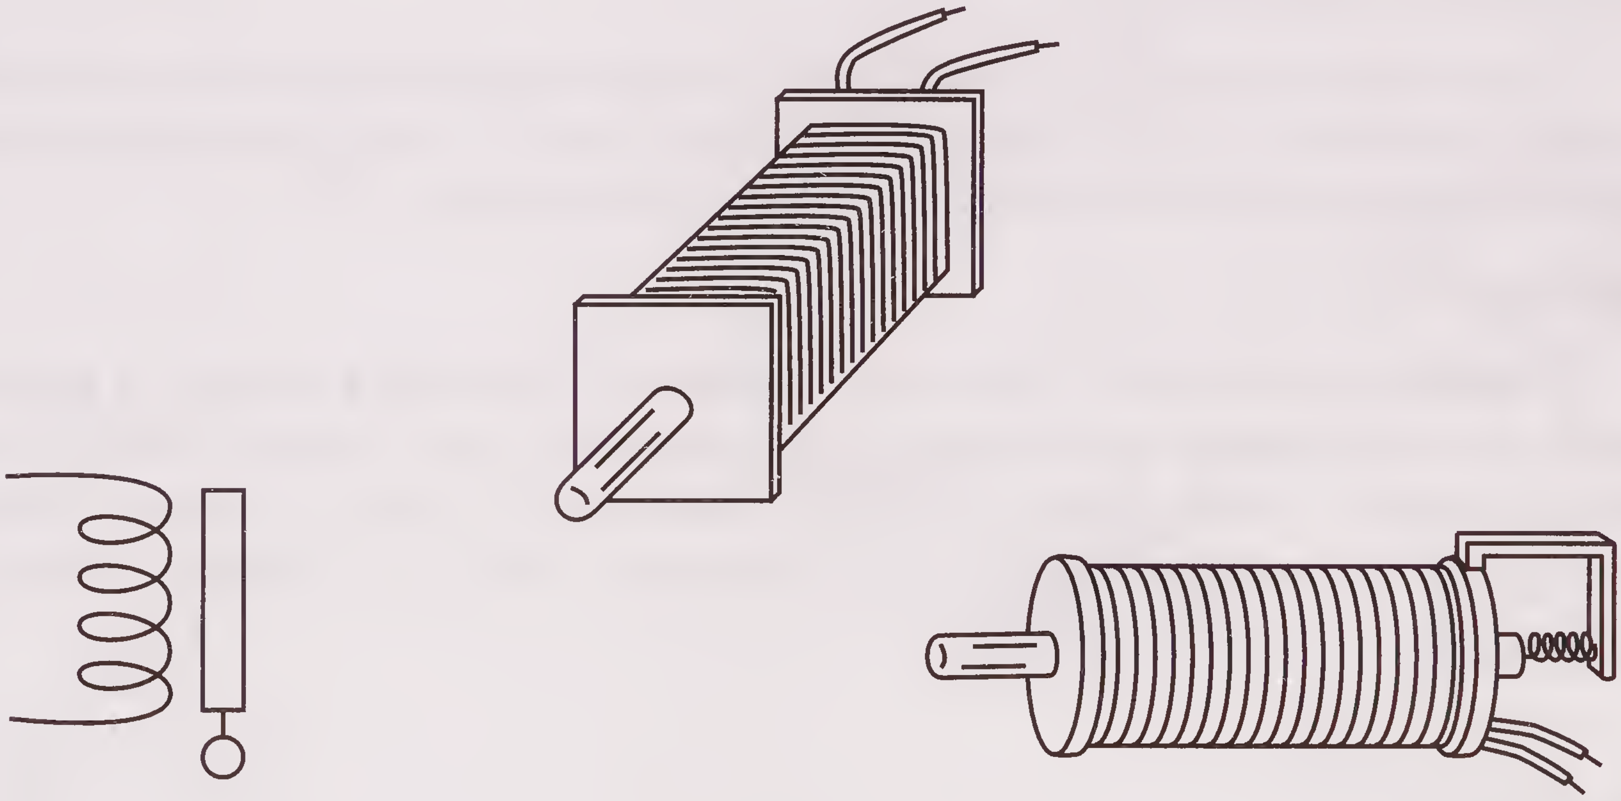
Solenoids

Solenoids are components formed by a coil with a moving core inside. When a current flows through the coil, the magnetic field acts on the core attracting it. Sliding inside the coil, the core can be used to move some mechanism.

Solenoids with different sizes and formats are found in electronic equipment. They are used to move mechanical parts of the appliances such as the tape-ejecting mechanisms in VCRs. Washing machines and dishwashers also use solenoids to control the flow of water.

Symbol and Views

The symbol of a solenoid and views of the common types found in electronic equipment are shown in Figure 73.



Symbol

Aspects

Figure 73

Small solenoids are formed by a coil with thousands of turns of a very thin, enameled wire. The core is a rod of iron that slides inside the coil. A spring and some mechanism can be found to return the core to the initial position when the current that causes the magnetic field disappears.

Specification

The main specification of a solenoid is the voltage that must be applied to energize it. As an important complement to this information, know the current drain when the nominal voltage is applied. In electronic circuits, solenoids with voltages ranging from some volts DC to AC power line voltage are found.

Where they are found

The electrician can find many types of solenoids in common electric appliances such as washers and electric doors. In electronic appliances, solenoids are found in items such as tape recorders, VCRs, CD players, and a large number of items with circuits where mechanisms must be controlled from electric currents. The solenoids found in these applications are generally very small and delicate. They are different from the ones found in electric appliances that are designed to operate with the AC voltage from the power line.

The important fact for the electrician to recognize is that solenoids used in electronic circuits are usually driven by DC currents supplied by active circuits using transistors and other components.

Testing

The electric test of a solenoid consists in the coil's probe. A multimeter, on the lowest resistance scale, can be used to see if the coil is not interrupted. A resistance varying from some ohms to a thousand ohms must be measured in a good solenoid. This test doesn't show a shorted coil.

Motors

In electronic circuits many types of small DC motors can be found. Basically a motor is a device that converts electric energy into motion. They can be used to move parts of a device from an in signal or control voltage. The electric motor is formed by one or more coils that produce a magnetic field when a current flows through them. The magnetic field acts on metal pieces or other coils causing a force that puts it in motion. In electronic applications, there are two main types of electric motors—DC motors and step motors.

These motors are formed by coils that, when energized, can place a shaft in a determined position. By energizing the coils in sequence, the shaft can run at a determined speed. DC motors produce continuous movement when a voltage is applied. Step motors can be used to place a piece in a predetermined position with great precision.

AC motors are more rare in electronic appliances. They are mainly high-power motors driving large mechanisms.

Symbol and Views

Figure 74 shows a parts view and symbols of some DC motors and step motors.

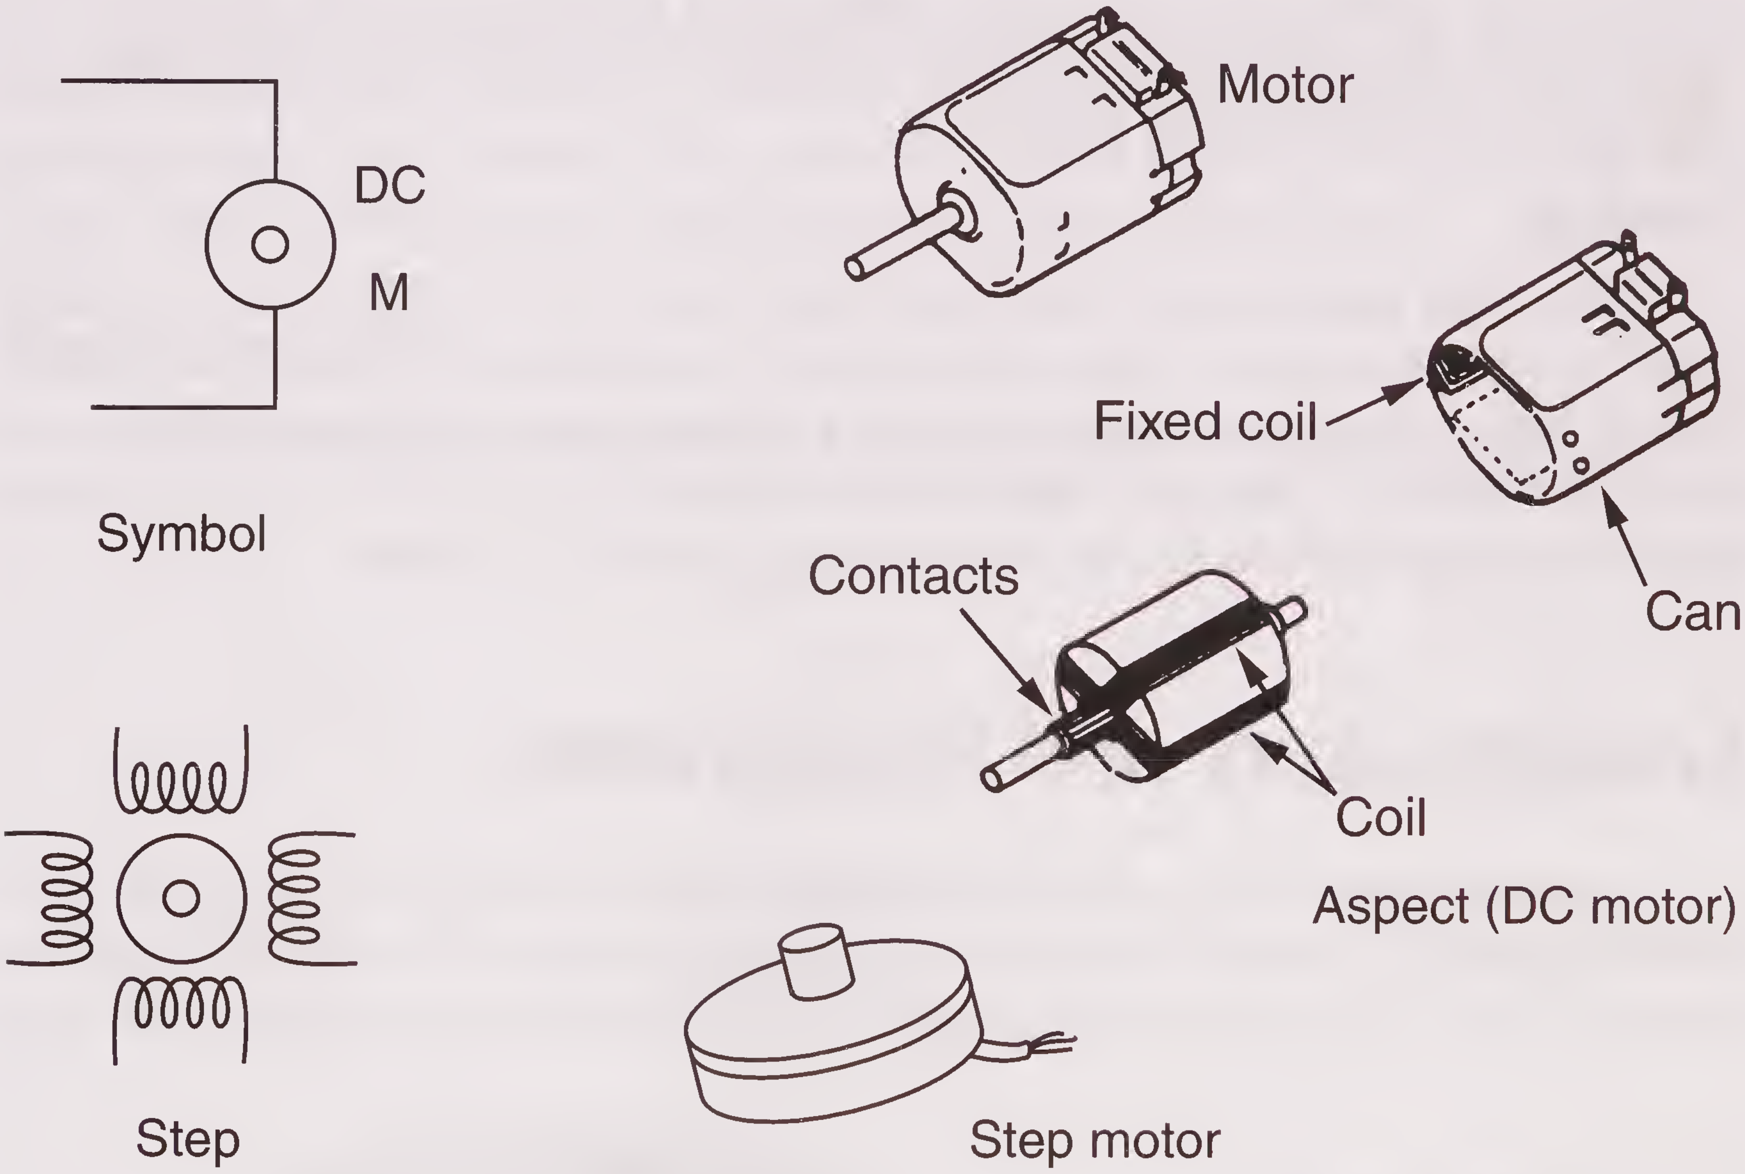


Figure 74

Specifications

DC motors are specified by the operational voltage and the nominal current. In these motors the current and the absorbed power are functions of the load. When running without a load the current is very low and the speed rises to the maximum value. When the load increases, the speed falls down and the drained current increases to the maximum. Another indication sometimes found is the speed given in rpm (rotations per minute) under nominal operation conditions.

The step motors are specified by the type (number of poles) and the voltage. The current drained is also an important specification for this kind of motor.

Where they are found

As stated, there are many electronic applications where motors can be found. Since they are delicate mechanisms, electricians will find that in more of the cases than not, the origin of a problem is not electric, but mechanical. Rotors and the coupling pieces such as the shaft can break or present other mechanical problems.

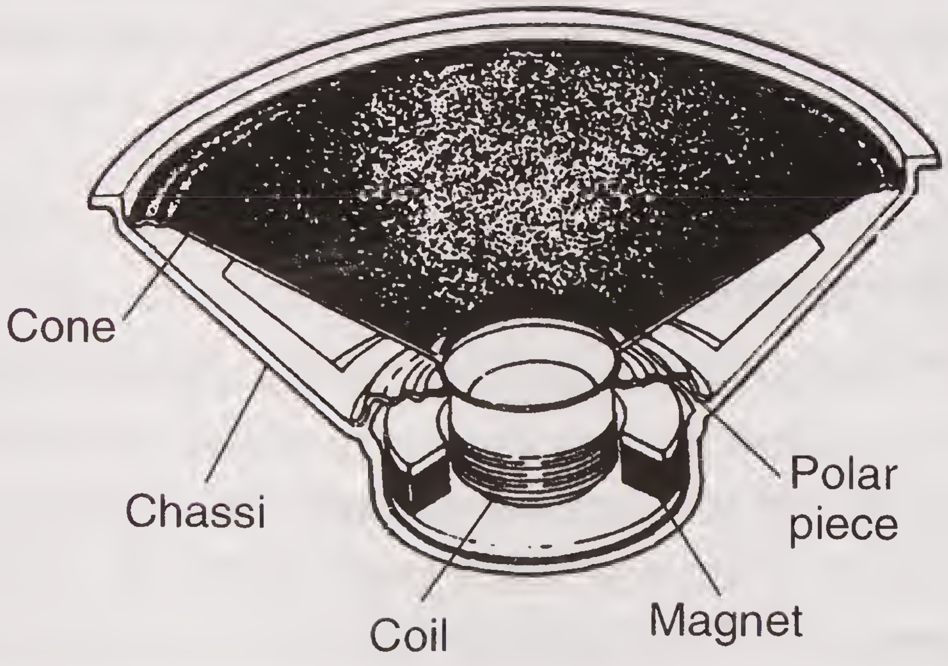
Testing

The only electric test the electrician can do on a DC motor or step motor is in the coils. An interrupted coil or a shorted coil is the main problem. A test using a multimeter adjusted to the lowest resistance scale can reveal if the coil is perfect. Resistances ranging from some ohms to some hundred ohms can be found when testing small DC motors.

Loudspeakers and Headphones

Loudspeakers and ear/headphones are transducers or devices that convert electric energy into sound (acoustic energy). The electric energy comes in the form of an electric signal whose frequency corresponds to a

Figure 75



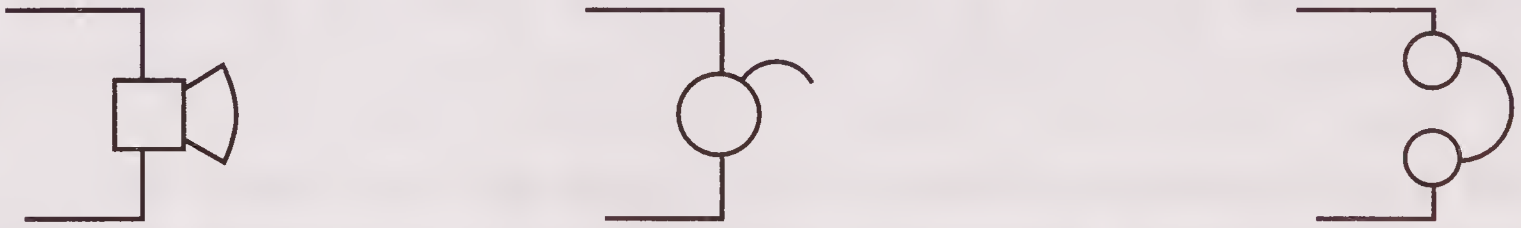
sound. The moving coil loudspeaker (the most common in audio applications) is formed by a coil involving a polar metal piece where a strong magnetic field is produced by a magnet as shown in Figure 75.

The coil is fixed in a cardboard or plastic cone. When the signal is applied to the coil, its magnetic field interacts with the magnetic field produced in the polar piece, resulting in a force that moves the coil and the cone forward and backward. Compression and decompression waves are produced in the air surrounding the cone. These waves have a waveform corresponding to the original sound being reproduced.

In magnetic headphones small devices that operate according to the same principle can be found. Remember that both loudspeaker and headphones exist that operate from other principles such as the piezoelectric units. (See in the item on transducers for more information.)

Symbols and Types

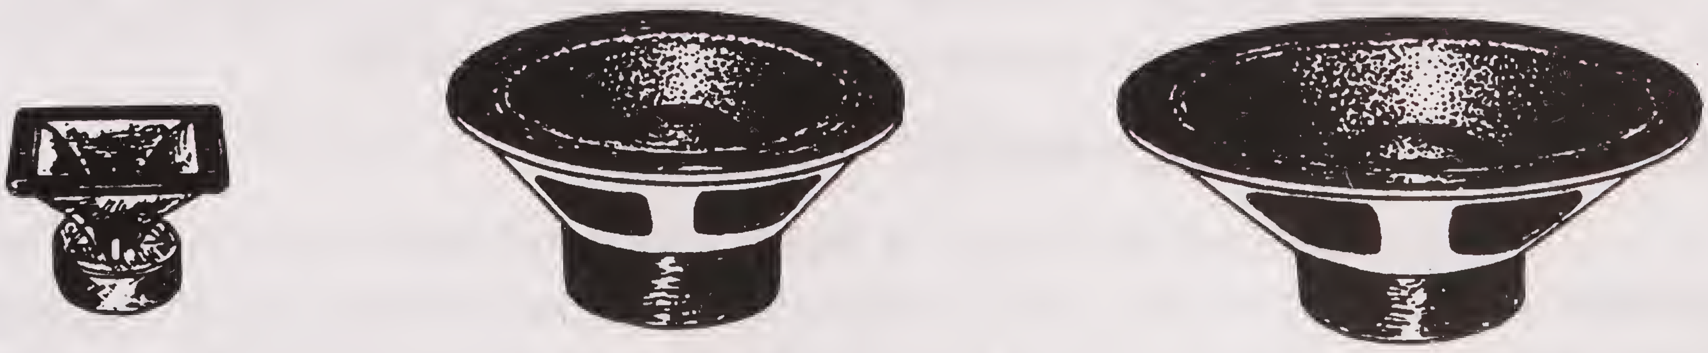
Figure 76 shows the symbols and the types of some loudspeakers.



Loudspeaker (Symbol)

Earphone (Symbol)

Headphones (Symbol)



Tweeter

Mid-range

Woofer

Figure 76

The larger the size of a loudspeaker, the easier the production of low-frequency sounds. This means that heavy magnets and large diameters are characteristics of low-frequency loudspeakers, also named bass speakers or woofers. Small loudspeakers are used for the reproduction of high-frequency sounds. These small speakers are called treble speakers or tweeters.

It is important to remember that many loudspeakers are designed to operate only inside enclosures.

Specifications

A. Impedance: When replacing a loudspeaker, next to the size, the impedance is the first electric specification to be observed. The impedance of a loudspeaker is measured in ohms and should not be confused with the ohmic resistance of the coil. Common types have impedances in the range between 3.2 and 16 ohms. Never use a loudspeaker with less impedance than the recommended; the output stage of the driver circuit can be forced and the components damaged.

B. Power: The amount of electric power that can be applied to a loudspeaker and converted in sound is another important specification for these components. Power is measured in watts (W). You'll never use a loudspeaker with less power capabilities than the output of your audio equipment. The loudspeaker can be overloaded and the coil burned.

C. Frequency range: In some cases is important to make sure the loudspeaker isn't a special type designed for the reproduction of a determined frequency range. Loudspeakers for high-frequency sounds (treble) such as the tweeters have different characteristics when compared with the low-frequency (bass) loudspeakers.

Headphone characteristics

The main characteristic of a headphone or earphone is the impedance. Two types are used in electronic applications—low-impedance types ranging from 3.2 to 600 ohms and high-impedance types ranging from 1000 to 10,000 ohms. Never use a low-impedance headphone or earphone in an application where a high-impedance type is recommended.

Testing

The electric test of a magnetic loudspeaker or headphone consists in the measure of the continuity of the coil. A common multimeter on the lowest resistance scale can be used for this task. The measured resistance of a good loudspeaker or headphone is very low, below 100 ohms for the low-impedance types. See that the measured resistance isn't the impedance but the ohmic resistance of the coil. Higher values, up to several thousand ohms, are common in high-impedance types.

Magnetic Transducers

Transducers are devices that convert one form of energy into another. A magnetic transducer transforms variable magnetic fields into electric currents. In the inverse mode, we can also consider a magnetic transducer to be any device that converts electric signals into magnetic fields. Many magnetic transducers can be found in electronic applications functioning as sensors. Basically they are formed by a coil that can be used to pick up any change in the magnetic field produced by a magnet under certain conditions, or a coil that produces a magnetic field from a current.

Loudspeakers and headphones are magnetic transducers, as explained previously, but are treated as a separate item because of their importance in electronics. Microphones and diskettes that read heads and position sensors are other examples of magnetic transducers used as sensors. The writing heads of a Winchester disk or disk drive are magnetic transducers operating in the inverse mode.

Symbols and Types

The symbols and types of some magnetic transducers are shown in Figure 77.

Specifications

Depending on the application, the transducer can show specifications as current, voltage, type of signal, or a part number. The most common is a part number specification.

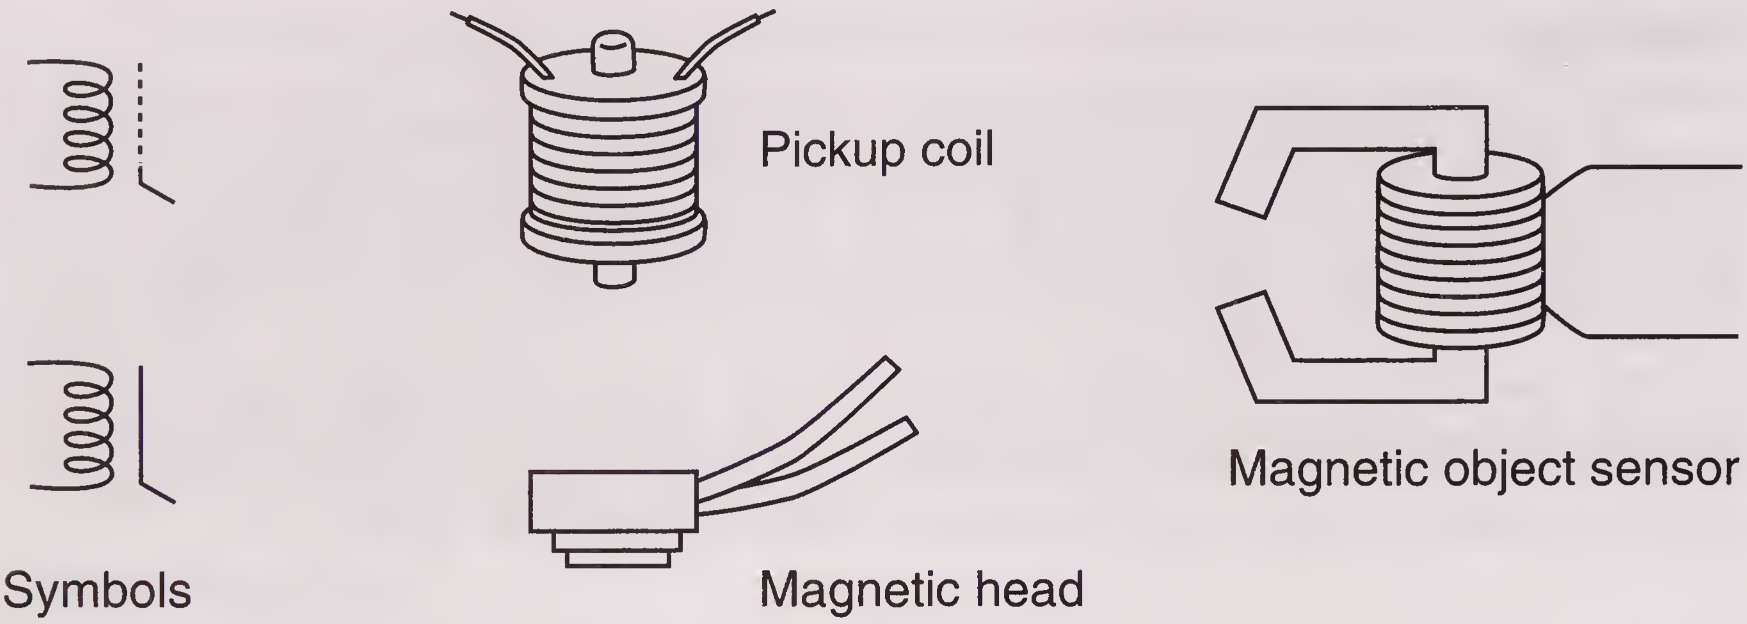


Figure 77

Where they are found

Pickup coils, sensors, microphones, Winchester disk, and disk drives are all examples of magnetic sensors.

Testing

A multimeter can be used to test the continuity of the coil. Magnetic transducers in general must present resistances ranging from less than 1 ohm to more than 1000 ohms based on the application. This test doesn't reveal other problems such as shorts or mechanical failures.

Piezoeletric Transducers

Some materials present piezoelectric properties due to their unusual crystal structure. Among these materials are quartz, Rochelle salt, and several kinds of barium and titanium ceramics. When a piezoelectric material is pressed, bent, or submitted to mechanical efforts or any change of form, electric charges appear in its surfaces. The same effect also works in the inverse mode; if we apply electric voltages to its surface, a mechanical deformation can occur. Some ceramic materials such as barium titanate and quartz crystals present piezoelectric properties.

These materials can be used to make piezoelectric transducers, piezoelectric sounders, piezoelectric loudspeakers and earphones, piezoelectric buzzers, and many other devices that convert electric energy into mechanical energy (sound or super sounds) or the opposite, such as microphones, vibration pickups, etc. Some components are very important in this family:

A. Quartz crystal: When excited by an electric signal quartz crystal tends to vibrate, producing signals of only one frequency. They can be used to determine the operational frequency of many circuits such as those in clocks, watches, computers, radio transmitters and receivers, and many others. The vibration frequency is established by the mechanical resonance of the crystalline plate.

B. Piezoelectric sound generators: A small piece of piezoelectric ceramic can be used to produce sounds in alarms, earphones, and high-frequency loudspeakers (tweeters). When an audio signal is applied, the ceramic vibrates producing sound waves. Ceramic transducers can also be used to produce supersonic sounds.

C. Piezoelectric high-voltage generators: Beating a piece of piezoelectric ceramic with a small, spring-triggered hammer, a ceramic piezoelectric transducer can generate very high-voltage pulses. The high voltage, up to 7000 volts, will produce a spark that is used in gas igniters and in other applications.

D. Piezoelectric microphones: Placing a diaphragm onto a piece of piezoelectric ceramic can be used to convert sounds or beats in electric signals. The sound waves beating the diaphragm make it press the ceramic piece producing the deformations needed to cause the electric signals to appear.

Symbol and Types

Figure 78 shows some piezoelectric transducers and their symbols.

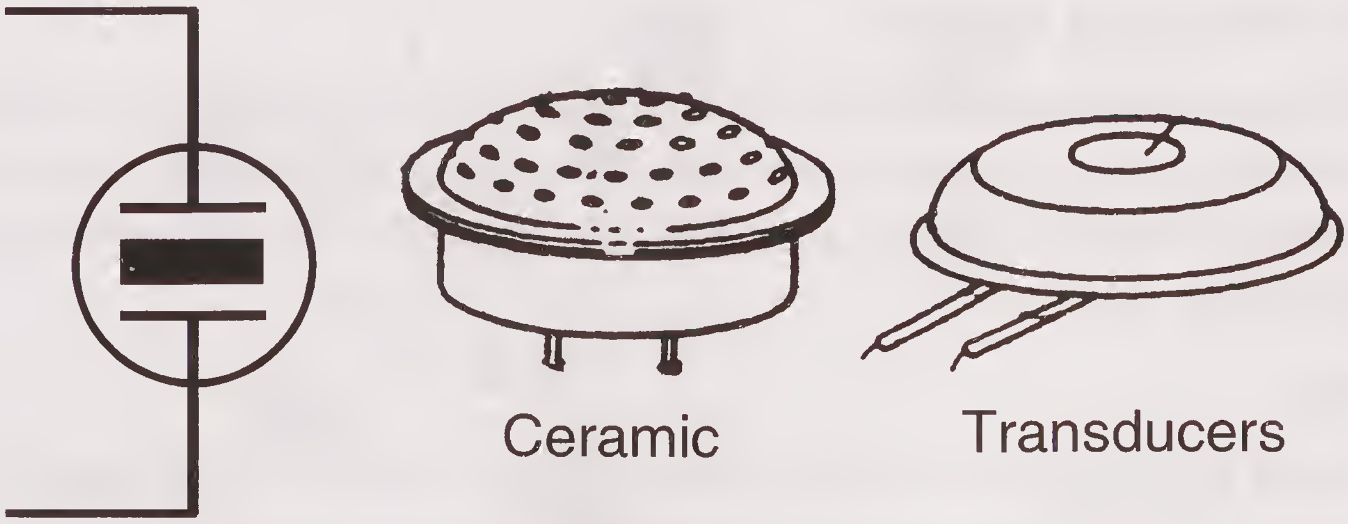

Figure 78

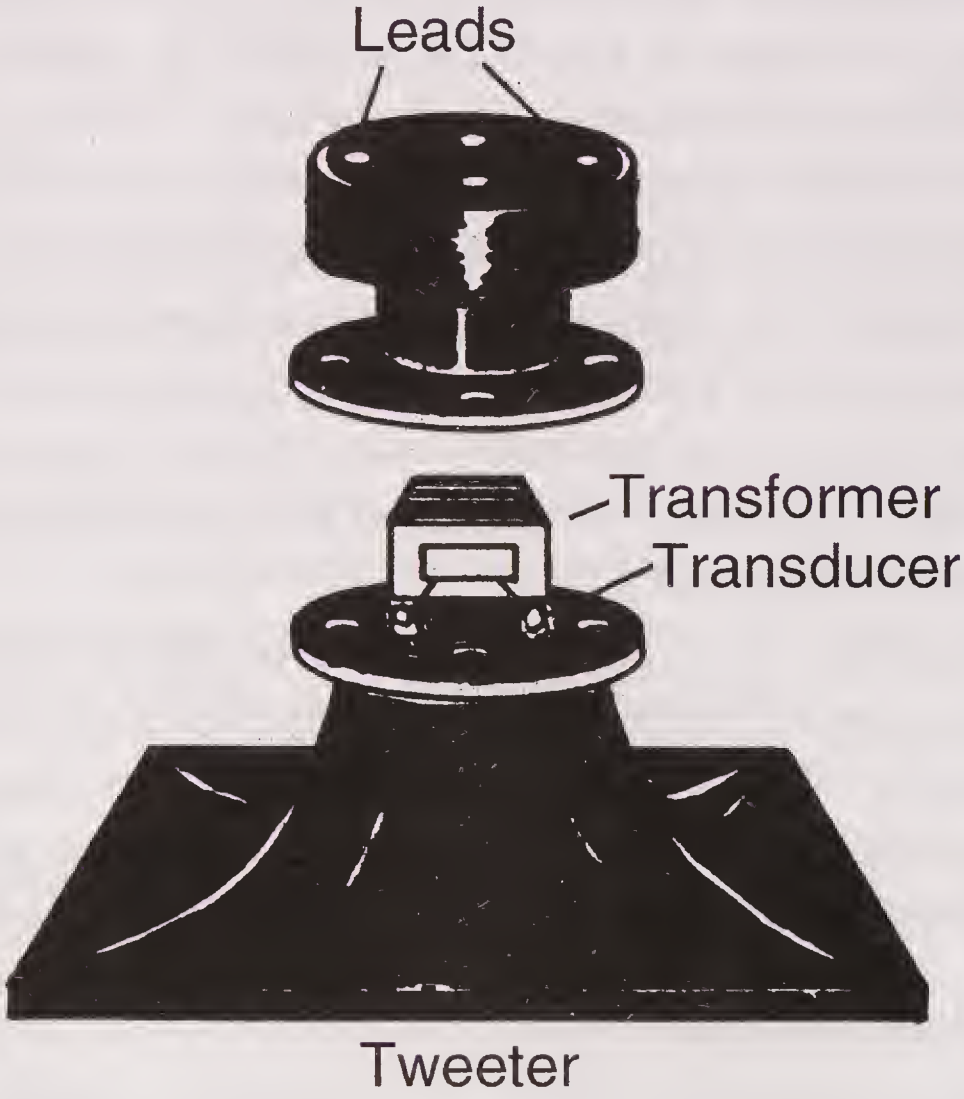
Specifications

Normally the piezoelectric components are indicated by a part number determined by the manufacturer. The quartz crystals are indicated by the frequency. They are high-impedance devices because the ceramic and the quartz are good isolators. In some cases, a drive circuit can be installed inside the component, such as in piezoelectric buzzers that include an audio oscillator. Piezoelectric tweeters, for example, include a small impedance match transformer to drive the transducer as shown in Figure 79.

Figure 79



Where they are found

Piezoelectric transducers are found in many applications. Quartz crystals are found in computers, watches, clocks, transmitters, and many other applications. The sound transducers are found in earphones, alarms, audio equipment, etc.

Testing

Quartz crystals are tested using proper circuits. The other transducers (ceramic) are tested using oscillators to drive them.

Semiconductors

Today, any practical application of electronics involves the use of semiconductors. Transistors, diodes, and their relatives form the great semiconductor family found in most any type of modern electronic equipment. With help, the electrician can understand how these components work and why it is important to start with some fundamentals of semiconductors.

Semiconductor Principles

According to modern physics all substances can be placed into one of three classes: insulator, conductor, and semiconductor. The main factor that determines in which of these classes the substance can be placed is the spacing of the energy band in its molecular makeup. Each energy band can hold two electrons at any time.

If the energy bands of a substance are filled, that substance cannot accept or donate electrons and so is an insulator. If there is one electron per band, or if the bands are so closely spaced that no gap exists between a filled band and an empty band, electrons can move through the material and it is a conductor. Now, the intermediate case: If small gaps exist between filled energy bands and vacant ones, the material acts like an insulator at low temperatures and becomes a conductor when the temperature rises. This is a semiconductor material.

Semiconductor types such as the silicon, germanium, gallium, and others have additional properties that make them ideal for use in electronics. They are elements that have four valence electrons each. Because of the valence bonds, they form a basic crystal structure as shown in Figure 80.

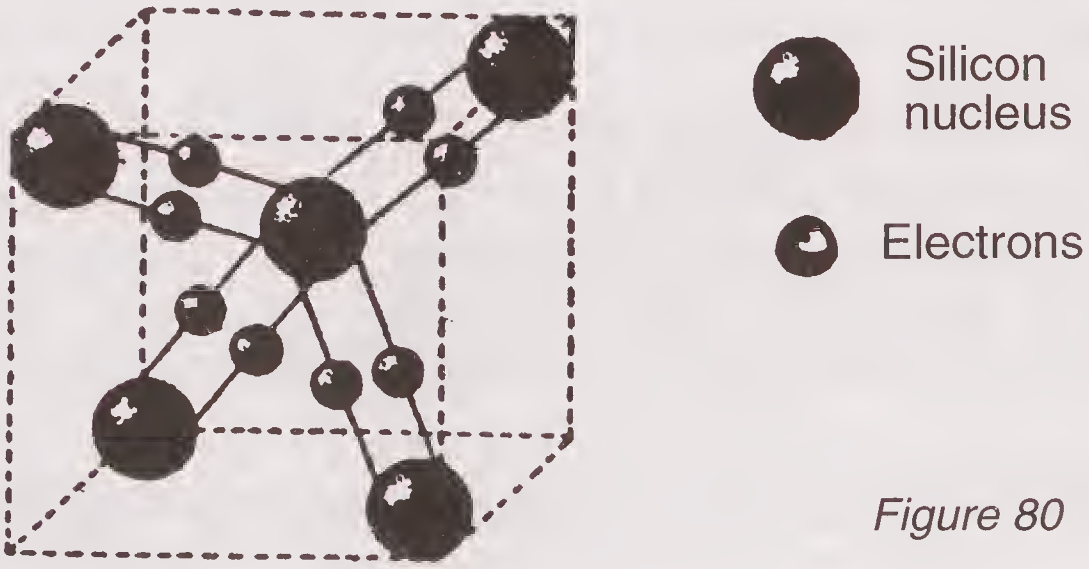


Figure 80

Any crystal is held together by the sharing of electrons between the atoms. In a conducting material the free electrons can drift through the structure under the influence of electric forces. On the other hand, in a semiconductor, availability of a path for free electrons to move along depends upon temperature. As the temperature rises, the path becomes available and high-energy electrons can move.

A crystal of semiconductor like silicon or germanium is composed of billions of atoms bonded together in an arrangement similar to the one shown in Figure 80. Crystals of pure semiconductors can be grown in laboratory conditions. They are called intrinsic materials and have no practical use. But, if we add small amounts of specific impurities to the intrinsic material, these impurities have the capability of joining right into the crystal structure at the atomic level.

There are two kinds of impurities resulting in different effects on the electric properties of the material. If a five-electron element, such as the antimony of boron and phosphorus, is added to the crystal, each of its atoms has one valence electron left over that finds no partner in the crystal structure. The net result is a surplus of electrons. Elements such as this are called donor substances and their presence provides an excess of negative charges. The semiconductor crystal is now called an n-type material.

Now, if we add a three-electron element, like aluminum, gallium, and indium, to the structure of the crystal, the net result is the presence of holes where the surrounding semiconductor atoms have electrons, but the impurity has no matching electrons to fill the valence bond. Elements with three electrons in the valence shell are called acceptors and form p-type materials when added to semiconductors.

Junctions

When crystals are being grown it is possible to add donor materials at one point and acceptors at others, producing single crystals composed of two different types of materials. The surface at which the type changes from one to the other is called a junction. The junction between semiconductor materials is the key of all events that made possible modern solid-state electronics. (As an aside, in early electronics circuits, vacuum tubes were the main elements. Inside these circuits, all events occurred in the vacuums. Today, the main elements of any circuit are semiconductors—solid materials—thus, the name "solid-state" electronics.)

Combining junctions and different semiconductor materials, engineers have created a large number of components that are found in every kind of electronic appliance. Let's take a look at the main types of semiconductor components, how they work, and where they are found.

Diodes

The first important electronic component of the semiconductor family is the diode. To understand how a semiconductor diode functions, look at what happens in a semiconductor junction such as the one described previously.

At a junction the surplus electrons of the n-type material diffuse across the junction filling the holes of the p-type material. This process is called combining and forms valence bonds that can no longer diffuse throughout the crystal. This means that in a small area, a depletion region is formed that is free of holes and electrons.

If, in a semiconductor junction, we apply a positive voltage to the n-type part of the junction, it tends to draw electrons out from the n-type material. At the same time, the electrons in the negative side of the power supply fill the holes in the p-type material. The net result is that the depletion region expands to the entire structure of the material. This situation prevents current flow. The diode is now reverse-biased.

If we reversed the applied voltage, the electrons would be forced away from the power supply toward the junction, and, at the same time, holes from the power supply forced to the junction. The electrical force involved in this process compresses the depletion region until it disappears. At this moment, the barrier is broken and the current can flow through the device. With germanium devices this occurs at about 0.2 V and with silicon devices at about 0.6 V. This way the junction is forward-biased.

The device formed by a single p-n junction is called a diode. Figure 81 shows what happens in the two described bias conditions.

(a) Reverse biased

(b) Direct biased

Figure 81

The practical semiconductor diode is formed by two pieces of semiconductor materials—n- and p-type germanium or silicon—placed inside an enclosure. The size of the materials is basically determined by the amount of current that they can conduct when forward-biased. Semiconductor diodes operate as one-way roads for the current and are found in a large number of electronic circuits.

Symbol and Types

The diodes are manufactured in different sizes and types according to their applications. Figure 82 shows common diodes and the symbol used to represent this component.

Figure 82

In (a) are germanium and silicon small-signal diodes that are used to handle low currents. In (b) are some rectifier diodes used in circuits where large currents are found.

Diodes are polarized components. Their position in a circuit is important. The identification of the poles is made using several resources. One method is placing the symbol and the component to correspond with the position of the poles and other is to use a strip or ring at the side of the cathode terminal.

Specifications

A. Reverse voltage: Since a diode represents an open circuit when reverse-biased, across the diode appears all the voltage of a circuit. The maximum voltage that a diode can be submitted to without being burned under these conditions is an important parameter to be considered in projects. This voltage is also abbreviated by Vrrm or Vr in data sheets.

B. Direct current: This is the largest current that can flow through the diode when it is forward-biased. It is also abbreviated by If.

C. Part number: The most common in real components is the manufacturer specification by a part number. In most parts of America, specifications of diodes are identified by the group “1N” followed by a number. So, types such as 1N914, 1N4148, and 1N4002 are common. In European specifications diodes begin with an “A” (for germanium) or “B” (for silicon) followed by a letter. For example, “A” for general-purpose diodes, “Y” for rectifiers, etc. A European part number might look like these: AA115, BA315, BY127, etc. Other manufacturers use proper codes to identify their diodes. Some examples are MR751 and P600D.

Where they are found

The diodes are used basically in functions such as detectors or signal clippers in audio and RF circuits or as rectifiers in power supplies.

As detectors, the electrician will find small diodes (silicon or germanium) in radio receivers, TV, remote-control receivers, computers, interfaces, wireless telephones, etc. As signal clippers, the diodes are used to convert an AC into a DC as shown by the diagram in Figure 83.

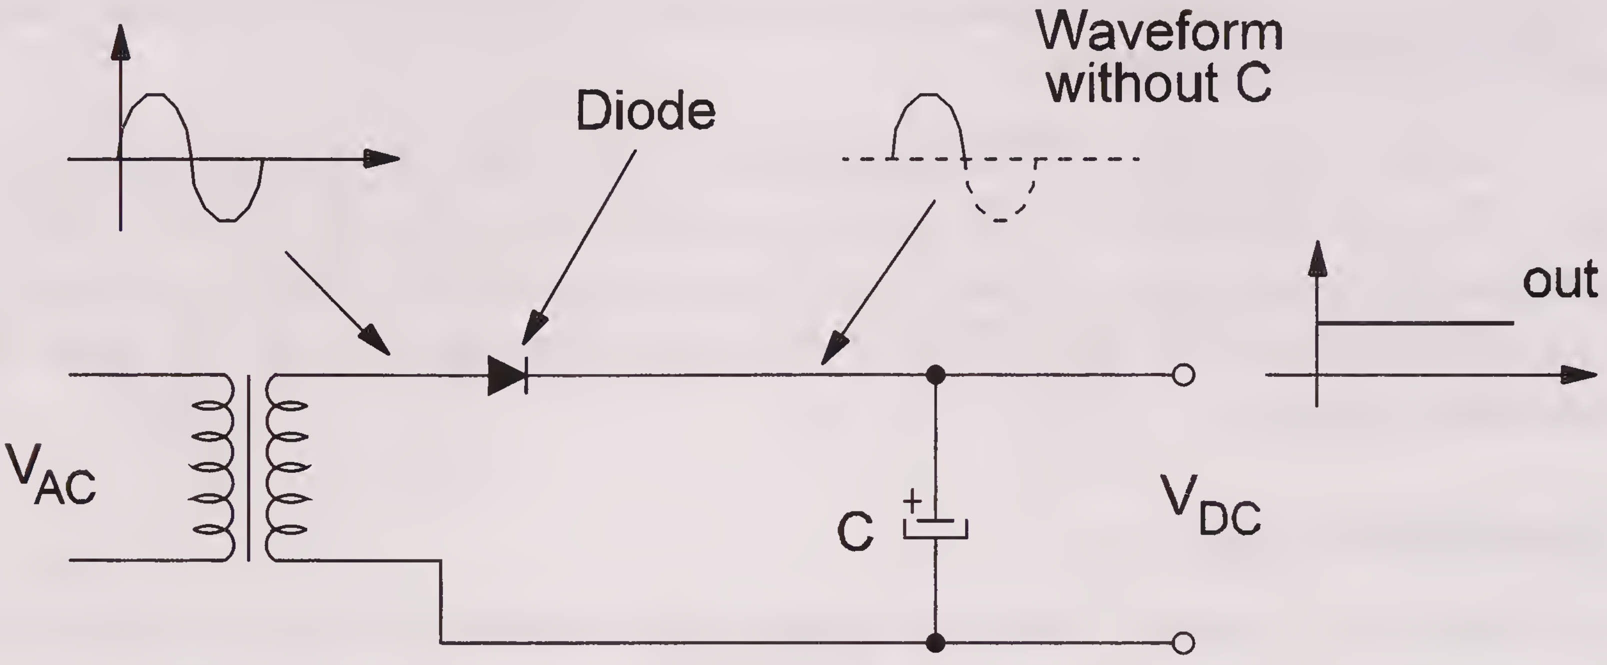

Figure 83

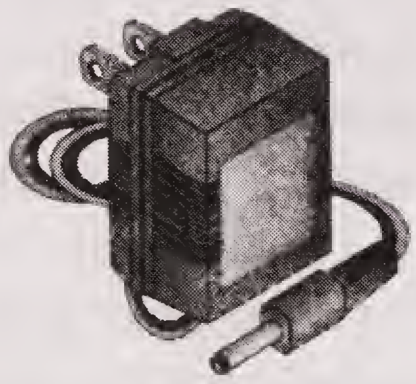

Figure 84

In this circuit, the diode conducts only the positive half-cycles of the AC voltage found in the secondary winding of the transformer. Filtering these positive pulses with a capacitor, a DC voltage can be placed at the output. Power supplies such as this are used to power small DC appliances like calculators, CD players, and transistor radios from the AC power line. Figure 84 shows an AC/DC adapter using an inside circuit like this.

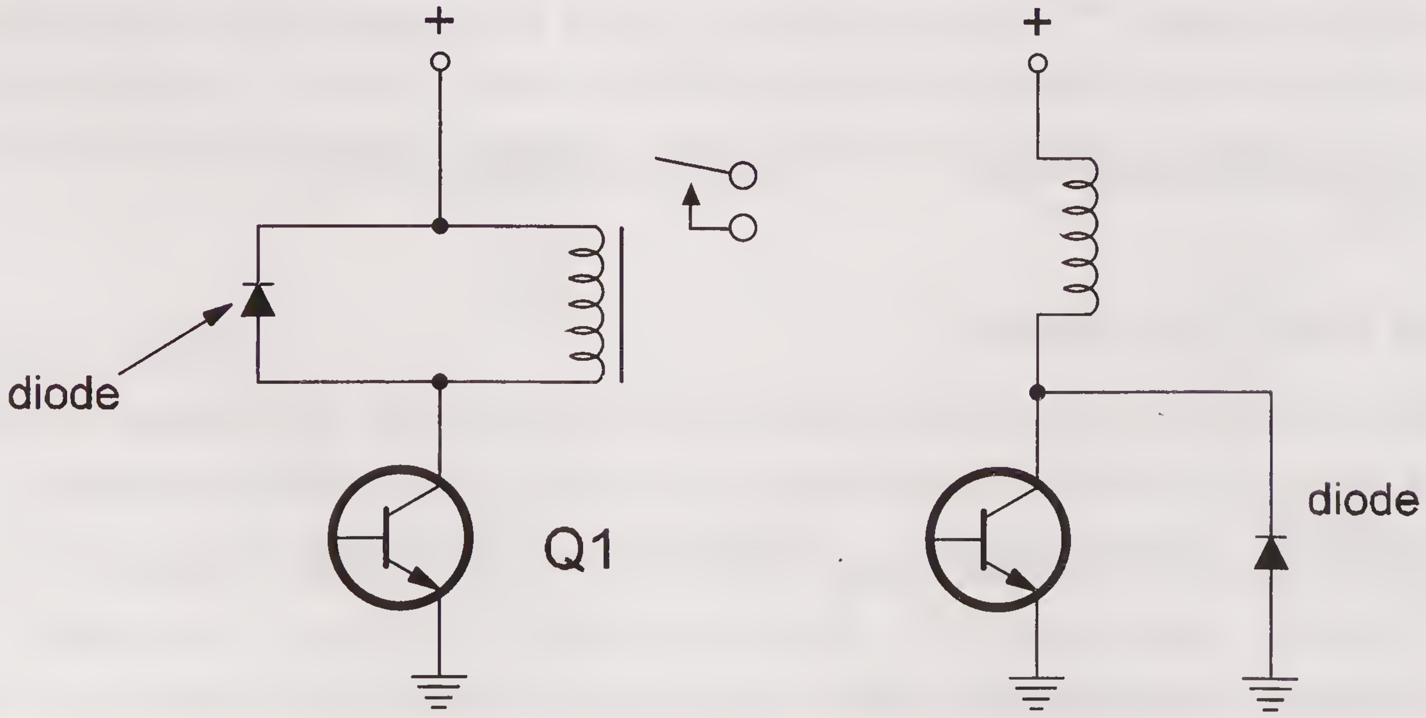

Figure 85

A third case to be included here, and one that is very important to electricians, is the use of a diode to protect semiconductors from voltage spikes generated when inductive loads are triggered. When a relay is open or a solenoid is turned off, it generates a voltage spike strong enough to damage the device used in the control circuit. The energy produced in this process can be absorbed by a diode wired in parallel with the load or with the control device as shown in Figure 85.

Testing

A diode can be tested using a common multimeter or any continuity tester. Adjust the multimeter to a medium resistance scale and place the probes in the diode's terminals. When biased forward the diode must present a low resistance (between 100 and 5000 ohms) and when reverse-biased a high resistance is read (above 1,000,000 ohms). A diode presenting low resistance when reversed and forward-biased is shorted, and the one that presents a high resistance of the two measurements is open. An intermediate read when reverse-biased (between 100,000 and 500,000 ohms) indicates a diode presenting losses.

Zener Diodes

When a diode is reverse-biased a limit value to the applied voltage exists. Beyond this limit, called breakdown voltage, the diode becomes a conductor and is destroyed as shown by the graphics in Figure 86. As shown by the curve, the diode, if not destroyed, tends to keep the voltage constant across its terminal in a range of currents.

Zener diodes are special diodes that are processed to have a nondestructive breakdown at a specified value of the reverse voltage. They are also called avalanche breakdown diodes or breakdown diodes.

The action of a zener diode can be used in many electronic applications. In fact, if you apply a reverse voltage to a zener diode its reverse resistance changes in a way to maintain constant voltage across it. This action can be used in voltage regulation, to clip signals, and many other applications.

Zener diodes are found in many types and sizes in electronic equipment. For the electrician, it is important to know how a common diode can

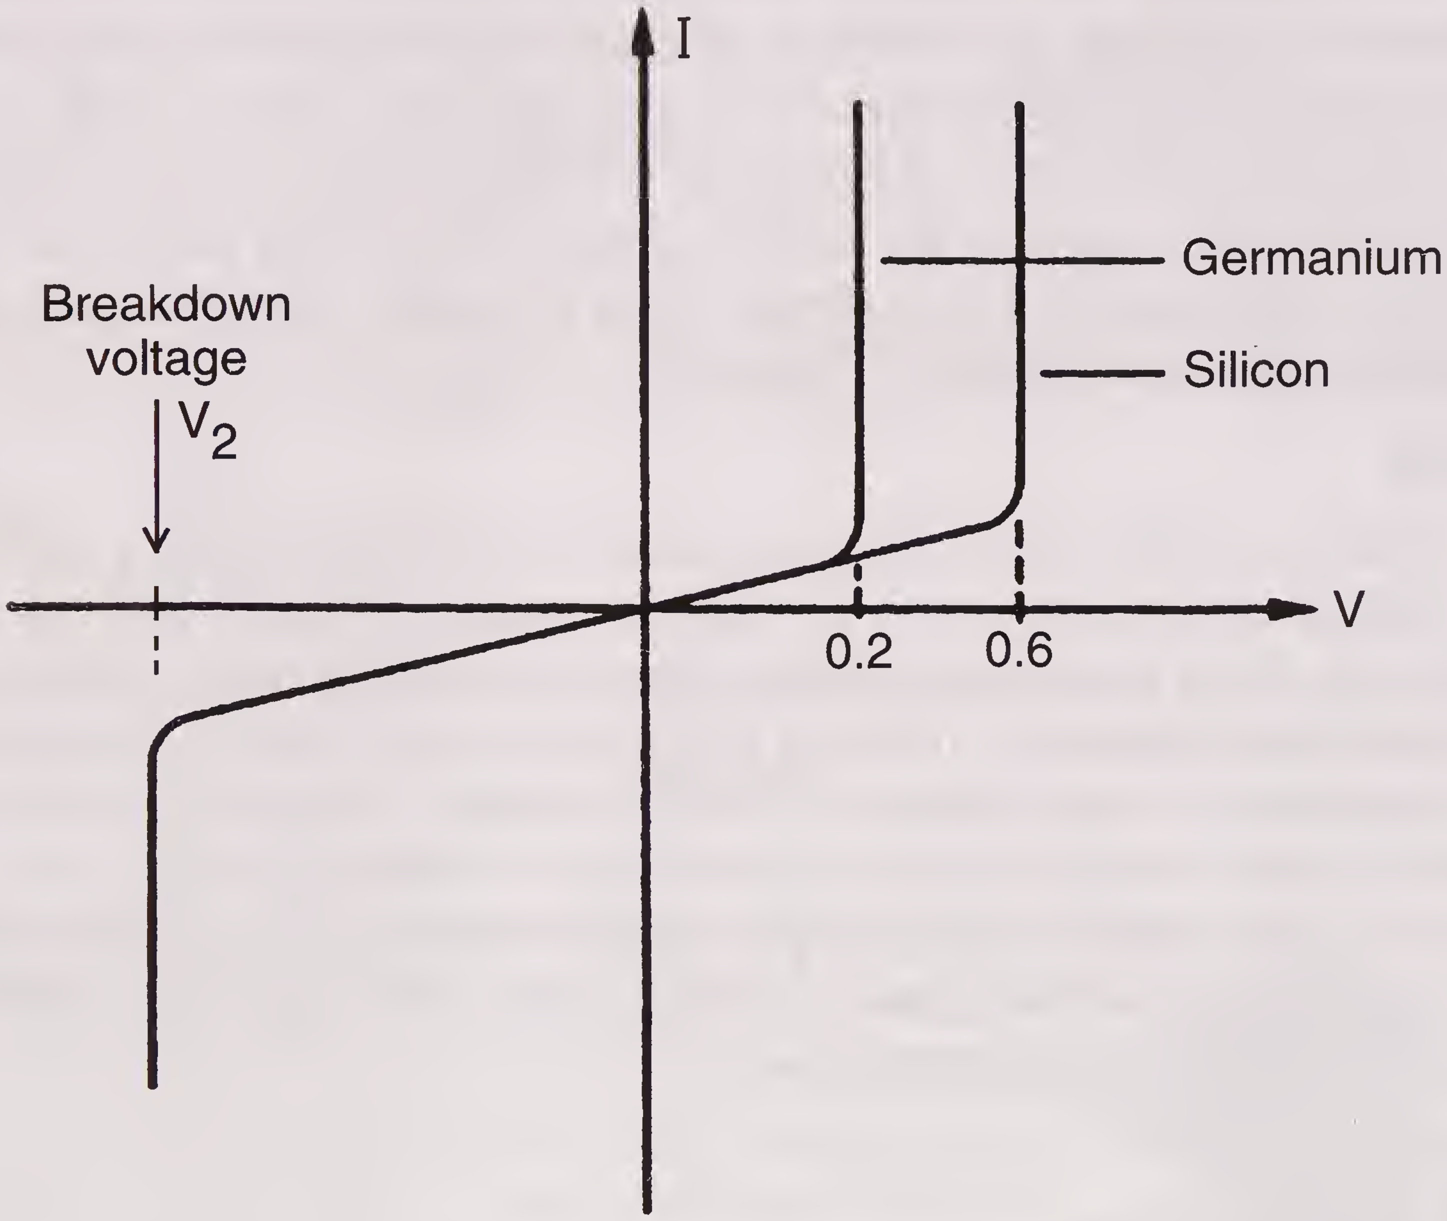

Figure 86

differentiate from a zener diode. Although they look the same, the way they are positioned in a circuit, the identification number, the symbol in the schematics, or any other specific information may differ.

Symbol and View

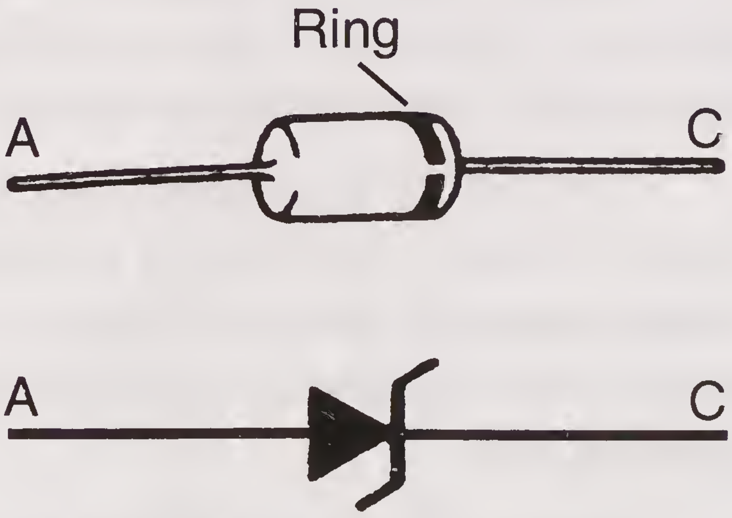

Figure 87

Figure 87 shows the symbol and a view of a common zener diode as the electrician will find them in electronic circuits.

Since zener diodes are polarized components, there must exist some identification for the poles in the component. It is usual to place a ring or strip at the cathode side of the component.

The size of the zener diode is determined by the amount of current it can control or the range of currents in which the diode can keep the voltage constant.

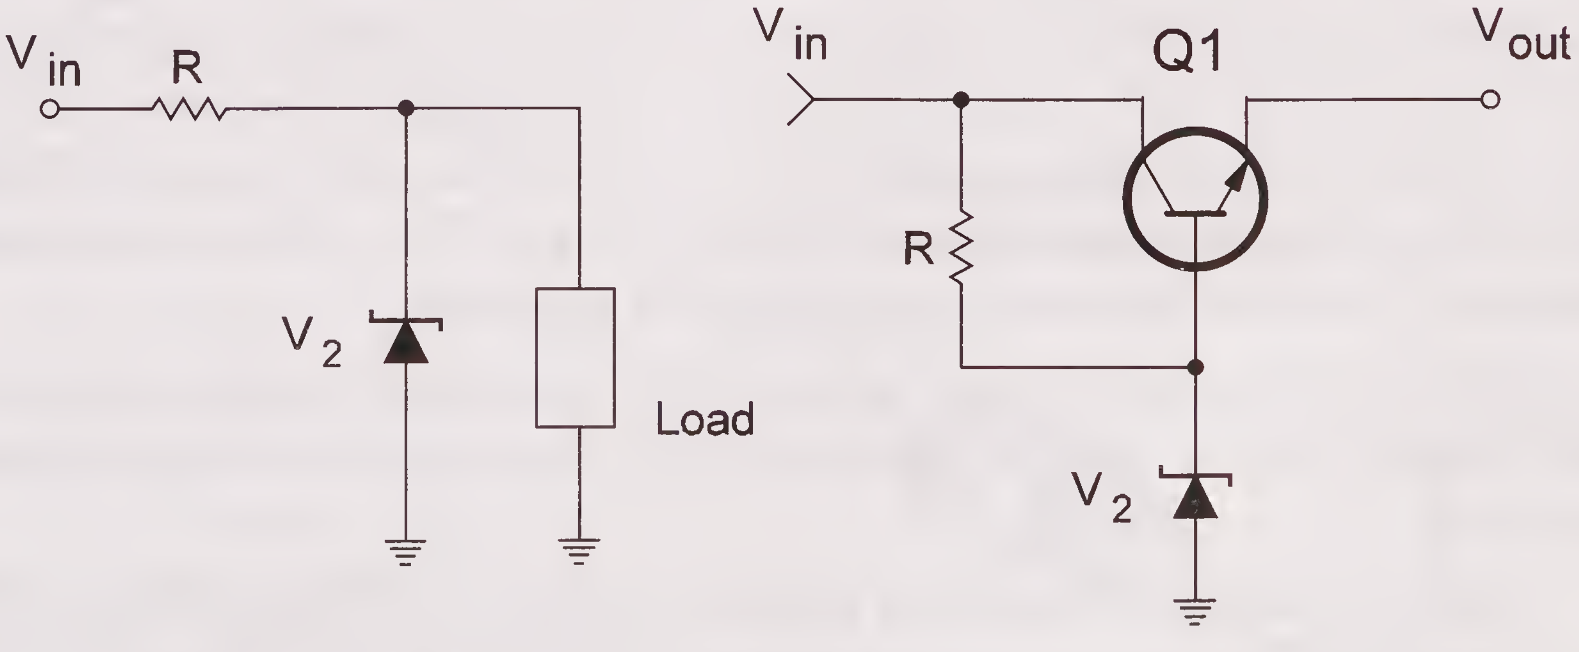
Specifications

The zener diode manufacturers used to indicate their products by a part number. So, a handbook with the main types or another kind listing of their characteristics is fundamental in order to know what they are. When replacing a zener diode without having the part number it is important to know two specifications:

1. Zener Voltage: the breakdown voltage or the voltage the device is designed to keep constant when reverse-biased. Zener diodes are made with voltages in the range between 1 and 2 volts to more than 100 volts for typical types found in domestic and industrial appliances.
2. Dissipation Power: the maximum amount of current flowing across a zener diode during operation. The zener voltage gives the dissipation power or the amount of electric power that the device can convert in heat. The larger the size of the device, the larger the dissipation power. Typical values are between 400 mW and 10 W.

Where they are found

Figure 88 shows some circuits where zener diodes are found. In (a) is a simple voltage divider in a simple power supply where the zener diode maintains a constant voltage in the load plugged into the output. A more



(a) (b)

Figure 88

complex power supply is shown in (b) where the transistor controls the amount of voltage applied to the load. This voltage is kept constant by the action of the zener diode placed at its base. How the transistor works in a circuit like this is discussed when explaining how transistors work.

Other applications of zener diodes include voltage reference voltage in instruments and signal clipping circuits.

Testing

The simplest way to test a zener diode uses a common multimeter on the lowest resistance scale. The zener diode is tested as a common diode; when forward-biased it must present a low resistance (100 to 10,000 ohms), and when reverse-biased it must present a high resistance (above 1,000,000 ohms). This test doesn't show anything about whether the zener voltage is altered or not. It is important to remember that this test is valid only if the zener voltage of the tested device is lower than the voltage used by the multimeter in the probe.

LEDs

Light Emitting Diodes or LEDs are special diodes that produce light when forward-biased. The current flowing to their PN junction causes the emission of visible light or infrared radiation. Researchers discovered that any semiconductor diode produces infrared light when conducting a current, the beginning of the LED's principle of operation. Advancing with the research, they found that special semiconductor materials, such as gallium when doped with special impurities like those of arsenium and indium, could result in diodes that emitted visible light when forward-biased. From this appeared a new class of diodes—the LEDs—that were primarily designed to act as light sources or infrared sources.

LEDs are monochromatic light sources because the light produced in their junction has a narrow spectral band as shown by the graphics in Figure 89.

LEDs are made of materials such as Gallium Arsenide (GaAs) doped with impurities like indium or phosphorus, in a degree that gives them their light emission characteristics or other spectral characteristics. The impuri-

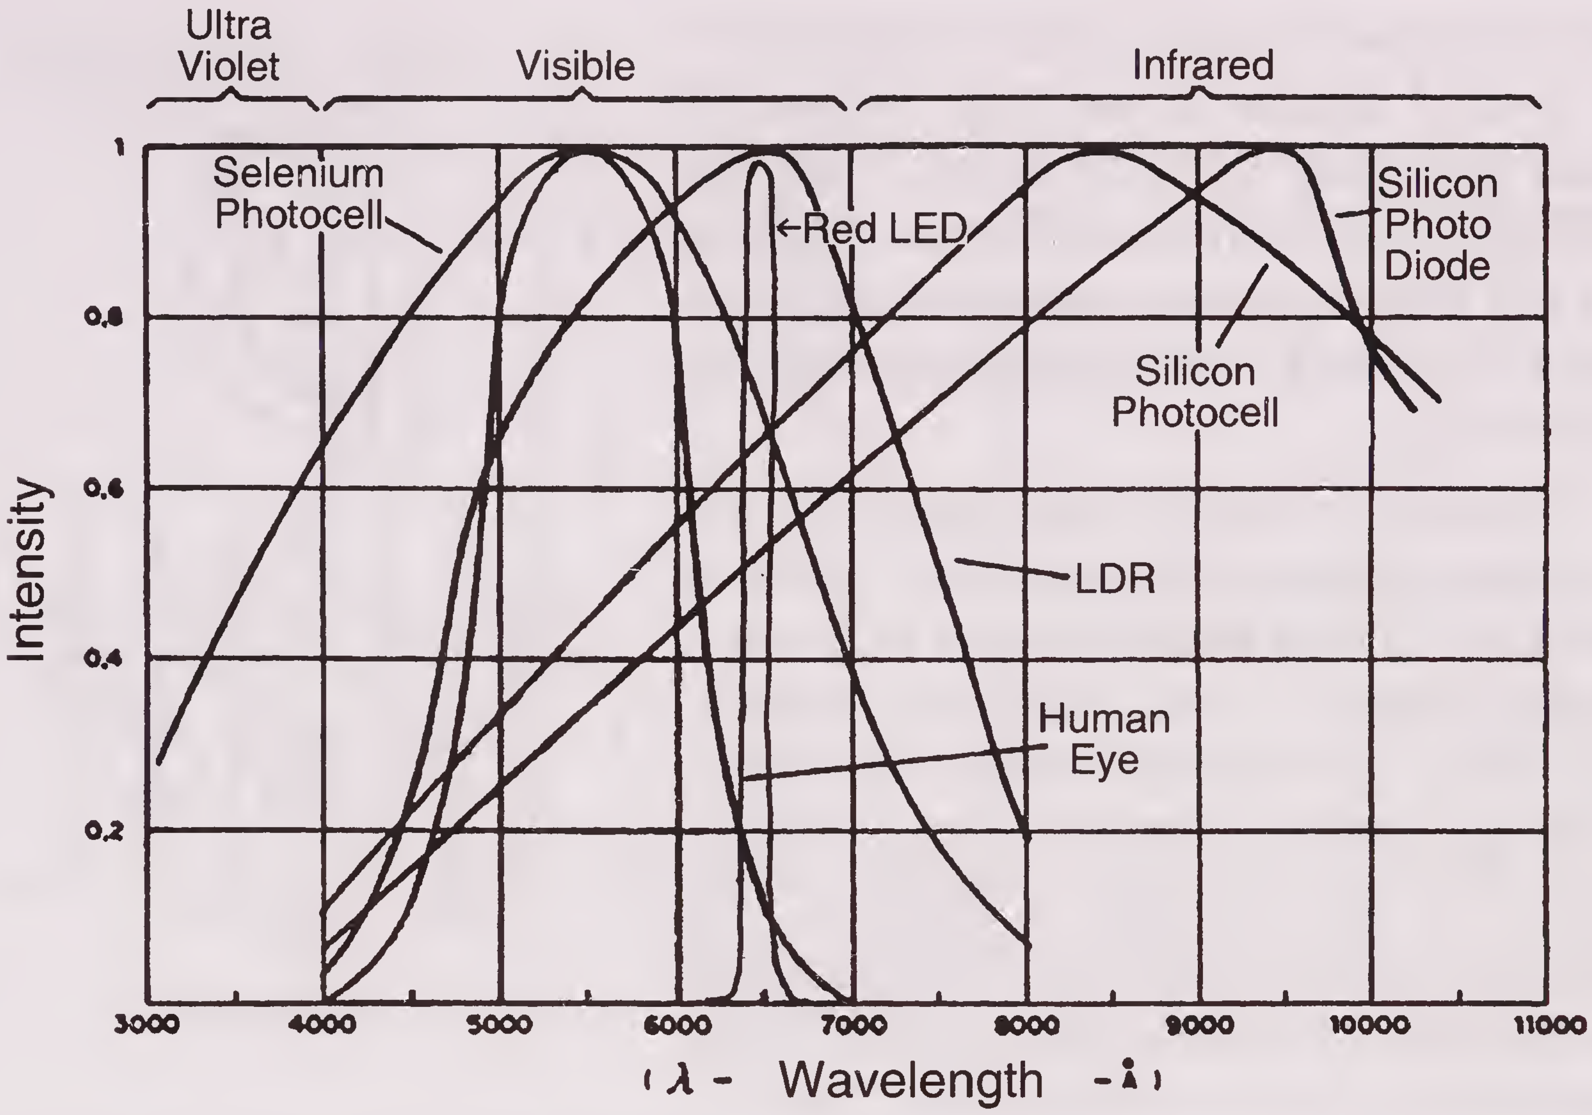


Figure 89

ties also determine the minimum voltage for forward-biasing an LED that makes it conductive. Red LEDs become conductive with 1.6 V; yellow LEDs need about 1.8 V, and blue and green LEDs need more than 2.0 volts.

Symbol and View

Figure 90 shows the symbol used to represent LEDs in schematic diagrams and in the same figure is the main type of LED.

The different types and sizes depend on the color of the light and also the application. IR (Infrared) LEDs are used in remote controls and as sensors. LEDs can also be placed to form an eight in a

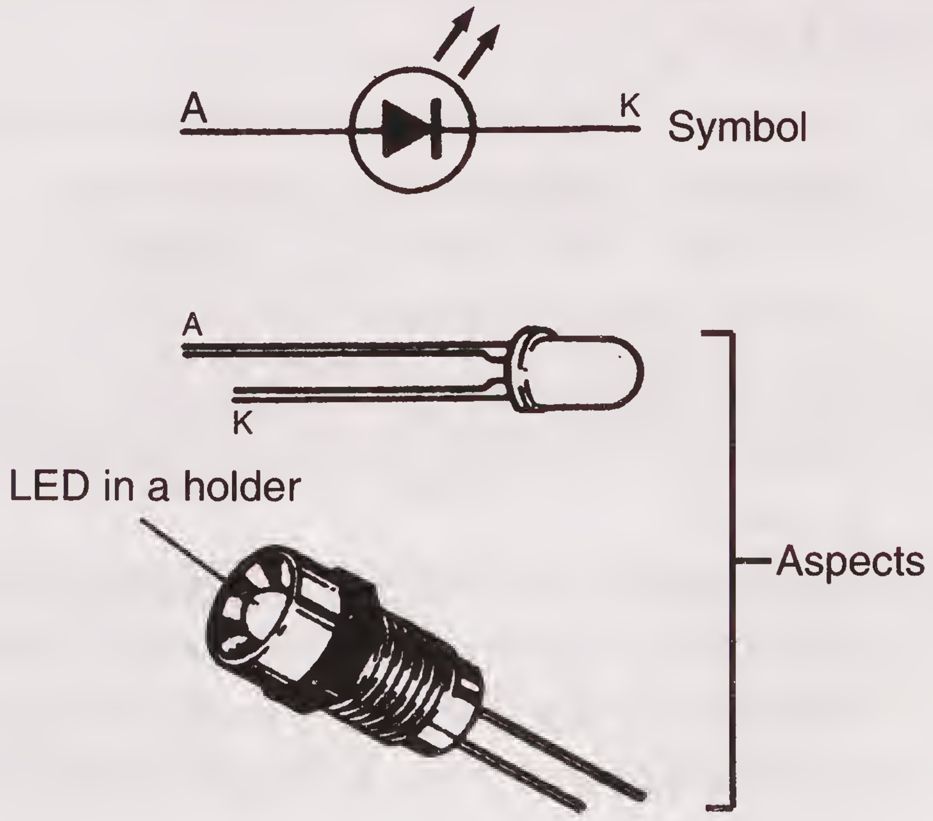

Figure 90

seven-segment display. Each segment in this kind of display is an LED. Figure 91 shows how they are connected. If all the LEDs are wired with the cathodes together they are called common-cathode displays. Figure 91 shows a seven-segment display using LEDs.

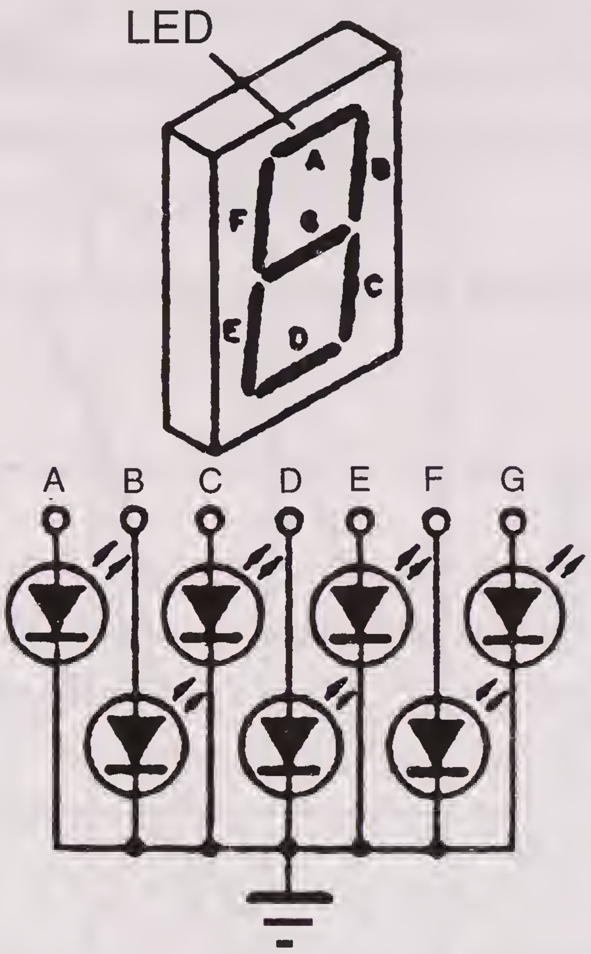

Figure 91

It is also possible to make a white LED by putting three LEDs on a chip with the basic colors (Red-Blue-Green or RGB) and powering them in a way that the combination of their light results in white. According to the amount of current in each of these LEDs, it is also possible to produce any color of the visible spectrum. The LEDs, like the diodes, are polarized components. Normally they are encapsulated in clear or colored plastic with a small, flat space or notch near the cathode lead.

Specifications

LEDs are specified by a part number provided by the manufacturer. But, catalogs also indicate other characteristics including the size, forward-bias voltage, maximum current, and the wavelength or color of the produced light.

A. Current: The amount of current flowing through an LED determines how much light or IR it can produce. Typical values are between 5 and 100 mA. This current is important to help the designer calculate the current limiting resistor (see how to use an LED).

B. The forward voltage: This is the voltage at which the LED becomes a conductor. It is the minimum voltage that can be applied to the LED in a circuit.

C. Wavelength of the light: The wavelength can be expressed in angstroms (Å) or nanometers (nm). 1000 A = 100 nm. The visible spectrum extends from about 4000 to 7000 angstroms or 400 to 700 nm. Figure 92 shows the placement of the emission curve of some common LEDs according to their colors.

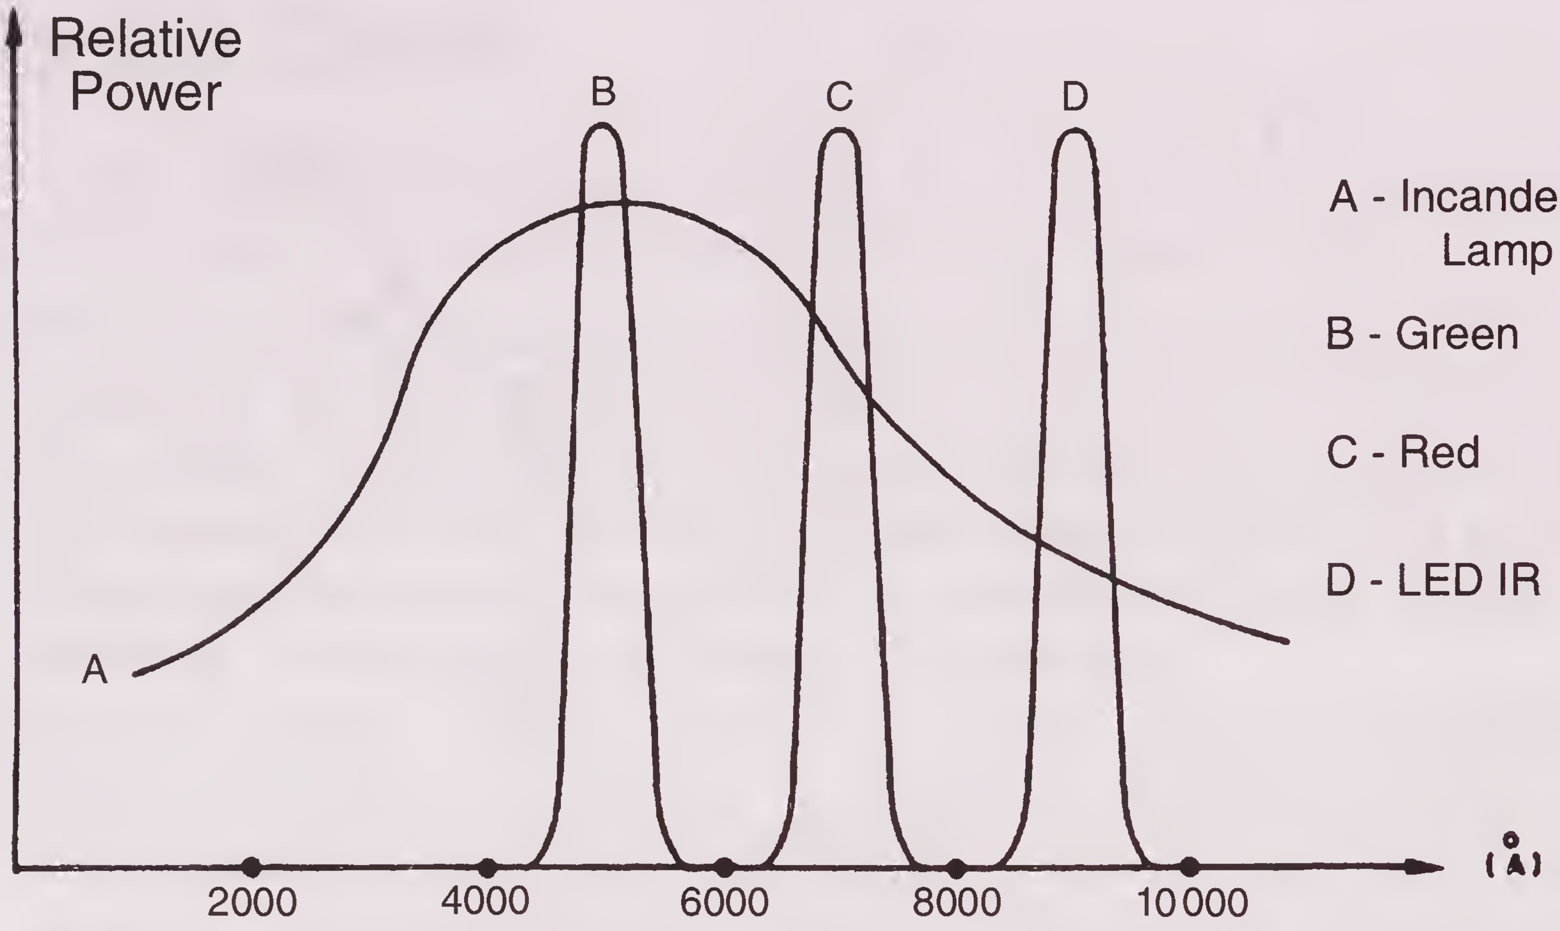

Figure 92

Where they are found and used

The main applications of LEDs in electronic equipment are as indicators. The electrician will find LEDs in panels of electronic, and even electric, devices indicating a function or displaying a number or even a figure as in the seven-segment types. The seven-segment displays also indicate the result of operations in calculators, the hours and minutes in clocks, time, and other information in microwave ovens, etc.

Infrared LEDs are found in remote controls of a variety of equipment like TVs, VCRs, automatic doors, car alarms, etc.

When using LEDs it is important not to exceed the maximum allowable forward current. Current is best limited by a resistor placed in series with the LED and the power supply as shown in Figure 93.

The resistances of the series resistor can be calculated by subtracting the LED's forward voltage from the power supply voltage and dividing the result by the desired current in amperes. For example, if we want to power a red LED at 20 mA from a 6 V power supply the math is as follows:

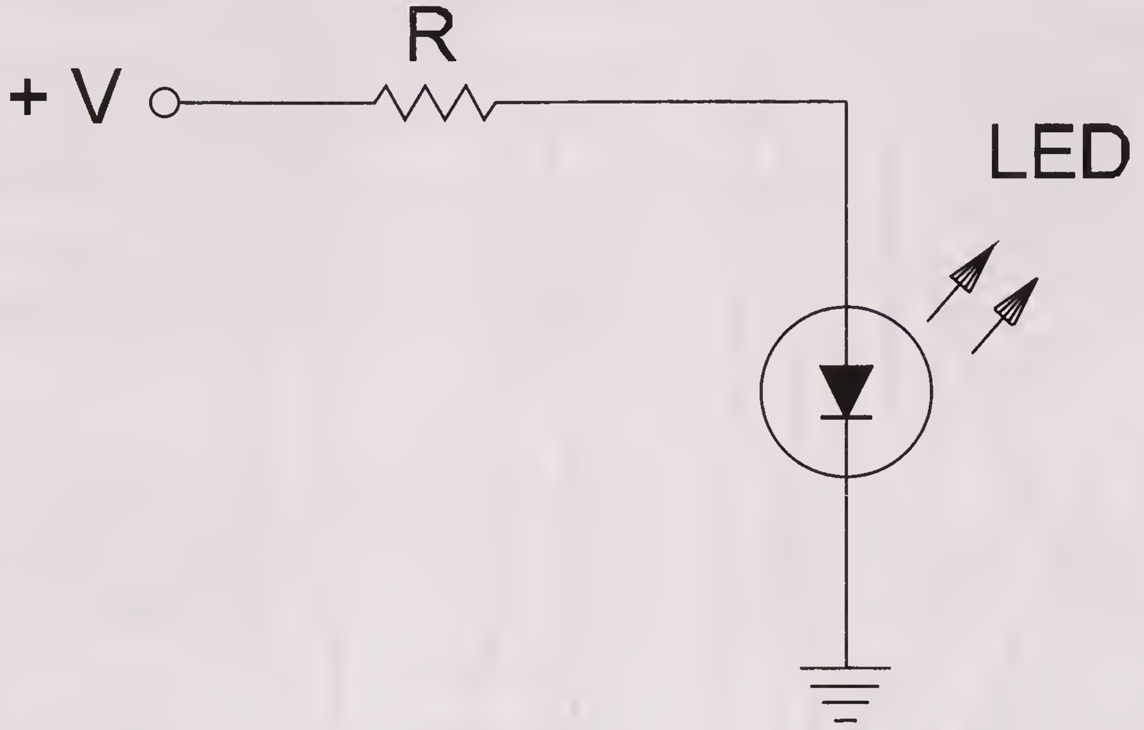

Figure 93

Subtracting 1.6 V (the forward voltage of a red LED) from 6 V results in 4.4 V. Dividing the result (4.4 V) by the current 20 mA (0.02 A) results in 220 ohms.

Testing

Never test an LED by plugging it into a power supply without a series current-limiting resistor. It can be burned. The best way to test is by plugging it into a 3 V supply (2 AA cells) in series with a 100 ohms to 270 ohms resistor as shown in Figure 94. The LED will glow if it is good. To check whether an infrared LED is producing radiation, some kind of detector must be used.

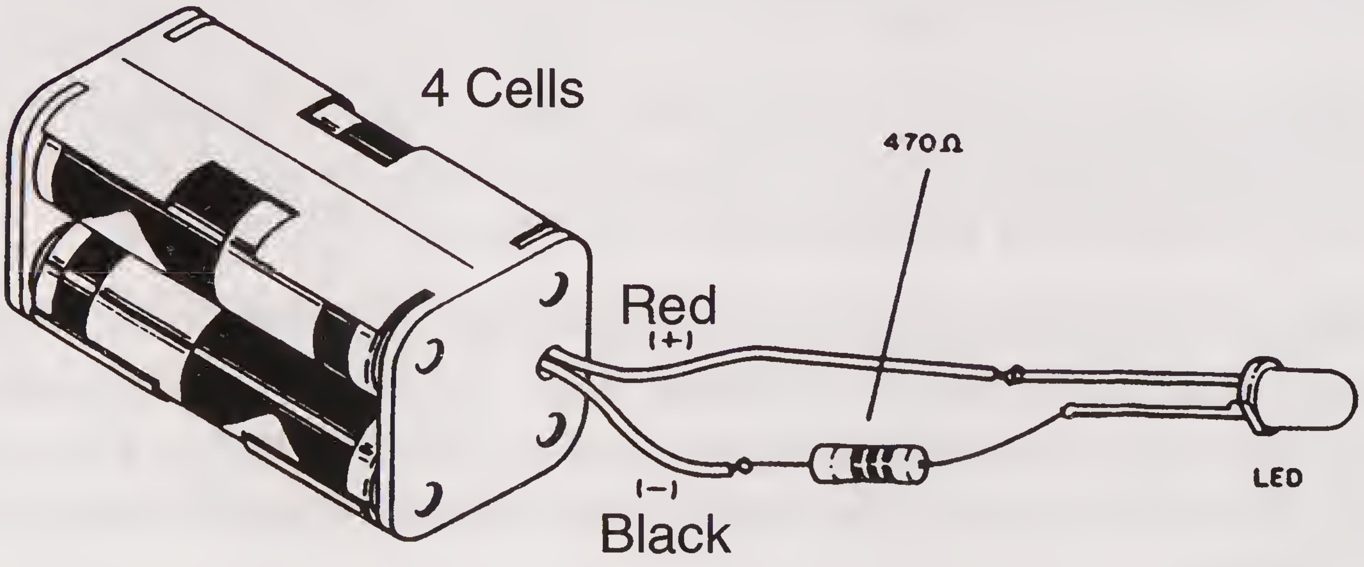

Figure 94

Special Diodes

The electric properties of a PN junction can be used in devices other than the LEDs. Many special diodes can be included in a list:

A. Photodiodes: Exposing the PN junction of a diode to light and reverse-biasing it, the current flow will depend on the amount of light falling on the junction region. Charge carriers are liberated by the light, increasing the reverse current. The semiconductor material with a PN junction is then manufactured in transparent enclosures and used as light or IR sensors. These devices are called photodiodes.

B. Tunnel diodes: Tunnel diodes are special devices presenting the characteristic of a curve in a negative resistance region. This characteristic makes the device ideal to produce very high-frequency signals. The tunnel diode is used as UHF (Ultrahigh Frequency) and SHF (Superhigh Frequency) oscillators and detectors in many applications like radar detectors.

C. Varicaps or varactors: When reverse-biased, a diode can be compared with a capacitor. The junction region is the dielectric and the PN materials with the plates as shown in Figure 95.

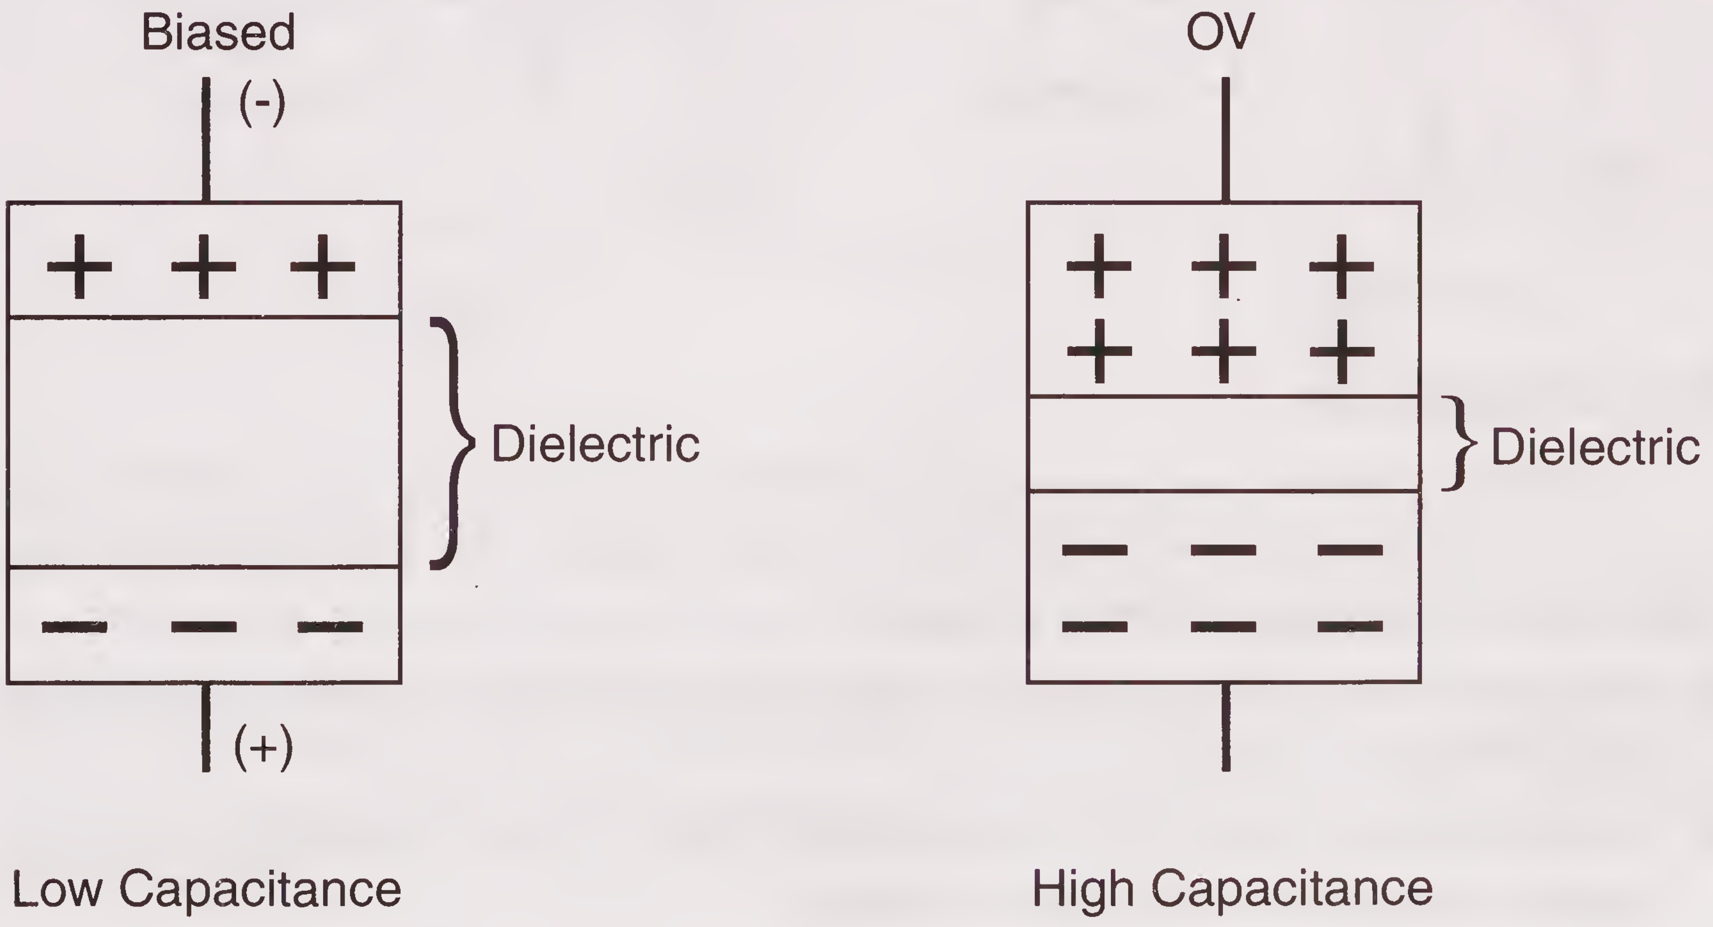

Figure 95

Depending on the applied voltage, the size of the junction region can be altered. If a low voltage is applied, the charges keep the junction region thinner. But, by increasing the voltage, the charges make the junction region fatter. This means that by applying a voltage in a reverse-biased diode we can control its capacitance.

Special diodes with large PN junctions (to get more capacitance) are fabricated to be used as variable capacitors controlled by voltages. They are called variable capacitance diodes or Varicaps. These capacitors are found in tuning circuits of TVs and radios.

Symbols and Types

Figure 96 shows the symbols and types of some special diodes. Remember that these diodes are also polarized components and some mark is used to the identification of their poles.

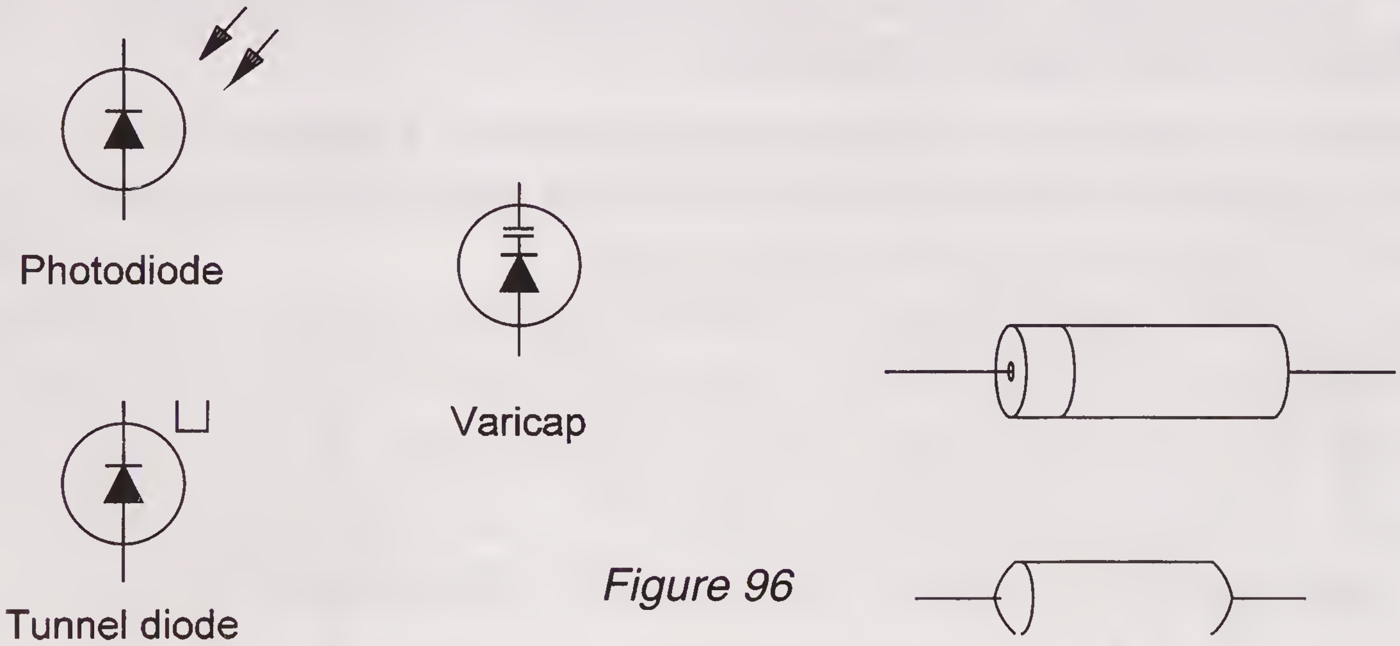

Figure 96

Specifications

Special diodes are generally indicated by a part number determined by the manufacturer. Depending on the application, it is important to know some specifications of these diodes.

- Photodiodes have, as a specification, the response curve (the wavelength of light they can "see").
- Tunnel diodes have, as a specification, the highest frequency they can operate and also the tunnel voltage.
- Varicaps can be specified by the capacitance range they can present between zero and a nominal voltage.

Testing

The test of many special diodes cannot be done using simple procedures. We can detect if a photodiode, tunnel diode, or varicap diode is shorted or open, but not determine any other important characteristics of these components, such as whether they are operating, for example.

Bipolar Transistors

Bipolar transistors are the most important of the semiconductor devices. They are formed by three pieces of semiconductor materials, forming two junctions in the same crystal with a structure such as the one shown in Figure 97.

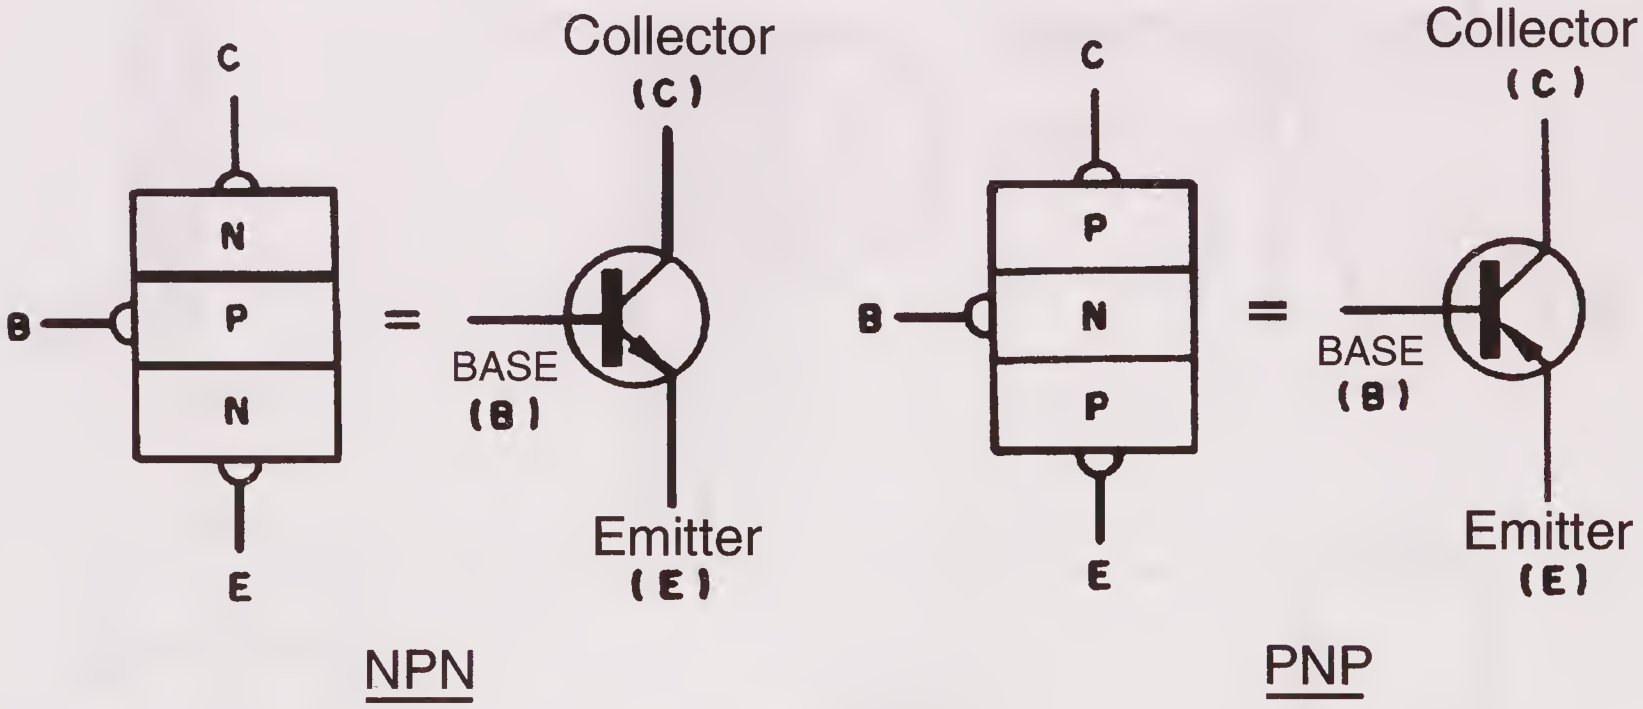

Figure 97

Although the structure can be compared with two diodes placed back-to-back, the fact that they are in the same crystal means the events occurring at one junction can influence those at the other. The possibility of control makes the transistor one of the most important of all the electronic components.

According to the type of semiconductor, the structures result in two types of transistors—NPN and PNP.

To each piece of semiconductor material, terminals or leads are placed corresponding to the three regions: base (B), emitter (E), and collector (C). The transistor forms a structure with special electric properties; a current flowing between emitter and collector can be controlled by a current flowing through the base. When connecting the positive pole of a battery to the emitter and the negative to the collector of an NPN transistor, because the two diodes are reverse-biased, no current can flow.

But, if the base-emitter junction is now forward-biased in a manner that a small current can flow, this current will cause a high current to flow between collector and emitter as shown in Figure 98.

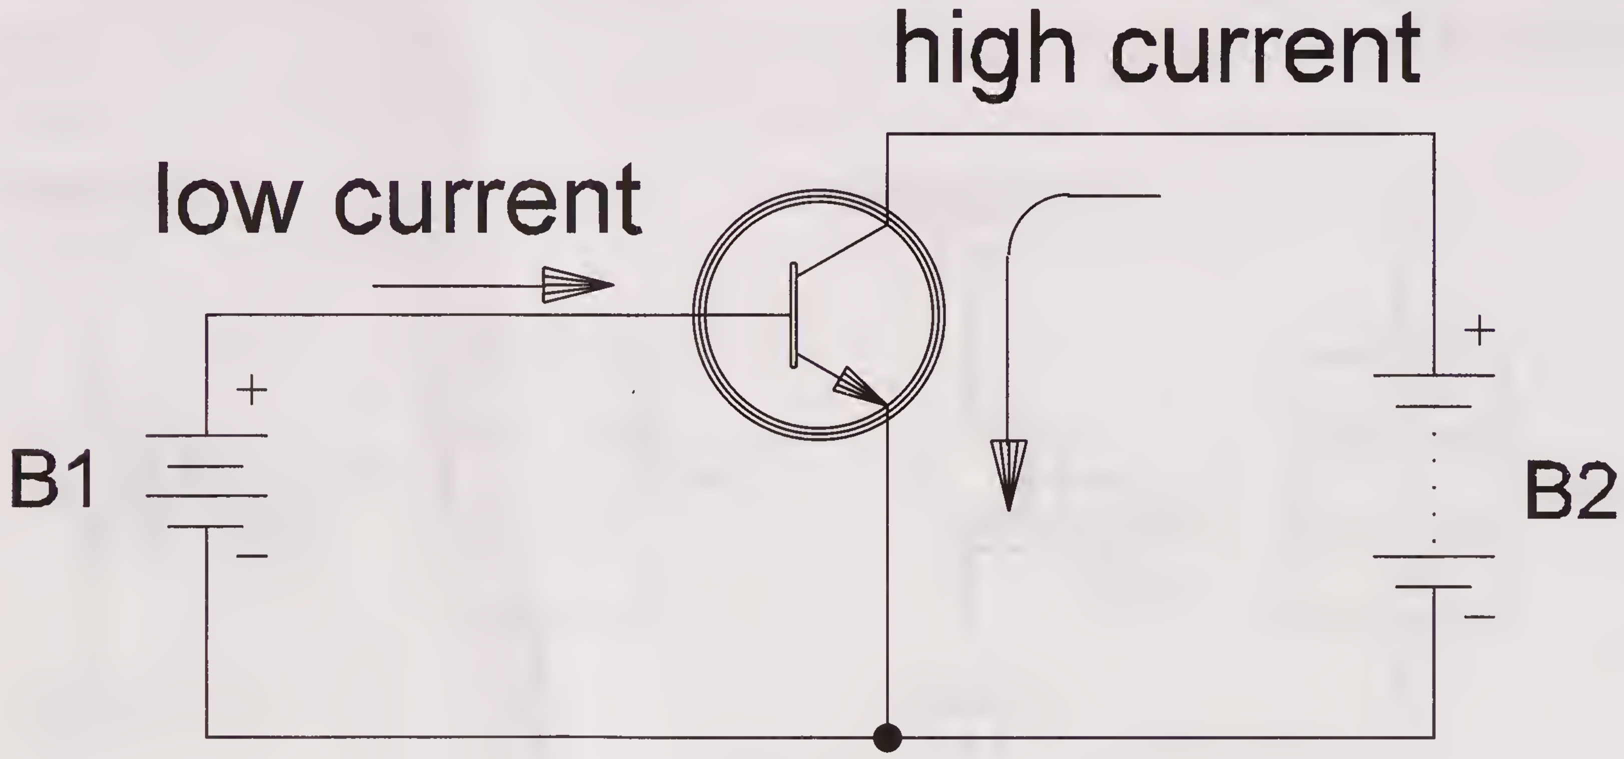

Figure 98

In other words, a small current flowing between the base and the emitter of a transistor can control a large current between collector and emitter. If a 1 mA current through the base causes a collector current of 100 mA, the transistor has a "gain" or "amplification factor" (also called Beta) of 100. This means that the transistor can be used to amplify signals or to act as an electric switch.

Based on the applications, we can find transistors of different sizes and formats with gains ranging from 5 to 10,000. Today there are millions of types of transistors identified by a manufacturer part number. Only with heavy, large “databooks” or “transistor manuals,” could the characteristics of all the main transistors be found.

In applications involving transistors, the use of about 100 or 200 main types with characteristics that are near most of other existing transistors is normal. These transistors can be found easily at a dealer, and in emergency cases, can be replaced with any other.

Symbol and Type

Figure 99 shows the symbols used to represent the two types of bipolar transistors and the common types of these devices. Notice the arrow in the emitter points outside in the NPN type and inside in the PNP type.

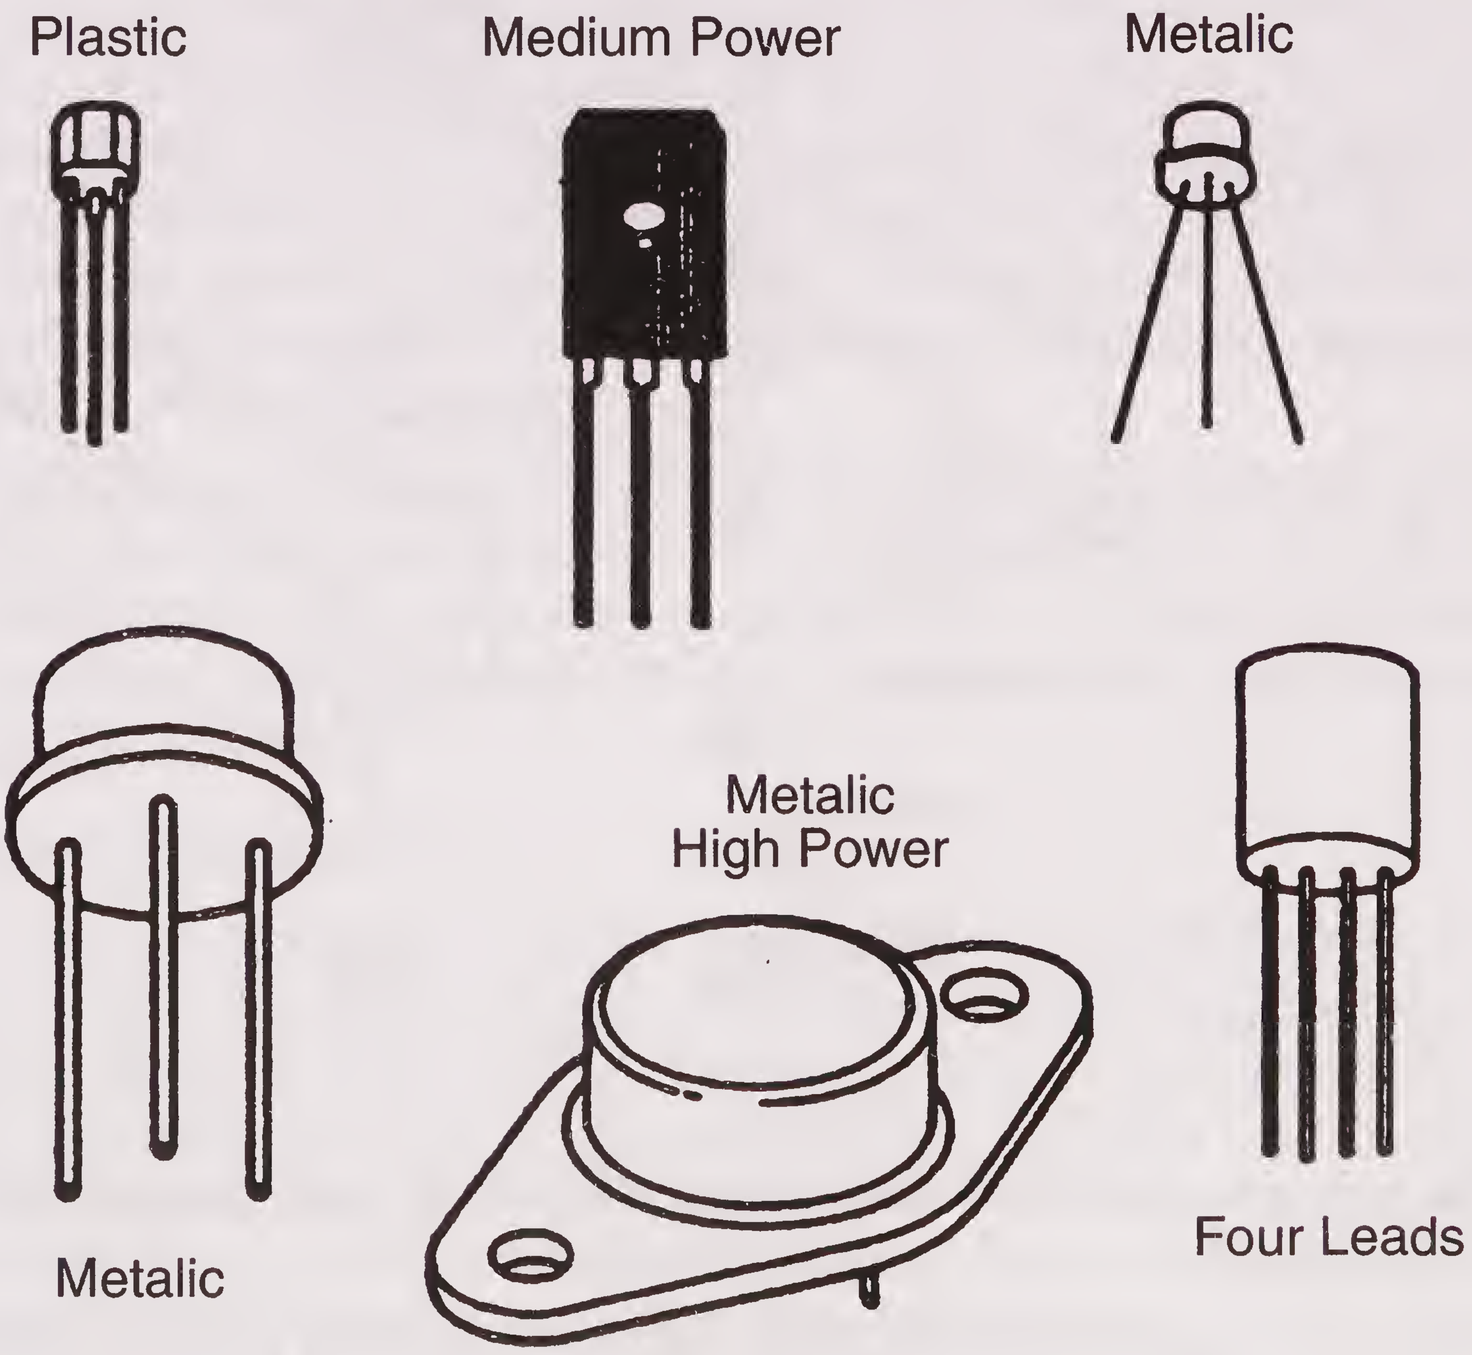

Figure 99

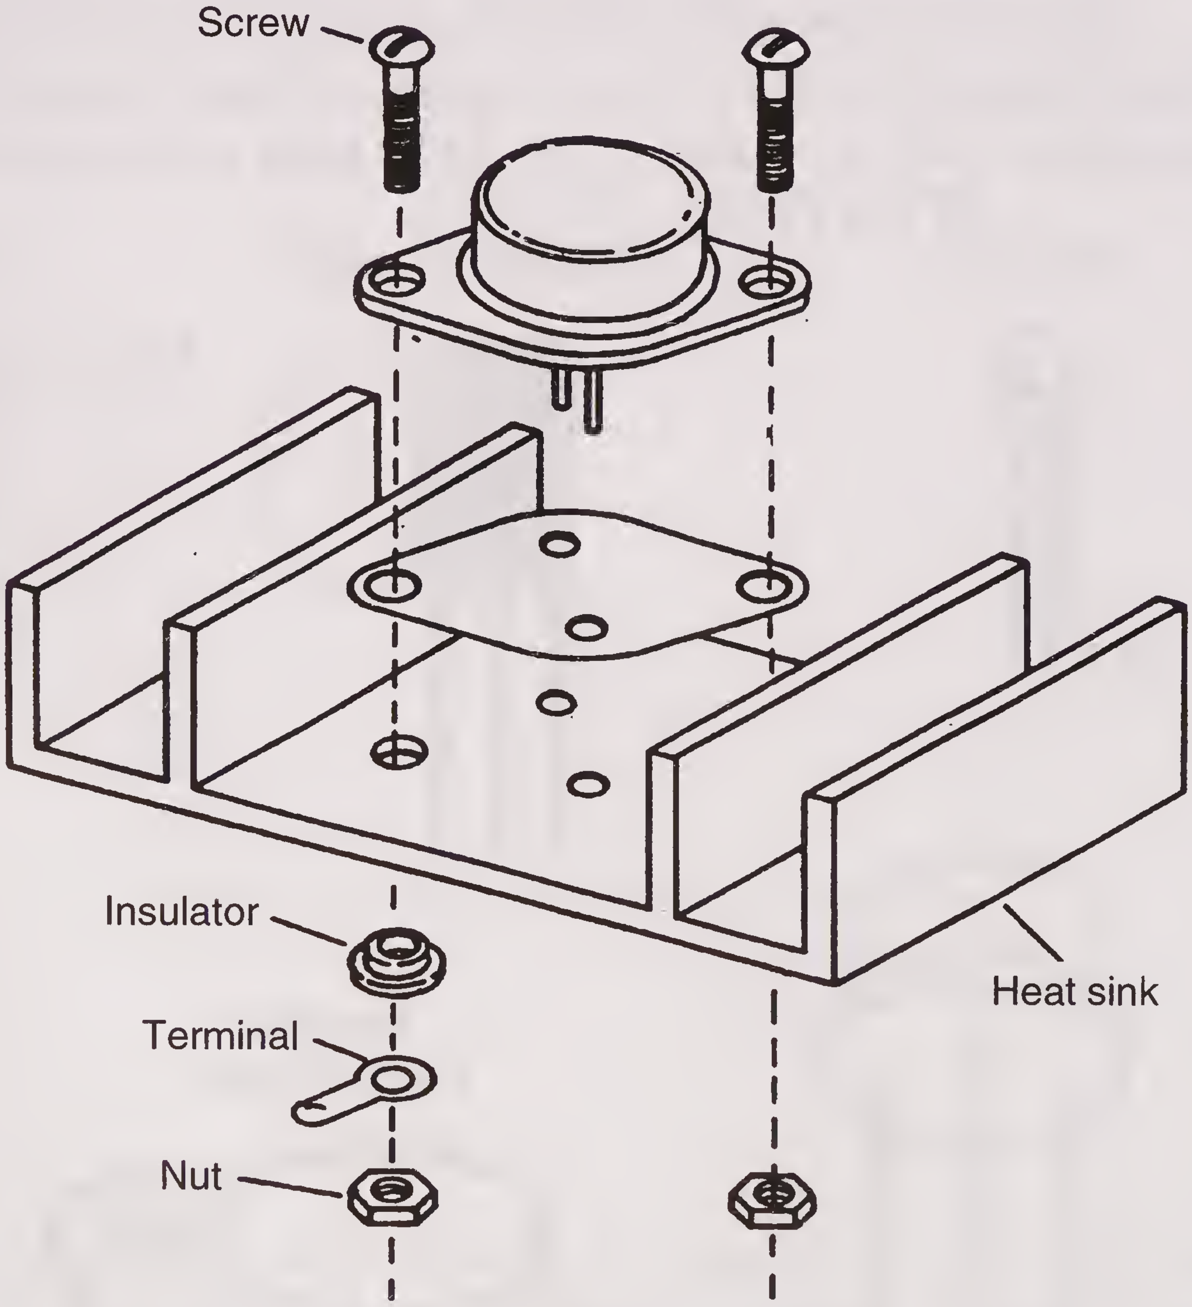
The size of a transistor is determined by the amount of current it can control. Transistors called general-purpose transistors or low-power transistors are small and encapsulated in plastic as shown in (a). Medium-power transistors are shown in (b). These transistors have a hole or another way to place them in heat sinks. In (e) is a high-power transistor that is mounted in a large heat sink. In (f) is a four-lead transistor. The fourth lead is the case acting as screen.

Figure 100 shows a high-power transistor like the one shown in (c), mounted on a heat sink.

Figure 100



These transistors produce a large amount of heat when operating with large currents.

The main problem the electrician has when working with transistors is the identification of the terminals or leads (emitter, collector, and base). Many special codes and marks are used for this task such as flat spaces, shafts, marks, color points, and others. With the specific information about one transistor, it is possible to know which terminal does what. Otherwise, using the multimeter is also a possibility to make identification by measuring the resistance between the terminals.

Specifications

Besides the size and type (NPN or PNP), the bipolar transistor can also be classified according to the application. The basic groups according to use are:

A. Low-frequency or audio: Low-frequency or audio transistors are components intended for use in applications where the signals are in the audio band or below some hundreds of kilohertz as in audio amplifiers, power supplies, etc. They can handle low-frequency signals such as the ones found in small amplifiers and the audio stage of radios.

B. High-frequency or RF (Radio Frequency): High-frequency transistors are devices specially intended to operate with signals ranging from some megahertz to gigahertz. They are found in radios, TVs, remote controls, wireless telephones, etc., in the stages where the high-frequency signals are present. They also can be found in sizes according the power to be handled.

C. Switching: Transistors that perform this action are used as switches in high-speed circuits. They are used to turn devices on and off in many applications. They can also appear in low-, medium-, or high-power versions. They are found in inverters, logic circuits, digital instruments, digital controls, etc.

Other specifications

The manufacturers indicate the transistor by a part number. With the part number, an electrician can find all the electric characteristics of the device needed to know what it does in a circuit. This is especially important when replacing a transistor because it is possible to find an equivalent or replacement type. The equivalent is a transistor with another part number, either from the same or another manufacturer, but with all the characteristics as the original to replace it in an application.

It is very important to remember that a transistor that is equivalent to another one in application can't be equivalent in another application or circuit!

The main electrical specifications of a transistor are:

A. Maximum voltages: Vce(max) is the maximum voltage that can be applied between collector and emitter. Vceo(max) the same, but with open base. Vcb(max) is the maximum voltage that can be applied between collector and base. Vcbo(max) the same, but with open emitter. Veb(max) is the maximum voltage that can be applied between base and emitter. Vebo(max) the same, but with open collector. In some case the absolute values can be specified as Vc, Vb and Ve.

B. Maximum currents: The most important current in a transistor is the collector current. It can be specified as Ic or If (max).

C. Maximum power: When conducting a current, the transistor generates heat that can be transferred to the air. The maximum amount of heat produced by a transistor is given by its maximum dissipation power. These specifications are given in watts. Small transistors dissipate power in the range between 50 and 500 mW. High-power transistors have power specification above 100 W. The parameter is indicated by P or Pd in the datasheets of transistors.

D. Gain: A small current forced to flow by the base element causes a larger current to flow between emitter and collector. The number of times the collector current is larger than the base current is the gain of the transistor or beta factor (β). If a 1 mA current in the base of a transistor causes a 100 mA current between emitter and collector the gain of this transistor is 100. Normally, the transistor has a specification range of gain or minimum gain. For example, the transistor 2N3905 has a gain range between 50 and 150. The gain also can be indicated by a hybrid parameter named hFE, which is equivalent to the beta factor.

E. Transition frequency: The gain of a transistor falls when working with high-speed signals. But, there is a frequency where the gain falls to unit. This means that in this frequency, a variation of 1 mA in base current causes a variation of 1 mA in the collector current, and the transistor cannot operate as an amplifier. The output current is the same as the input current. This frequency is called transition frequency or fT.

Working with transistors

The electrician who is not very experienced with electronics sometimes can be confused when working with transistors. Millions of types and too many characteristics to observe when trying to replace one are the main factor of this embarrassing situation. It is even more aggravating when one considers that they have three terminals, not just two as the others.

How are the transistors used? How do you test a transistor? How do you find an equivalent? How do you know how they work? How do you know which is the base, collector, and emitter leads?

As the transistor is one of the most important of the electronic components in any electronic device, more information will be provided on this component later.

How the transistors are used

Figure 101 shows how a transistor is used in the two basic operation modes (linear and saturated). In (a) the load is placed between the power supply and the collector of an NPN transistor. The resistor in the base determines the amount of base current. This resistor is called the biasing resistor. When closing S1 the base current causes the current to flow through the load.

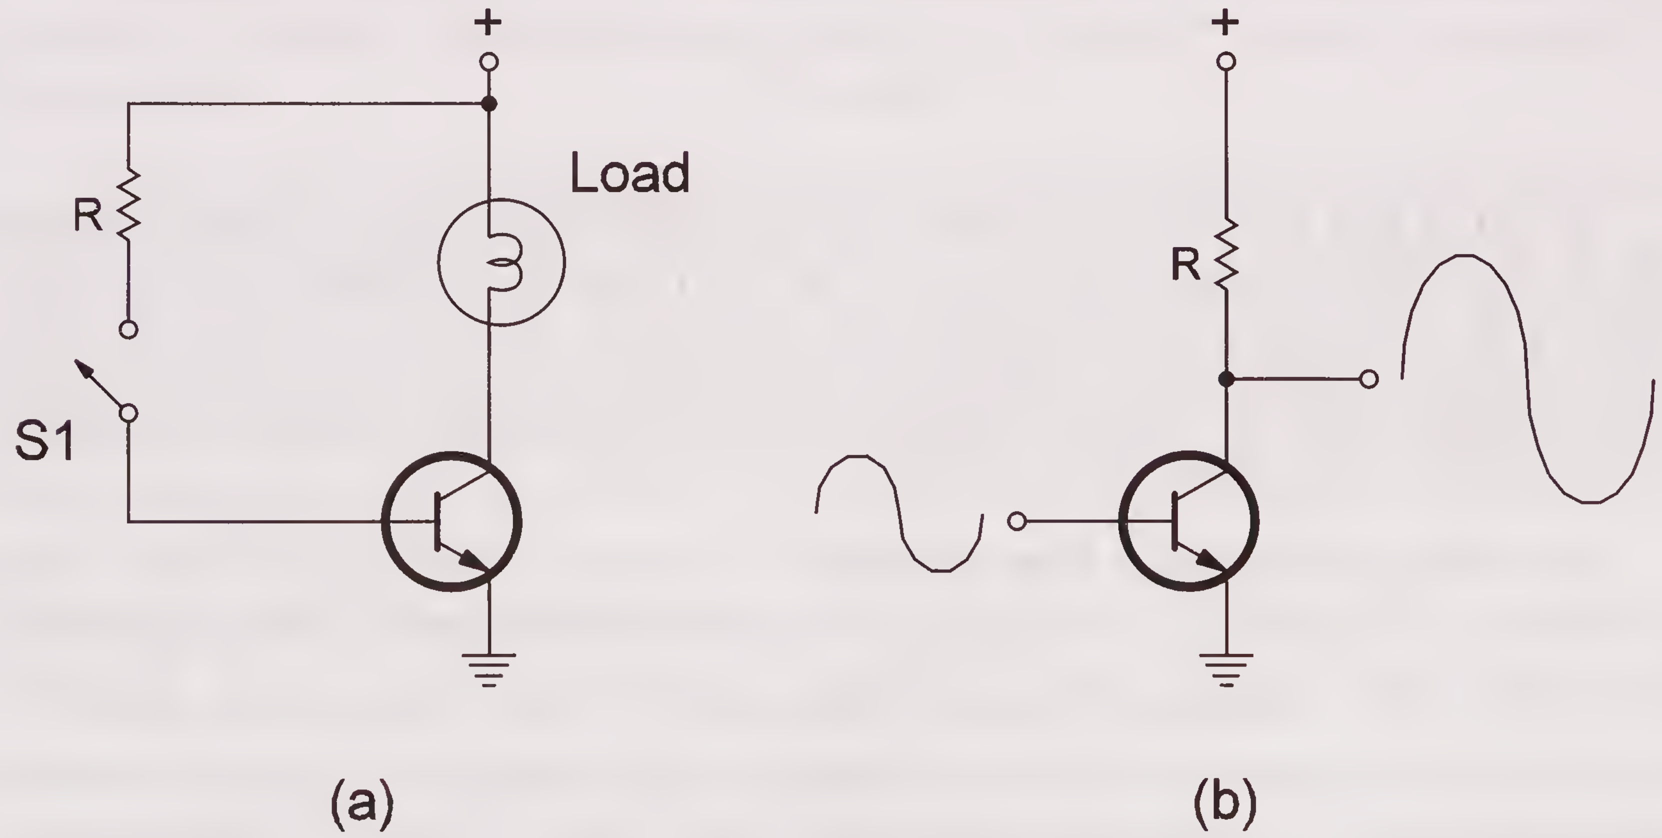


Figure 101

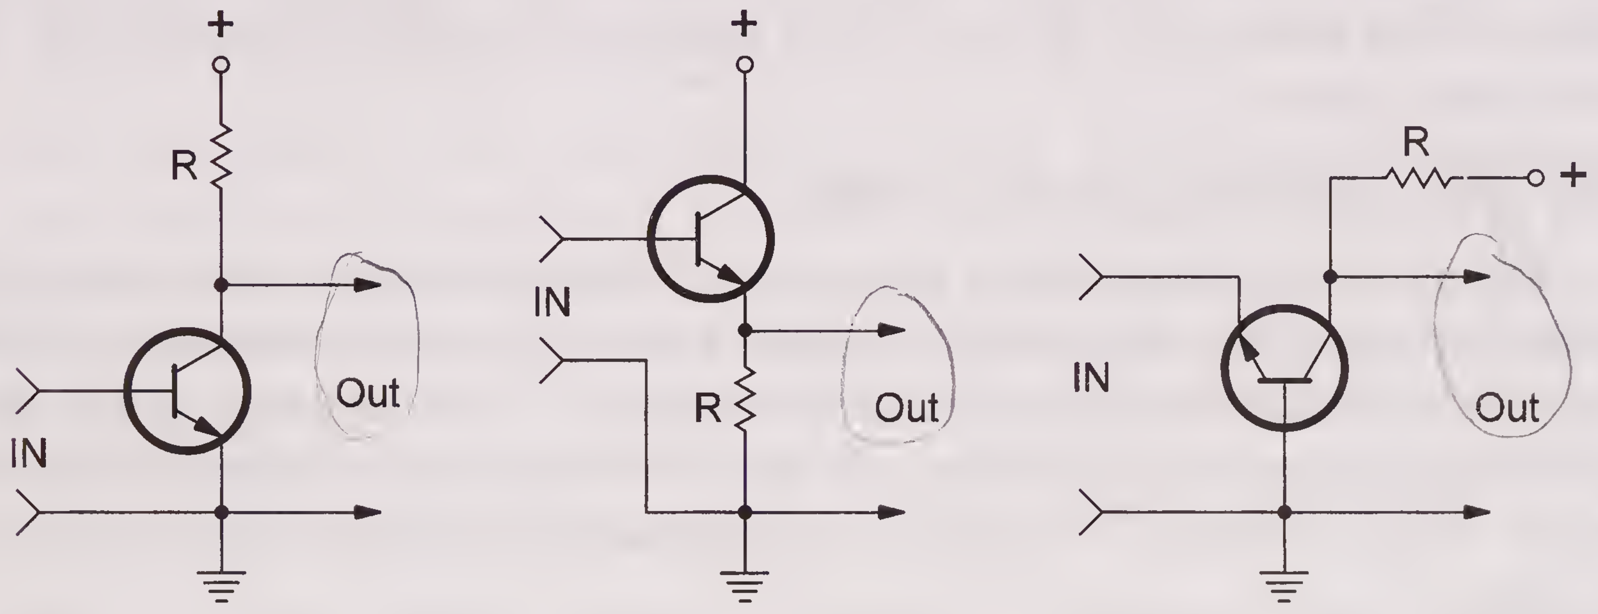
If as shown in (b), a variable current as the correspondent to an audio signal is applied to the base, the small variations of this current will produce large variations in the collector current.

The way the transistors are biased and how the signals to be amplified can be applied and taken off a circuit determine three basic configurations of the transistors. The three ways or basic configurations are shown in Figure 102.



a) Common emitter b) Common collector c) Common base

Figure 102

In (a) is the common emitter configuration presenting larger voltage and current gain (power gain), in (b) is the common emitter configuration giving a high current gain but low-voltage gain, and in (c) the common base configuration is shown. Based on the application, one configuration can have the best performance and is preferred.

Normally, more than one transistor is used in any application. Each transistor is the center of a stage and the amplified signals must pass from one to the other stages being amplified until the desired level is reached.

An audio amplifier, for example, has many stages. Starting from the point where the preamplifier takes the weak signal from a microphone, passing it to intermediate amplification stages, and ending in a power output stage, it can source enough power to drive a loudspeaker reproducing sound with a desired volume. Figure 103 shows a typical circuit of an audio amplifier using two transistors.

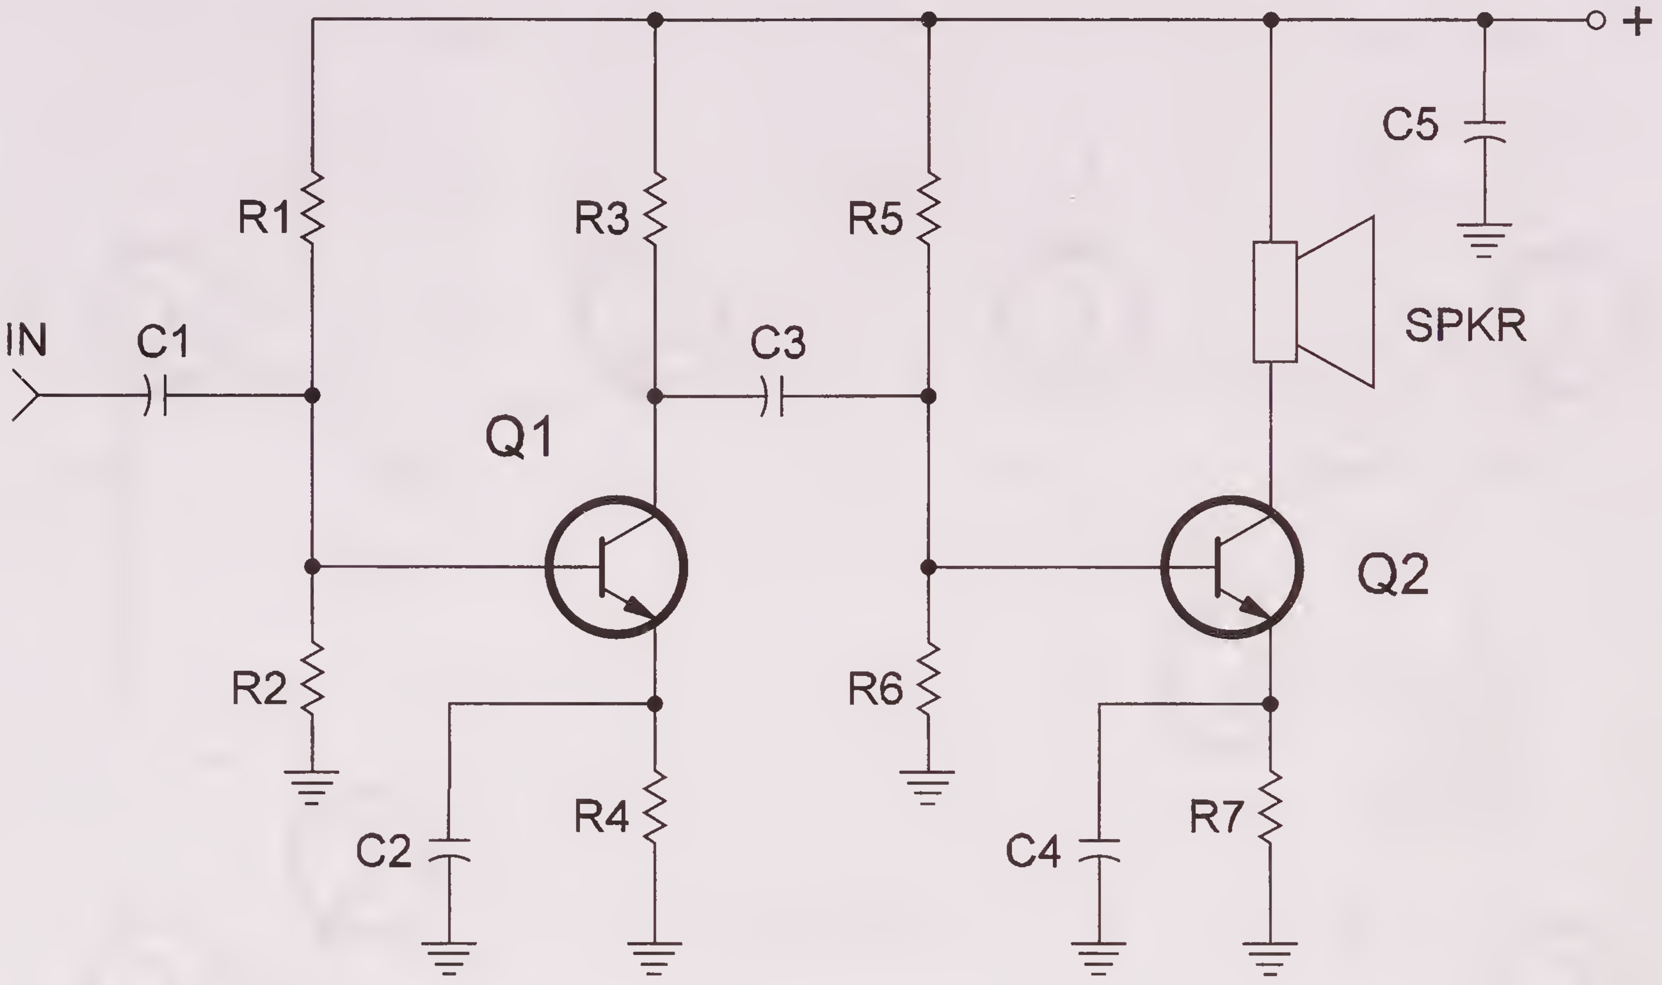


Figure 103

The way the transistor transfers the signals from one stage to another is called coupling, and there are several coupling methods as shown in Figure 104.

In (a) is an RC coupling. The signal is transferred from one transistor to another by a capacitor. In (b) is an LC coupling. The capacitor is also used to transfer the signal from one stage to another. In (c) is a transformer coupling, and in (d) is the direct coupling. A special method of direct coupling, called a Darlington coupling (not shown), is when two NPN or PNP transistors are used.

Testing and identification

The electrician who is just starting with electronics may find some appliances using transistors that are in trouble. How should one proceed in this case? Transistors are found practically in all equipment, forming the central element of many stages. Each stage can have as core one or more transistors in one of the configurations we have seen before. The main test that the electrician can do is measuring the voltages in the leads of the transistor using a multimeter.

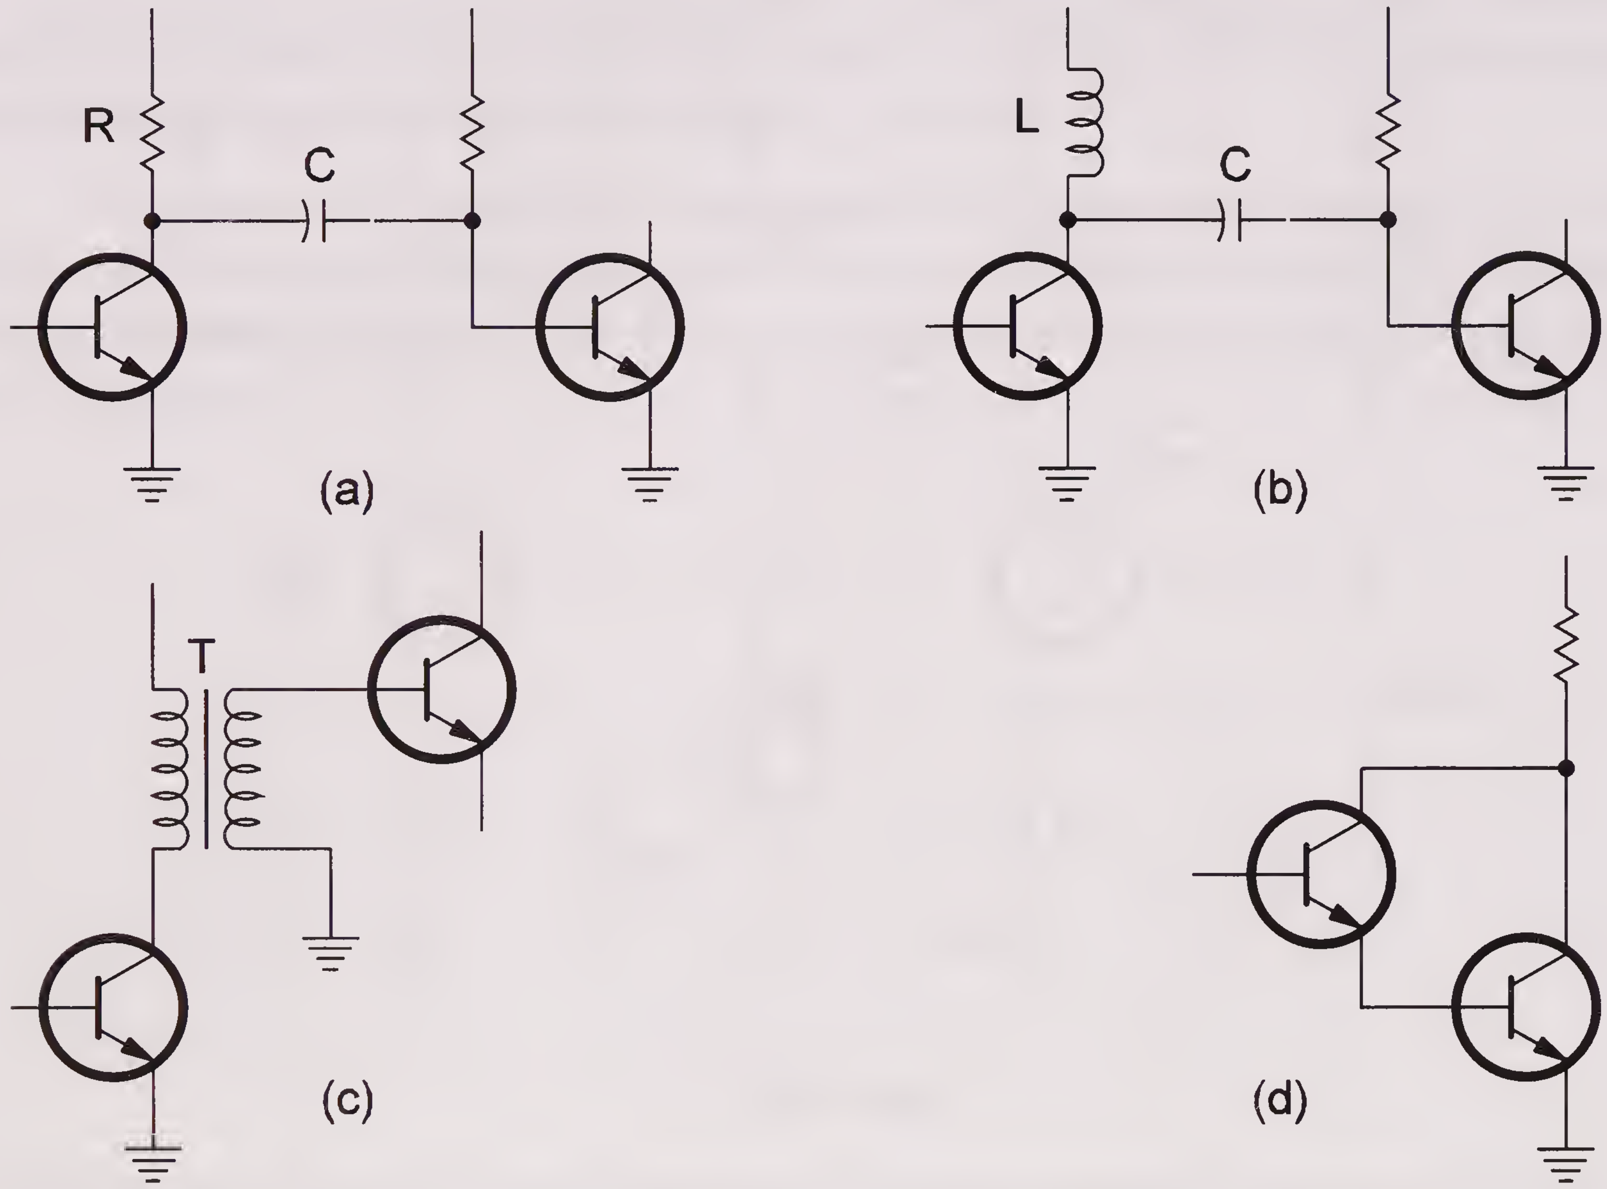

Figure 104

As a general rule, the collector voltage is higher than the emitter voltage in an NPN transistor and the inverse in a PNP transistor as shown in Figure 105.

The base voltage is 0.6 V to 0.7 V above the emitter voltage in an NPN silicon transistor and the same below the emitter voltage in a PNP silicon transistor. In old germanium transistors the difference is 0.2 V. If the voltages are different, the biasing resistor or other elements surrounding the transistors can have problems.

The static test of a transistor or the test out from a circuit, is done by measuring the resistance between the elements (EBC) using a multimeter. It is a "junction test" where it is verified whether the two junctions (base-emitter and base-collector) are okay.

The basic test consists of "seeing" if the two "virtual" diodes corresponding to the two junctions are good. Simply adjust a multimeter to a

Figure 106

Both measures, when placing the probes between collector and emitter, must result in a high-resistance reading. Any different result indicates a transistor with problems, either shorted or open.

If the expected resistance is high (more than 1,000,000 ohms), and we find some value between 20,000 and 500,000 ohms, the transistor is presenting losses. It is also a bad transistor. But, the main problem for the electrician who has to replace a transistor is how to identify it.

As this book is directed toward beginners, the indications given touch only the surface of the problem, although they are enough to give you an idea of how to solve the problem.

If a problem in a circuit using a transistor is found, the first step is to test the transistors to certify that they are the cause of the trouble. Always remember that a transistor can burn if associated components (capacitors and resistors) fail. A capacitor, in short, can cause high currents across a circuit burning a transistor. So, before replacing a burned transistor, test all the components near it as well.

For the replacement, if the original cannot be found, look in a handbook for equivalencies, replacement types, or the characteristics. As a practical rule, a transistor for the same function (small signal for instance) and the same type (NPN or PNP) with the same or greater gain, the same or greater Vce, and the same or greater collector current (Ic), can be used as replacement. In some critical applications such as high-frequency circuits, the fT (transition frequency) must be equal or higher.

Phototransistors

As in diodes, the junctions of a transistor are sensitive to light. If the junctions of a common transistor are exposed to light, the current flowing through the component changes and it can be used as a sensor. The current flow between collector and emitter can be controlled by the amount of light falling onto the device.

By mounting the silicon chip of a transistor inside a transparent enclosure or an enclosure with a window to let the light fall onto it, it becomes an important electronic device—the phototransistor.

Phototransistors are used the same way as the photodiodes—as sensors in many electronic applications. One important aspect of phototransistors when compared with LDRs is that they can be used to detect very fast changes in the light intensity.

Symbol and Types

Figure 107 shows the symbol adopted to represent the phototransistor and a few types. The phototransistor can "see" light invisible to the human eyes. They can be used to detect both IR (infrared) and, in some cases, UV (ultraviolet).

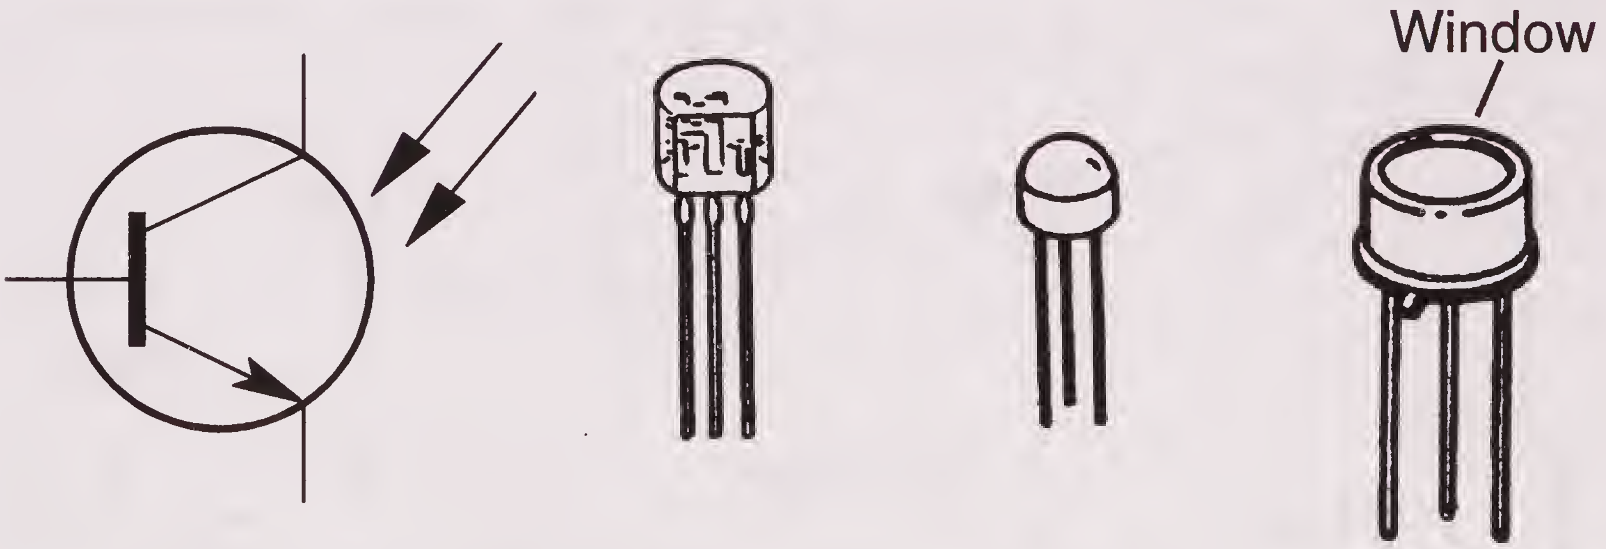

Figure 107

Specifications

The manufacturers mark their phototransistors with a part number. Characteristics such as wavelength response, gain, collector current, maximum operating voltage, and others must be found from using the part number to consult the manufacturer's documentation.

A common series of phototransistors are the one made by Texas Instruments. The first letters (TIL) indicate that it is an optoelectronic device and the next number indicates a special type. Examples of these part numbers are TIL81 and TIL411. The same initial letters are used to indicate other components working with light, such as LEDs and optocouplers.

Where and how they are used

The electrician will find phototransistors in many applications related to professional activities. In fact, alarms, motion detectors, remote controls, and many other applications use the phototransistor as a sensor.

Because the phototransistor is much faster than the LDRs, they have different uses. The electrician will find the LDR in light detectors where the changes or amount of light are slow as in emergency lights and automatic nightlights. In the applications where fast changes of light must be detected or where information must be sent through a light beam (visible or not) the photodiode and the phototransistor are preferred.

In a typical application the phototransistor is used as a diode, as shown in Figure 108.

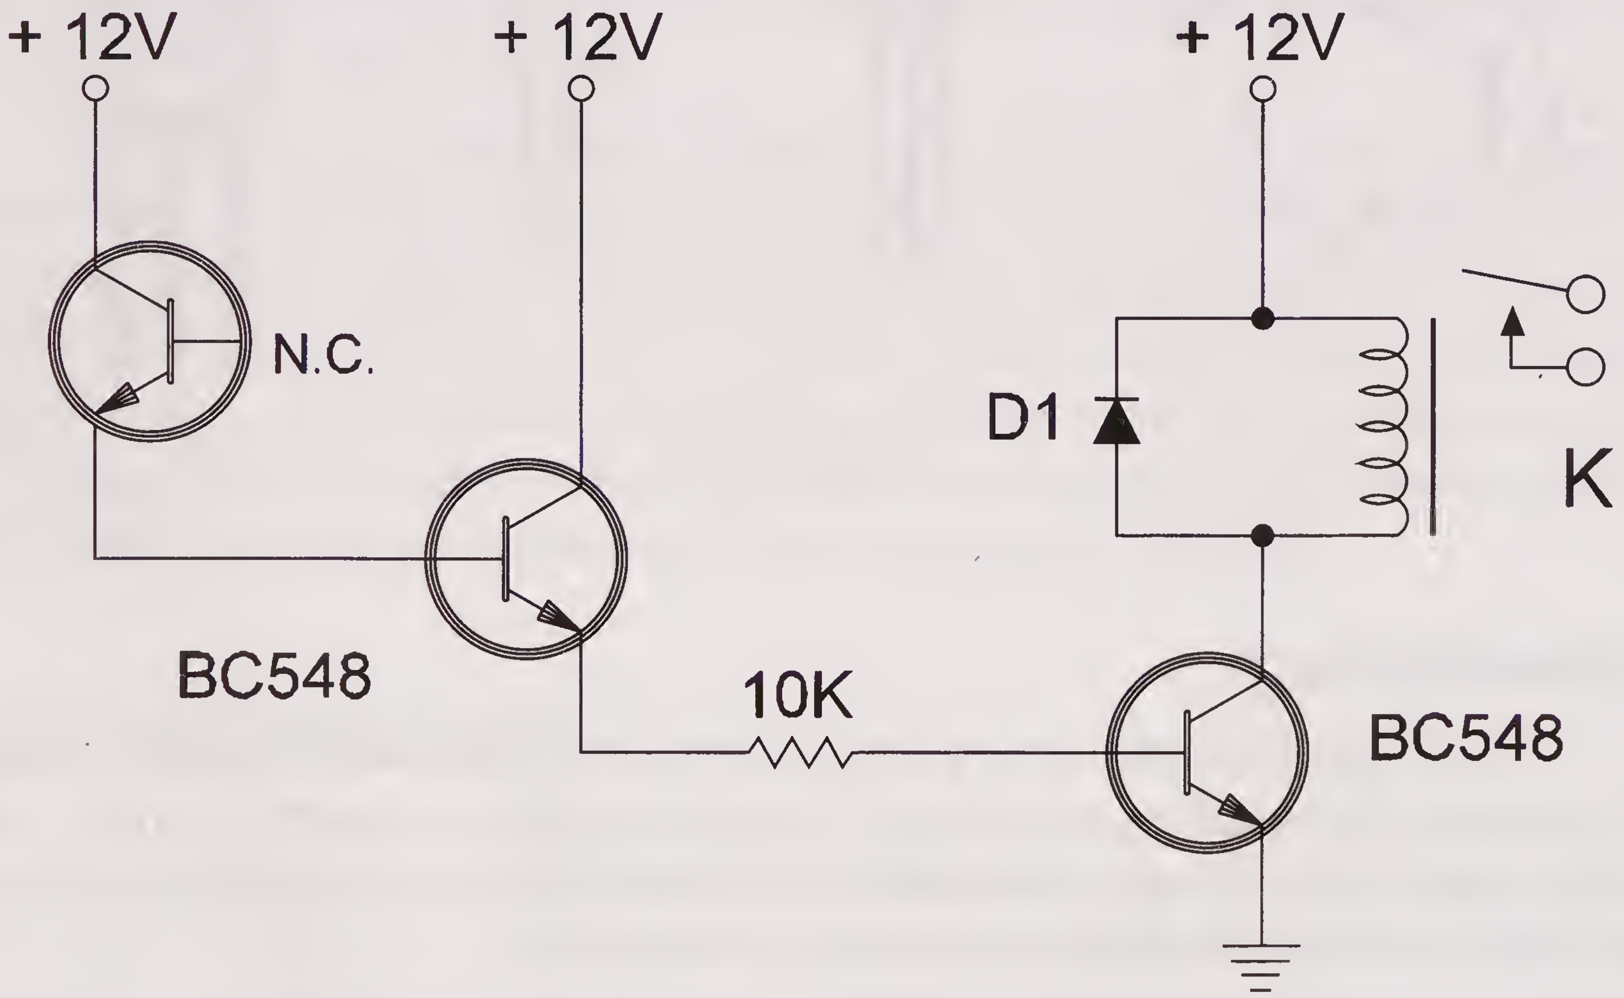

Figure 108

In the circuit the base terminal is let free and the component acts as a photodiode. The current flowing between emitter and collector depends on the light picked up by the device. In many cases, although the component is a transistor, the package doesn't present the base terminal.

In order to increase the amount of light picked up by a phototransistor a lens can be placed in front of the transistor. It is important to place the transistor in its focus as shown in Figure 109.

Alarm

Figure 110

The infrared LED sends a light beam that is focused on the phototransistor. If the light beam is interrupted (cut by an intruder) the circuit detects the cut and triggers an alarm.

Optocouplers

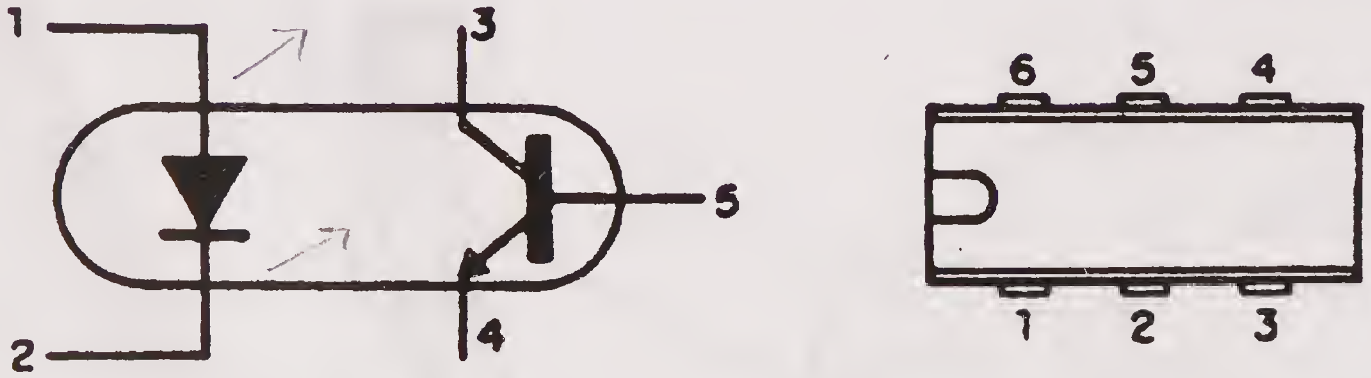
Optocouplers are devices formed by an LED (IR) and a phototransistor or a photodiode installed inside the same enclosure. The LED is pointed to the phototransistor in a manner in which the light emitted by one can be detected by the other.

If a signal is applied to the LED it can be transferred to the transistor by a light beam. This means that no electric connections exist between them, so the transmitting circuit and the receiving circuit are electrically isolated one from the other.

The use of an optocoupler is important when isolation problems are important.

Symbol and View

Figure 111 shows a view and the symbol used to represent an optocoupler.



Symbol Aspect

Figure 111

Specifications

There are many important specifications for an optocoupler. The first thing it is important to know is if the sensor element is a photodiode, a phototransistor, or other light-sensitive device (there are many others). The part number is important, but gives no information on this topic. The electrician will need a handbook with the characteristics or documentation from the manufacturer.

The main characteristics and their meanings are:

A. Isolation voltage: This is the maximum applied voltage between the LED circuit and the sensor. Typical values range from 3000 to 7000 volts.
B. LED characteristics: These are the maximum forward current and voltage.
C. Sensor characteristics: This is the maximum voltage between collector and emitter if a transistor is used.

Where they are used

The electrician can find optocouplers in applications where a signal coming from a circuit or the power supply line must be isolated from other circuits. For example, a circuit that can be triggered from the AC power line voltage, but must not be connected directly to it by security requirements. Another application is interfacing PCs and microprocessors with circuits powered from the AC power line. Using an optocoupler, the delicate circuits of the PC are isolated from the AC power line. If something goes wrong with the circuit, the PC is protected against damage.

Testing

The optocouplers can be tested by independent verification of the LED and the phototransistor. Another way is to excite the LED from a power source (doen't forget the limiting resistor) and see if the resistance between collector and emitter of the internal transistor falls. A multimeter on the highest resistance scale can be used in this test.

Darlington Transistors

Two transistors wired as shown in Figure 112 form a Darlington stage or a Darlington Amplifier. This stage acts as a super transistor or a single transistor with gain corresponding to the total product of the gains of the individual transistors.

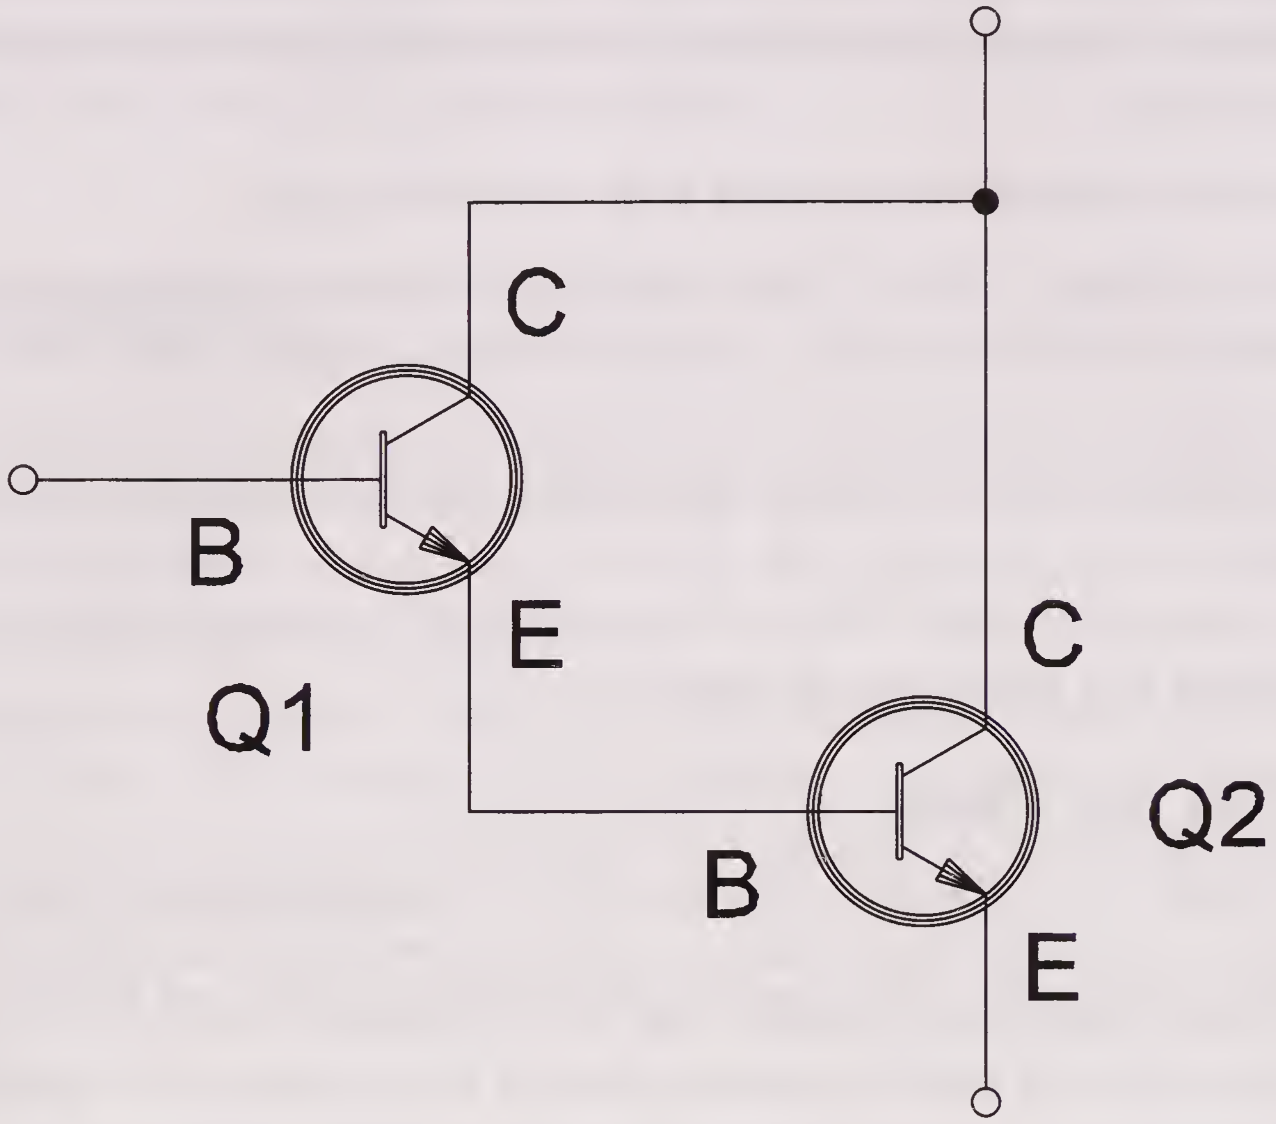


Figure 112

For example, if two transistors with gains equal to 100 ($\beta = 100$) are placed together to form a Darlington pair the final gain will be 100 x 100 or 10,000! They function as a single transistor with 10,000 of gain.

A Darlington transistor can be manufactured by placing two transistors in the same silicon chip, packing them inside a common enclosure forming a super transistor. Darlington transistors are useful where high gain is necessary, such as in solenoid, motor, relay, or lamp drivers as well as high-power audio amplifiers.

Symbols

The symbols for Darlington transistors are shown in Figure 113. As a common bipolar transistor, they are found in the NPN and PNP versions. In (a) is a low-power general purpose Darlington transistor and in (b) a high-power type that must be mounted in a heat sink.

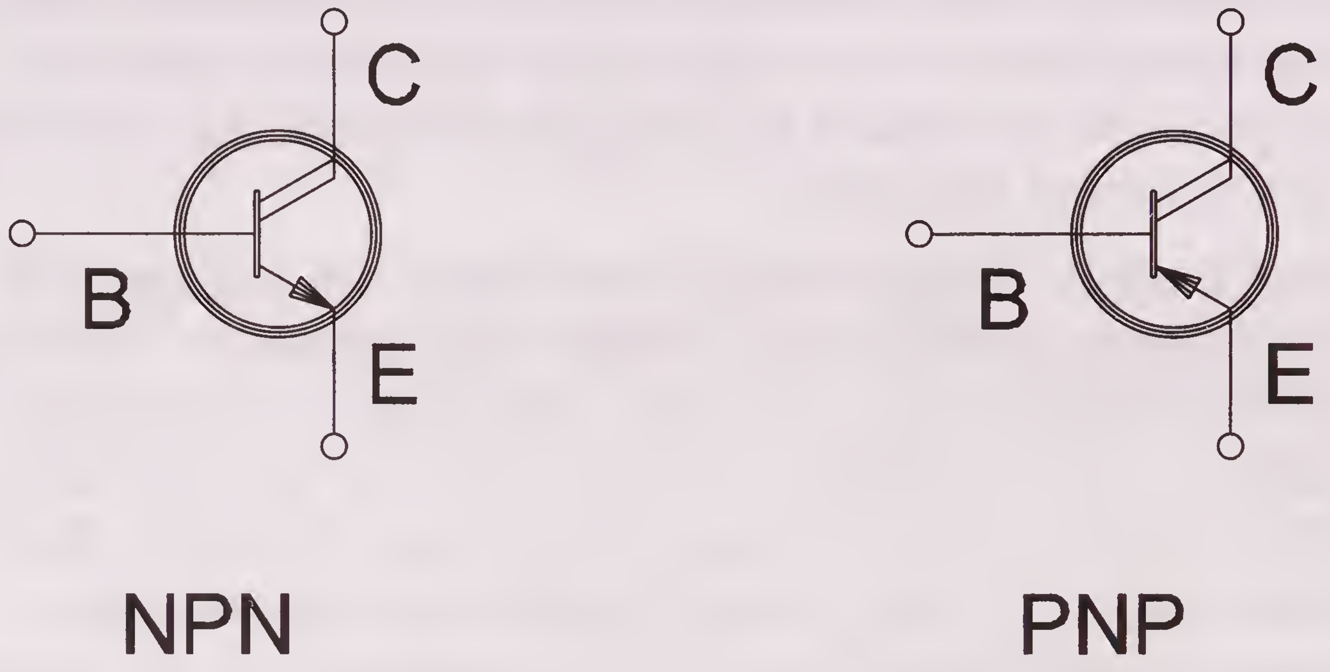

Figure 113

By the simple look of the component it isn't possible to know if it is a common transistor or a Darlington transistor, or any other semiconductor because they all use the same bodies. The identification is made by the type or part number that is normally a figure on the component's body.

Specifications

If you have a handbook of transistors or the specific data sheet (or diagram) for the equipment, it is possible to know if the component is a Darlington transistor.

A common series of Darlington transistors found in many electronic appliances and even in electric applications is the TIP series of Darlington transistors first manufactured by Texas Instruments and now by many other manufacturers. This series is formed by a number of Darlington NPN and PNP transistors designed to control currents from 1 A to more than 10 A and voltages up to 100 V and possibly even higher.

Some Darlington power NPN transistors in this series are TIP110, TIP111, and TIP112 for 2 A of collector currents. The complementary PNP types are the TIP115, TIP116, and TIP117.

Important: Not all transistors beginning with TIP are Darlington transistors!

The data sheets or data books normally have a lot of information about transistors including many curves and numerical information about performance. For electricians or even electronic technicians who only want to know enough to use or replace a Darlington transistor the following specifications are the most important.

A. Collector-Emitter Voltage (Vce)—the maximum voltage that can be applied between collector and emitter of a transistor. Typical values range from some volts to more than 400 volts. In some data books a third letter or group of letters is found after the "ce" indicating special conditions for the value. We can find a (max) indicating that it is the maximum value or a (typ) indicating that it is a typical value.

B. Collector Current (Ic)—the maximum current that can be controlled by the device. This current flows between collector and emitter when the transistor is in the conducting state and varies from some milliamperes to more than 20 amperes to even more heavy-duty types. The additional indication of (max) can also be found with the values.

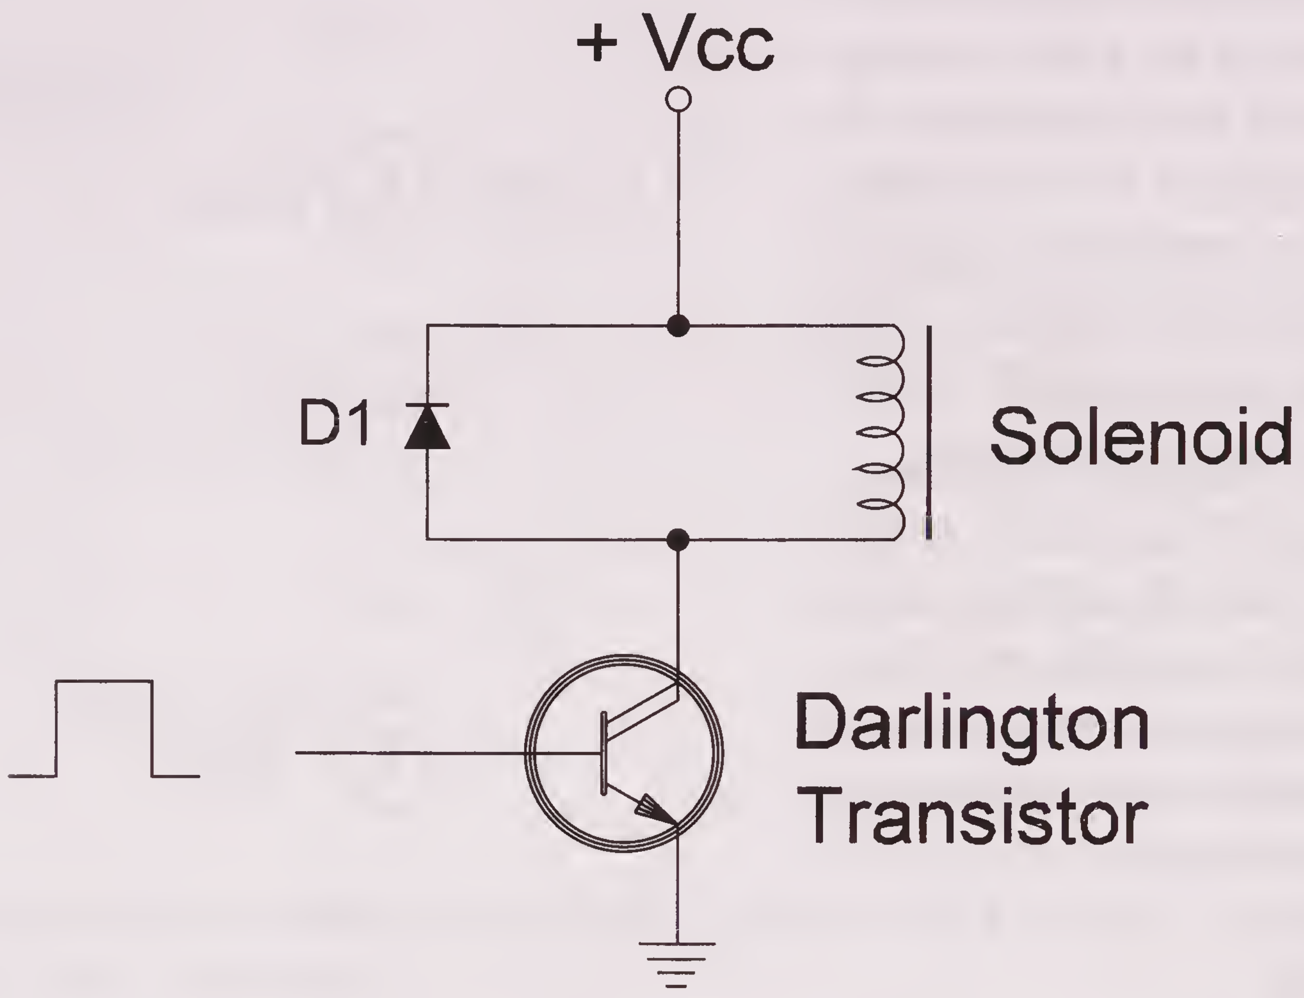
C. Gain (hFE)—Gain for common Darlington transistors can vary from 1000 to more than 10,000. For what the gain means, refer to specifications in for bipolar transistors.

D. Dissipation Power (Pd)—The transistor generates heat when it conducts a current, which is transferred to the area surrounding the transistor. The Dissipation Power in watts gives the maximum amount of heat that can transfer to the surrounding area. Small-signal transistors can have dissipation in the range of milliwatts, but high-power types can dissipate powers up to 250 watts and more.

E. Transition Frequency (fT)—Darlington transistors are slow devices and can't operate in frequencies above some hundred kilohertz. The maximum theoretic operation frequency is given by the transition frequency of fT (the gain falls to 1) and is typically near 100 kHz for most common types.

Where they are found

Many common appliances use Darlington transistors to drive high current loads including solenoids, electromagnets, motors, and lamps. This is shown in the example circuit in Figure 114.



+ Vcc
D1
Solenoid
Darlington
Transistor

Figure 114

The load is connected between the power supply and the transistor's collector. When the transistor is biased it conducts the current energizing the load. In this configuration the transistor acts as a switch turning on and off the load according to the base current.

You can find transistors like these driving solenoids in electric appliances, electric doors, and in electronic equipment such as VCRs and DVD players. Darlington transistors can also be used as low-frequency amplifiers in other applications (Figure 115).

Figure 115

The audio signal (corresponding to a sound) is applied to the transistor's base where it is amplified. Then the transistor triggers a loudspeaker where the signal is reproduced.

Two complementary Darlington transistors (Figure 116) are found in many hi-fi audio amplifiers. This kind of circuit can drive a loudspeaker with powers up to 250 watts.

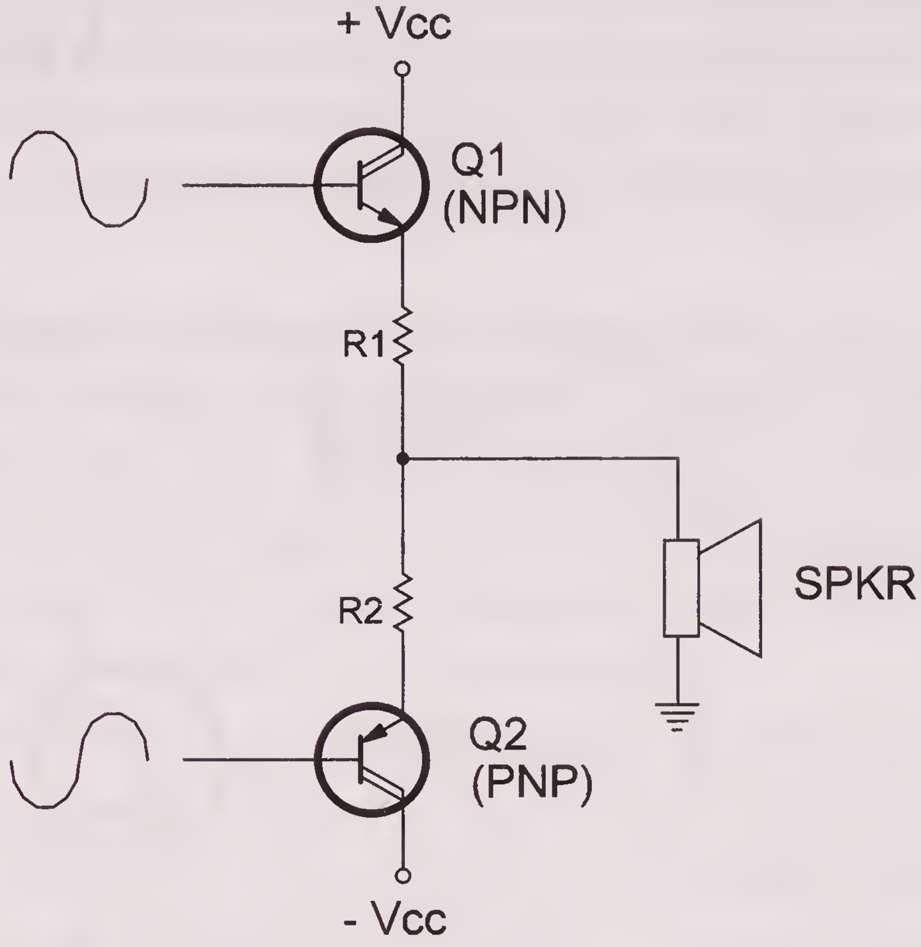

Figure 116

Testing

Darlington transistors can be tested the same way as common bipolar transistors. Using a multimeter, you can measure the resistances between electrodes (base, emitter, and collector) according to the type (NPN and PNP). Refer to the item about bipolar transistors and how to test them. Remember that some multimeters have the transistor test function that can be used with Darlington transistors.

Unijunction Transistor (UJT)

Unijunction transistors are three-terminal devices, but unlike the common bipolar transistors, they have only one junction (as the name suggests). The unijunction transistor or UJT exhibits a negative input resistance that is useful in a number of low-voltage circuits, such as low-frequency oscillators, saw-tooth generators, timers, etc.

As shown by the structure in Figure 117, an N-type silicon bar forms the UJT where two terminals called base 1 and base 2 (B1 and B2) are placed. Between these terminals the device presents an ohmic resistance.

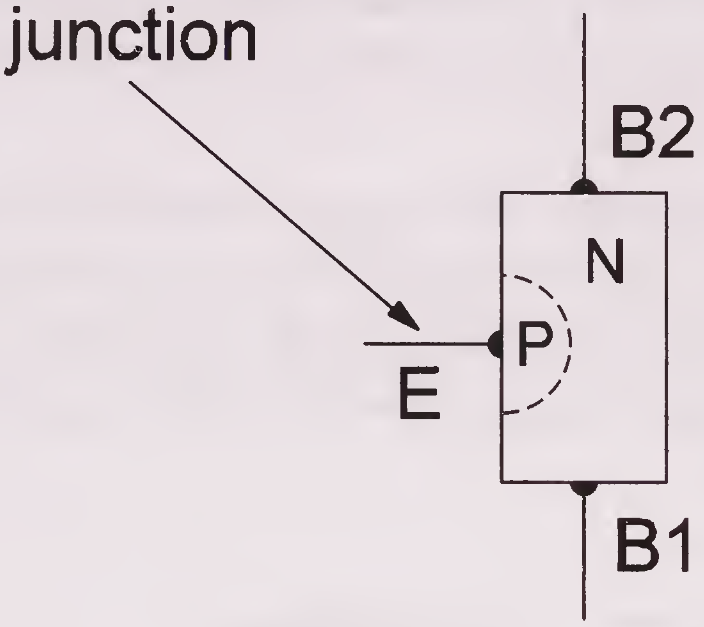

Figure 117

A PN junction is formed in the middle of the N-region where an emitter terminal is placed. In a typical circuit, such as an oscillator, the device is biased as shown in Figure 118.

The N-material placed at the middle of the bar acts as a voltage divider placing a certain voltage in the emitter region. The capacitor placed at the emitter of the transistor charges until the voltage between its plates rises to the value of the emitter voltage plus about 0.6 volts.

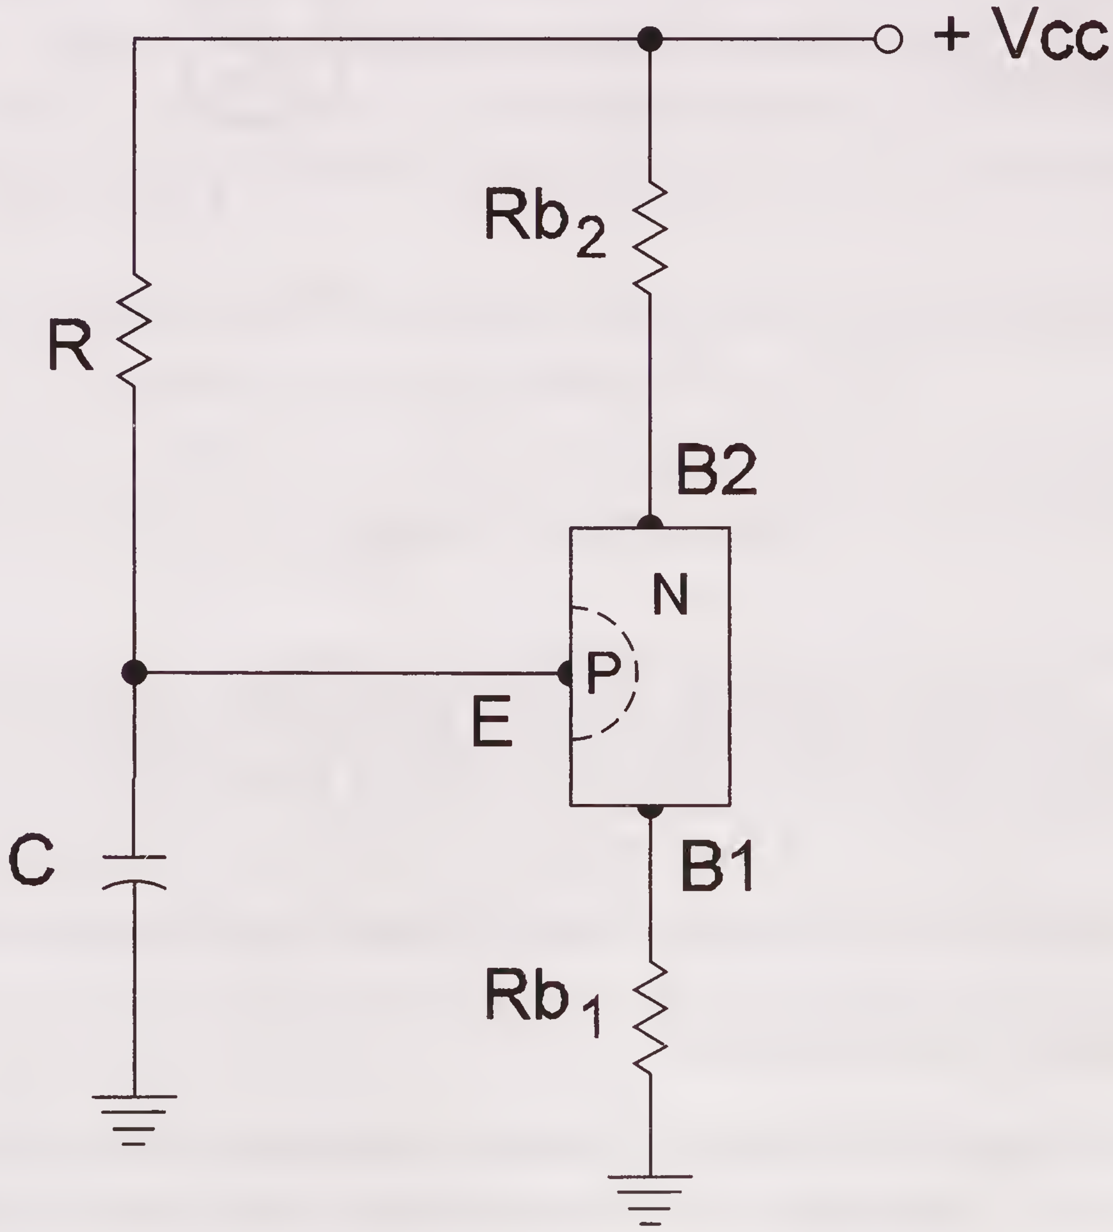

Figure 118

When this voltage is reached the device turns on and the resistance between the emitter to Base 1 falls to a very low value. The capacitor can then discharge through this circuit. A high current pulse is produced in this process.

As long as the charge in the capacitor is reduced, and the voltage across it falls to an appropriated value, the transistor turns off and returns to the nonconductive state. The charging process of the capacitor starts again and a new oscillation cycle begins. Figure 119 shows the waveforms of the signals produced by this circuit.

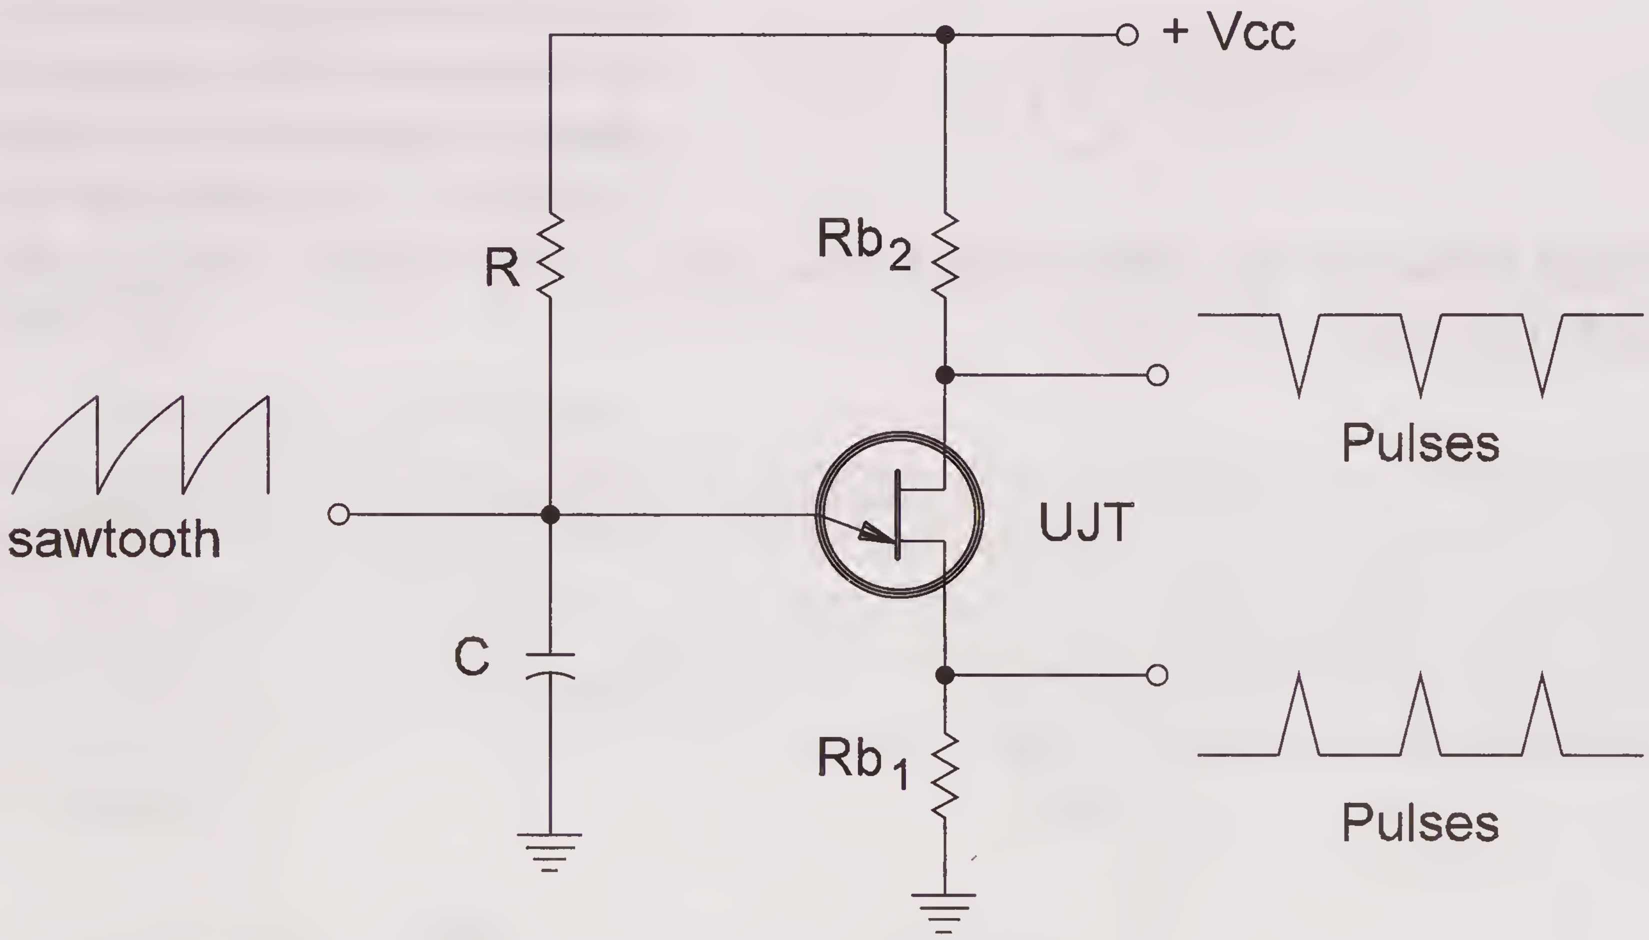

Figure 119

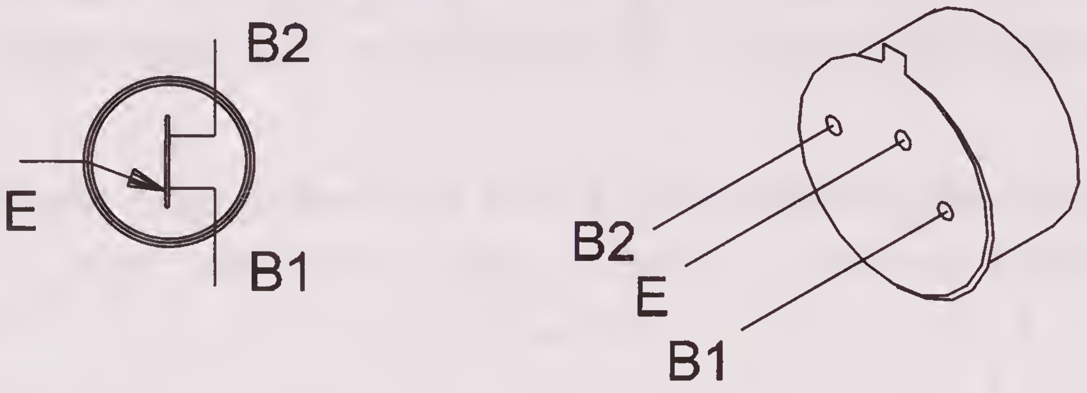
We can consider this the solid-state equivalent of the previously described relaxation oscillator using a neon lamp.

The UJT is a low-frequency device and signals of no more than some hundreds kilohertz can be produced by this basic configuration.

Symbol and Diagram

Figure 120 shows the symbol used to represent a UJT. In the same figure is a diagram, (b). One of the most popular UJT transistors, found in projects published by electronics magazines and even in some kits and appliances, is the 2N2646.



(a) Symbol (b)

Figure 120

Specifications

As in any other transistor, there is a part number figured on the device's body for its identification. But, when building a project and trying to understand how the circuit works or looking for a replacement type, it is important to know some electrical specifications of a UJT. The most important are listed here.

A. Voltage between bases (Vbb)—the maximum voltage that can be applied between bases. For the 2N2646 the specified value is 35 V.

B. Voltage between emitter and base 1 (Vb1e)—the highest voltage that can be applied between the two indicated electrodes. For the 2N2646 the value is 30 V.

C. Intrinsic standoff ratio (η)—the position of the emitter junction referring to the bases. This value is used to calculate the trigger point as a function of the applied voltages. For the 2N2646 this value is in the range between 0,56 and 0,75.

D. Resistance between bases (Rbb)—the ohmic resistance that can be measured between bases. Typical values for the 2N2646 are in the range between 4.7 and 9.1 k ohms.

E. Peak Pulse Emitter Current (Ie)—the maximum current that can flow between emitter and Base 1 when the transistor is triggered.

Where they are found

The UJT isn't a modern device—it was introduced on the market around 1960. Today equivalent circuits using modern devices are used to perform the same functions of a UJT. They are still found in many electronic and electric applications depending on the date they were made or their purpose.

The basic configuration of a UJT is as a relaxation oscillator. This type of circuit is found in timers, alarms, motor controls, toys, and others. For the electrician, it is important to know that the frequency of the signal produced by the UJT depends on R and C and can be calculated with a certain degree of precision by the formula:

$$f = \frac{1}{RxCx\ln\left[\frac{1}{1-\eta}\right]}$$

Where

f is the frequency in Hertz (Hz)

R is the resistance in ohms (Ω)

C is the capacitance in Farads (F)

1n is the natural logarithm

η is the intrinsic standoff ratio (about 0.6 for the 2N2646)

How to test

Using a multimeter you can make two tests in a UJT:

1. The resistance between the two bases in any direction is between 4.5 and 12 k ohms for a common UJT.
2. Placing the probes between the emitter and Base1, a high resistance can be measured in one direction and a low resistance in the opposite direction. This means that the junction (acting as a diode) is good.

The best way to test this device, however, is to mount a simple probe circuit like the one shown in Figure 121.

If the transistor is okay, the LED will flash at a rate that can be adjusted by the potentiometer.

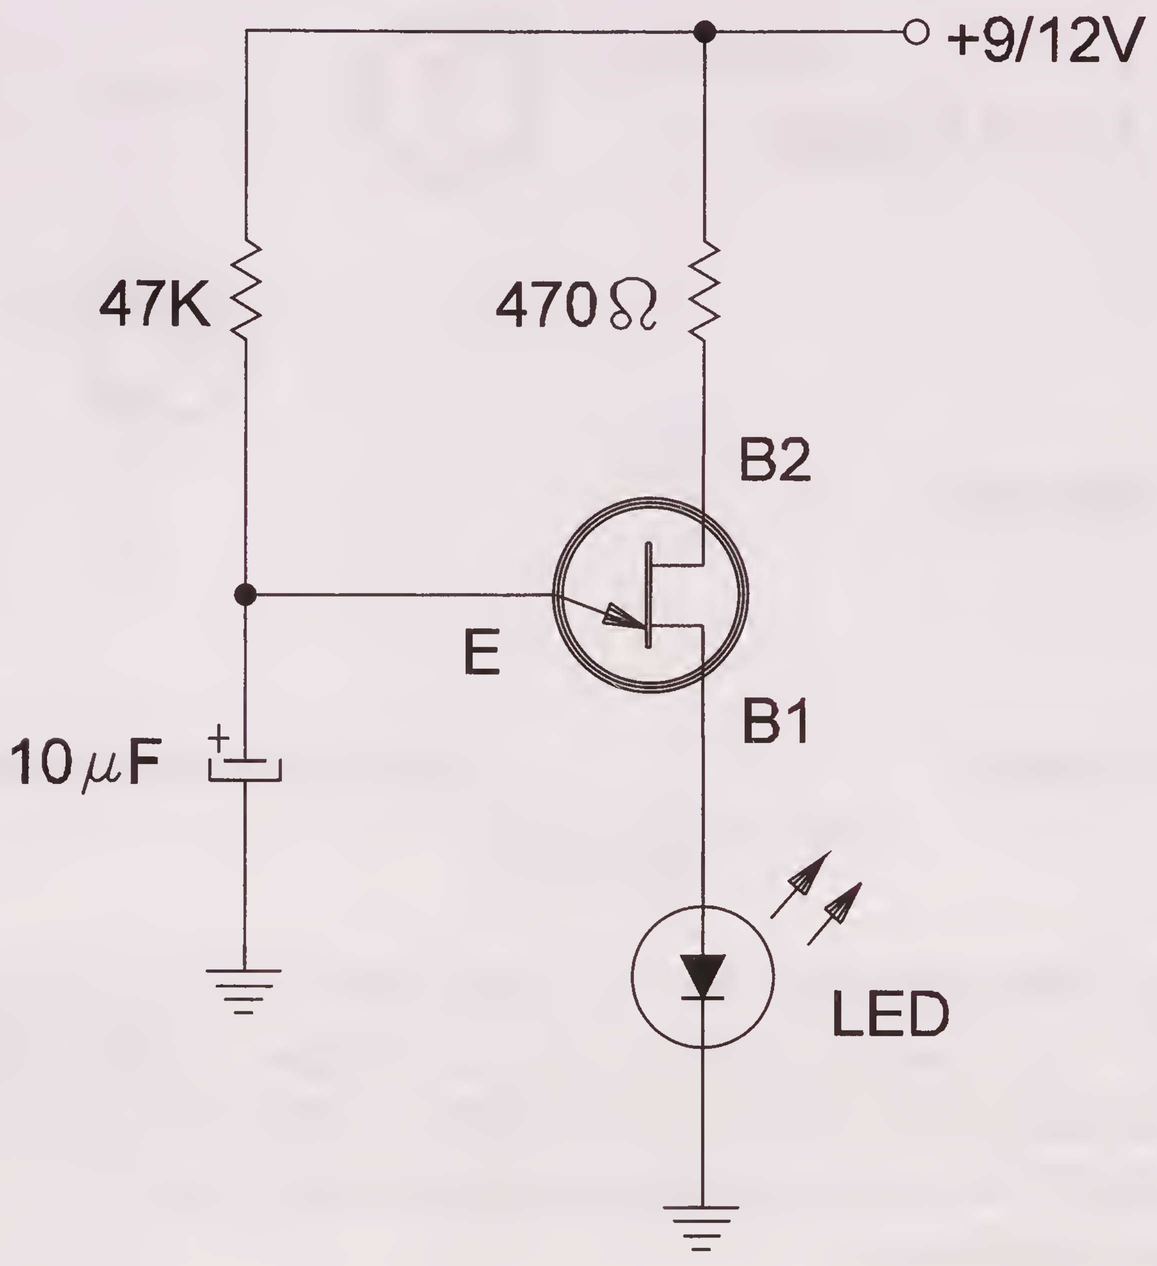


Figure 121

Programmable Unijunction Transistor—PUT

Although this device operates the same way as a UJT, its structure is different. It is a four-layer semiconductor placed in the category of components called thyristors. The structure of a PUT is like the one shown in Figure 122.

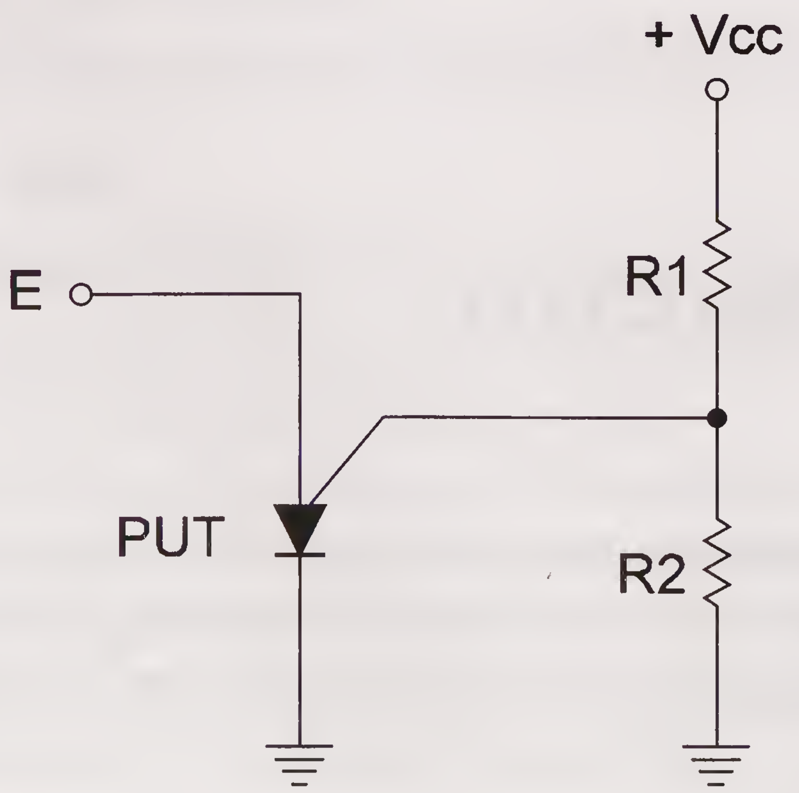
(a) Structure
(b) Equivalent circuit

Figure 122

The basic difference between the UJT and the PUT is that the trigger point of a PUT can be programmed by a voltage divider placed in the anode terminal as shown in the circuit of Figure 123. The PUT is used the same way the UJT is—as a low-frequency oscillator and timer. It is found in the same applications.



+ Vcc
E
R1
PUT
R2

Figure 123

Symbol

The symbol of a PUT is shown in Figure 124.

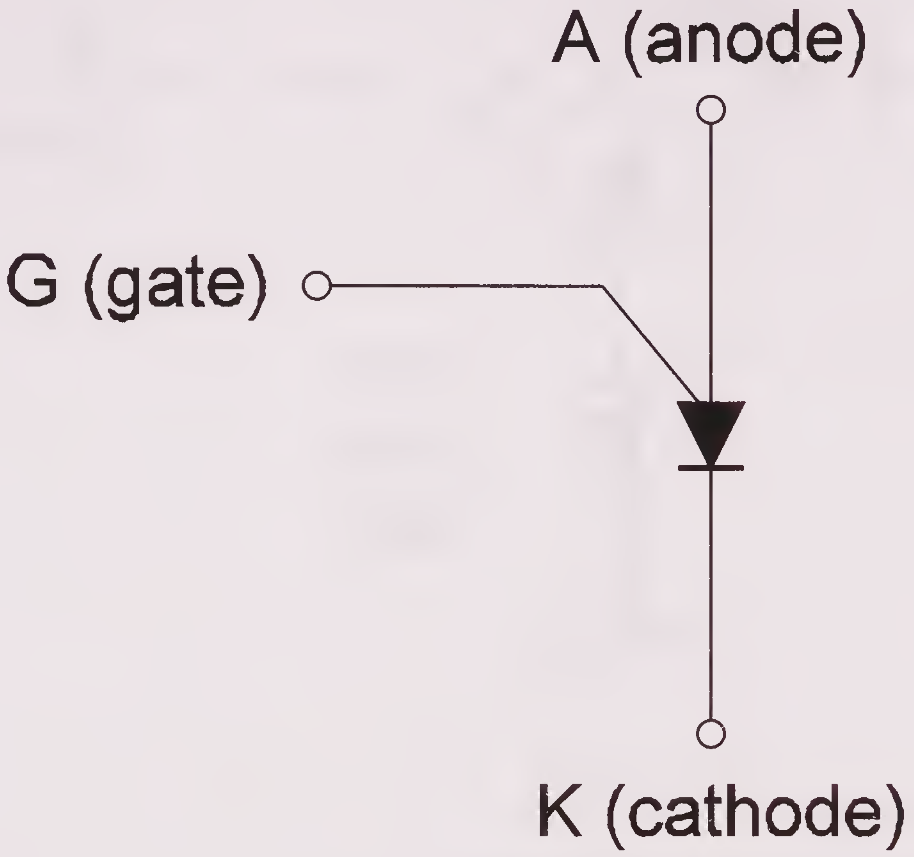


Figure 124

Specifications

The PUT is identified by a part number but there are electrical specifications that can be found in data sheets as the maximum voltage between anode and cathode, and the maximum operation frequency are all similar to the UJT.

Where they are found

The PUT is not a common device in modern applications, but the electrician working with electronics will find it in the same equipment where UJTs are found—timers, motor controls, audio oscillators in alarms, etc. The use of the PUT as a discrete device is not common because manufacturers use the same function in complex integrated circuits that include other functions. Knowing how it works is important because, although the device is not common, the function is.

Testing

The best way to test a PUT is using a circuit where it can drive an LED (Figure 125). If the PUT is okay the LED will flash.

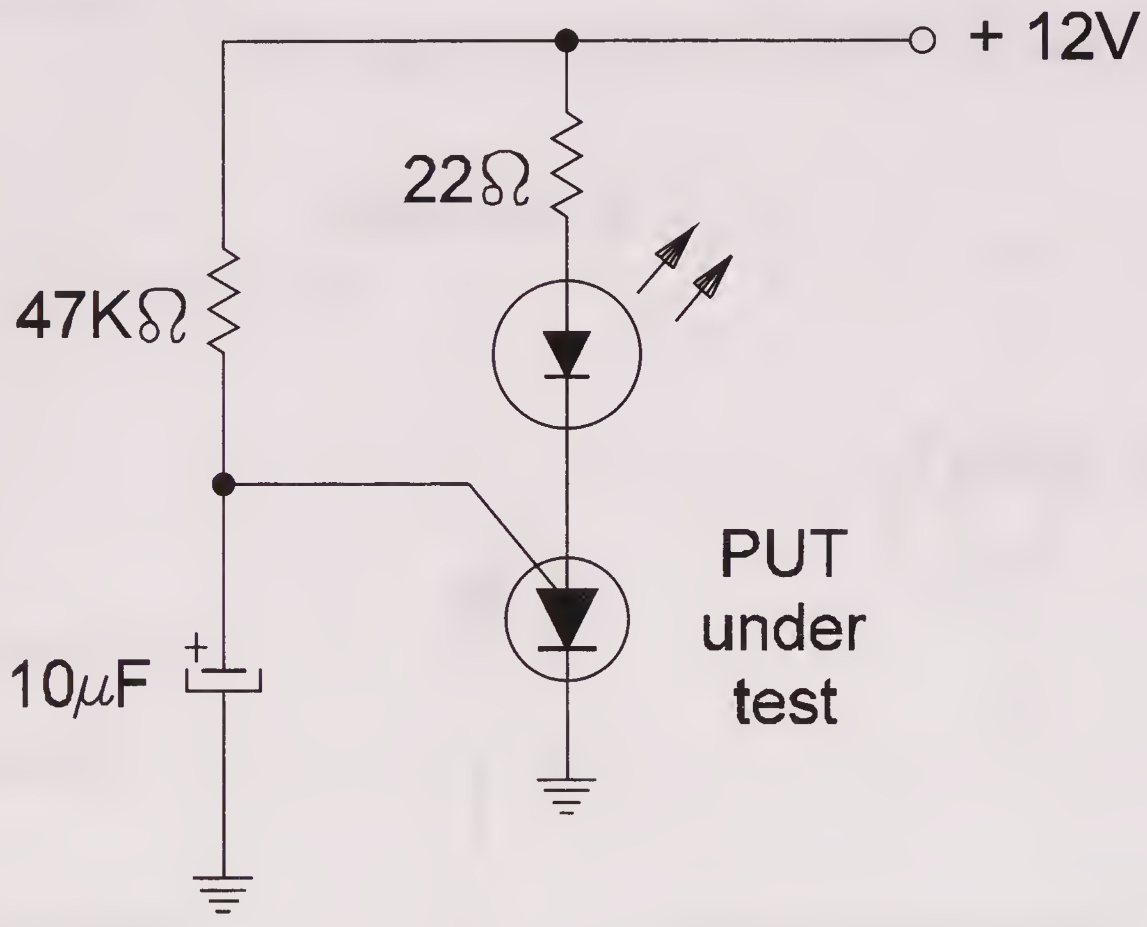

Figure 125

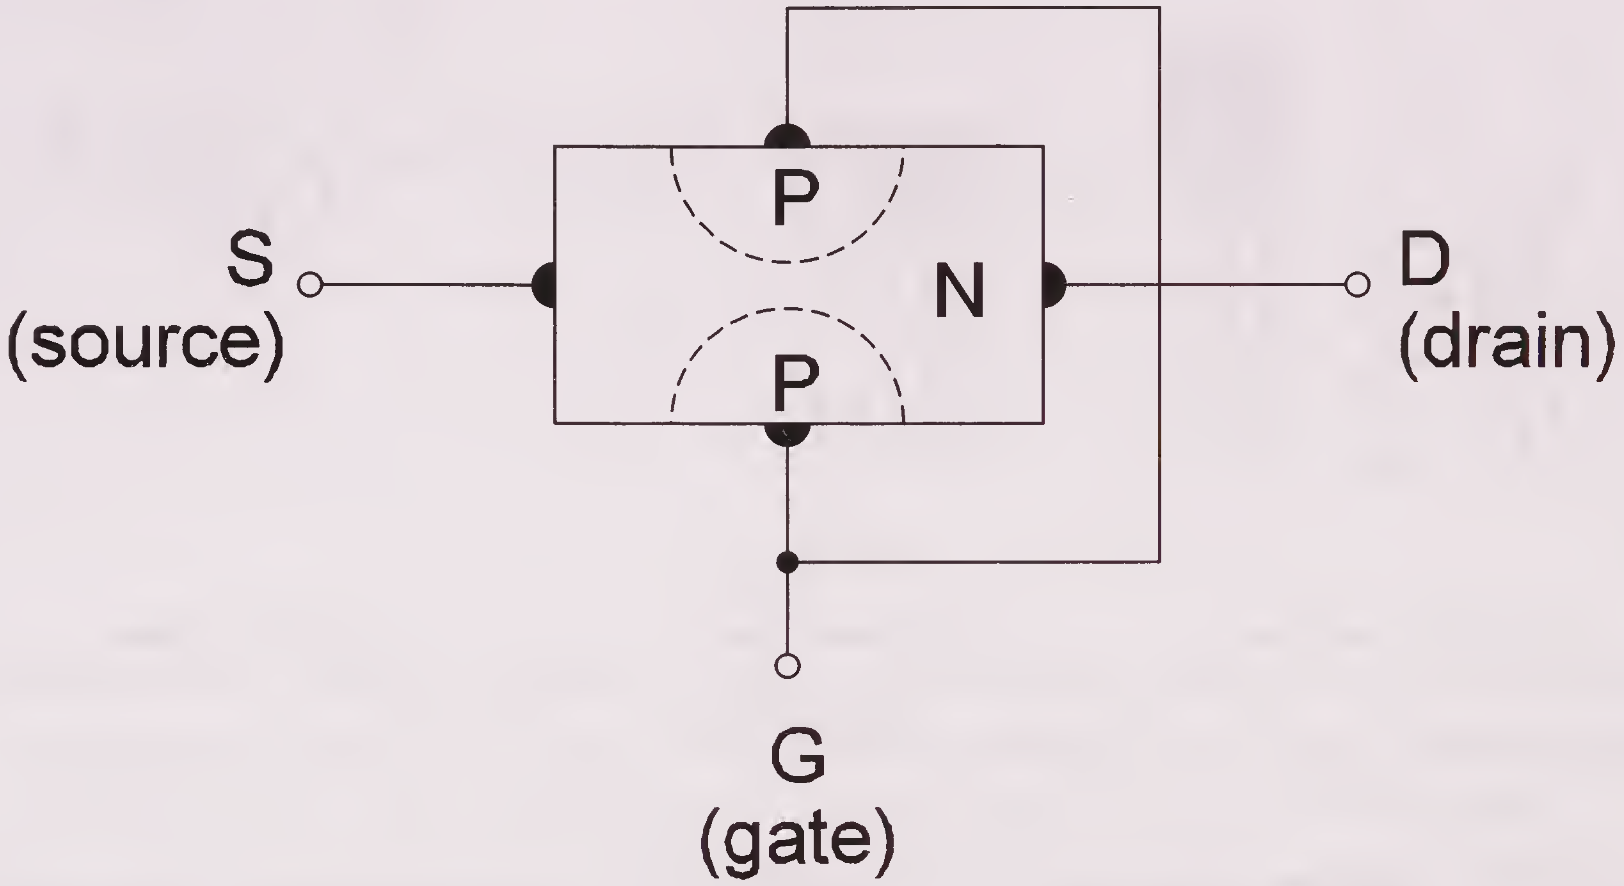
Field-Effect Transistor—FET

The Field-Effect Transistor (FET) is a semiconductor device that can be used in basically the same functions as the bipolar transistor: amplification, switching, or as an oscillator.

The basic FET is formed by a piece of N-type semiconductor material (silicon) where two P regions are formed (Figure 126).

The current through the channel of ~~P~~ N material, where the drain (d) and source (s) terminals are placed, can be controlled by a voltage applied to the gate (g) region. The basic difference between a bipolar transistor and the FET is that, unlike the bipolar transistor that controls a collector-emitter current from a base current, the FET controls a current between drain and source from a gate voltage. The bipolar transistor is said to be a typical current amplifier and the FET is a typical voltage amplifier.

Like the basic material where the drain and source are placed (N and P), the FETs can be found in two types: N channel and P channel. This



P

Figure 126

basic FET is referred to as JFET or Junction FET because, between the gate and the channel where the drain and the source are placed, exists a PN junction.

In the basic application the FET is wired as shown in Figure 127.

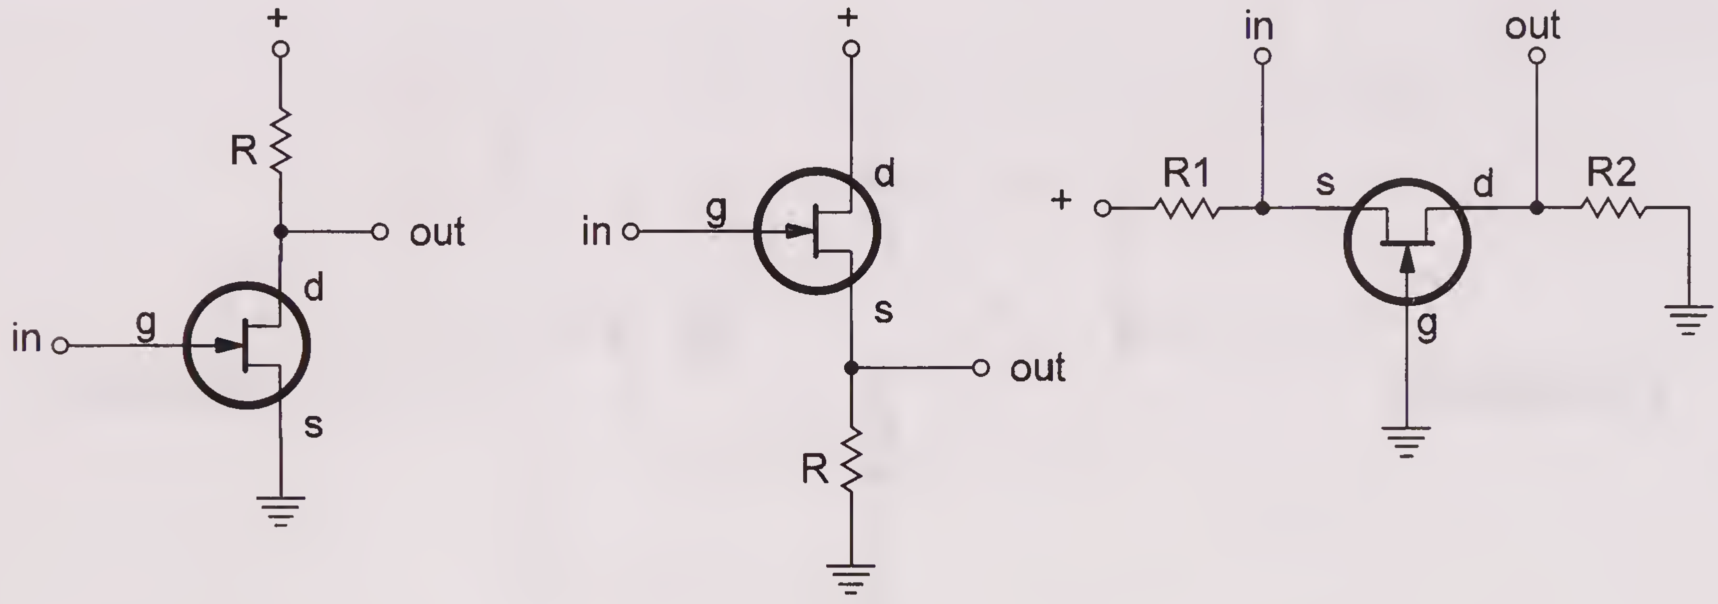
S ≈ emitter

Figure 127



a) common source b) common drain c) common gate

Figure 128

The voltage changes in the gate will be transformed into current changes between drain and source. If a signal is applied to the gate, this signal can be taken already amplified from the drain or source of the transistor according to the configurations. The FET can be used in the same configurations as the ones found in bipolar transistor circuits. The common drain, common source, and common gate configurations are shown in Figure 128.

***Warning:** FETs are very sensitive devices. The electric charge of your body can destroy the device if you touch its terminals.*

Symbols and Types

Figure 129 shows the symbols used to represent both the P-channel and the N-channel JFET. The common types of these devices are shown in the same figure.

Observe that no external differences exist between a common bipolar transistor and an FET. The only way to know which one is which is by the part number or referring to the schematic diagram of the device.

Specifications

The electric specifications for an FET are important to help the electrician find a replacement type or to know if it can be used in a project. The main specifications for an FET are:

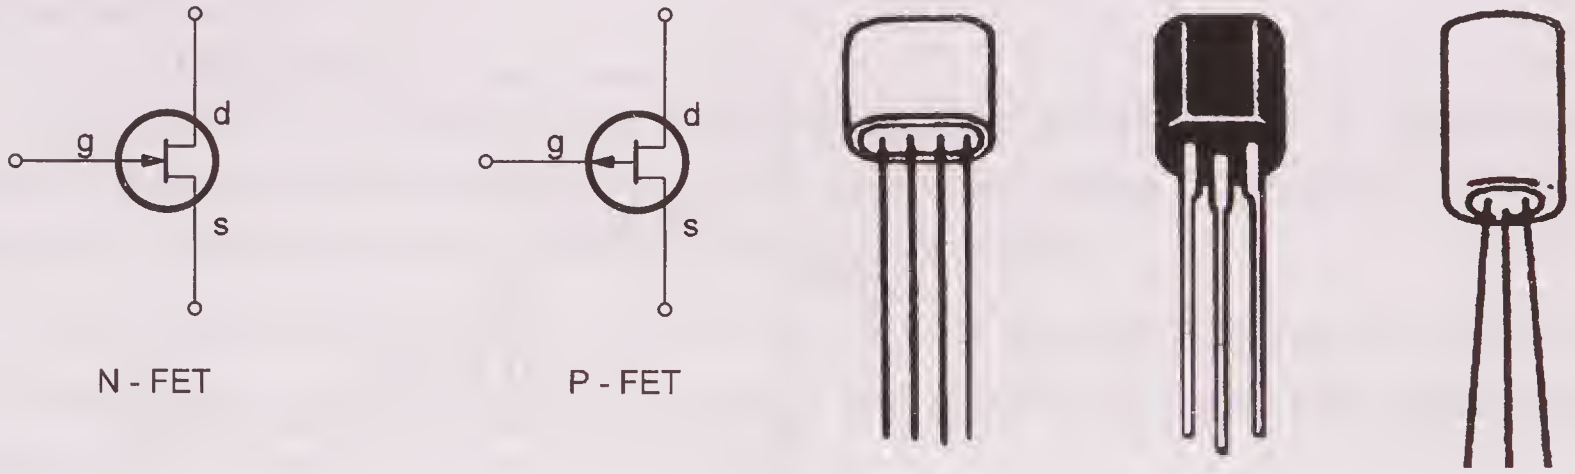


Figure 129

A. Maximum voltage between drain and source (Vds)—the maximum voltage that can be applied to the FET, typically in a range between 20 and 60 volts. This specification can be abbreviated as Vds (max).

B. Maximum drain current—the maximum current that can be controlled by a FET. A common abbreviation in the databooks is Id.

C. Transconductance—the equivalent of the gain of bipolar transistors. It measures the inverse of the resistance between drain and source under certain conditions. The transconductance is measured in Siemens (S). In old publications, the antiquated unit mho (the word "ohm" inverted) is used.

D. Dissipation power—the same as in bipolar transistors and is specified in watts. Small FETs have dissipation powers in a range from 50 to 500 mW.

Where they are found

The JFET or FET is found in circuits where signals must be generated or amplified. Audio circuits and sensor circuits in alarms can use an FET in their input. They can be used in the linear mode as amplifiers or switches like the common bipolar transistor. Figure 130 shows a typical stage where an FET is used as an amplifier for signals from a microphone or any other transducer.

Stages like this can be found in commercial equipment such as alarms, radios, and remote controls.

When replacing an FET it is important to know the type and, if a replacement is used, the placement of the terminals as they can change from type to type.

Figure 131

MOSFETS

MOSFET or Metal-Oxide Semiconductor Field-Effect Transistor is a device derived from the common FET but with some changes in the basic structure and also in the electrical characteristics.

As shown by the structure in Figure 132, MOSFETs have a thin layer of metal oxide (silicon oxide) isolating the substrate from the gate region, instead of a junction found in the JFET.

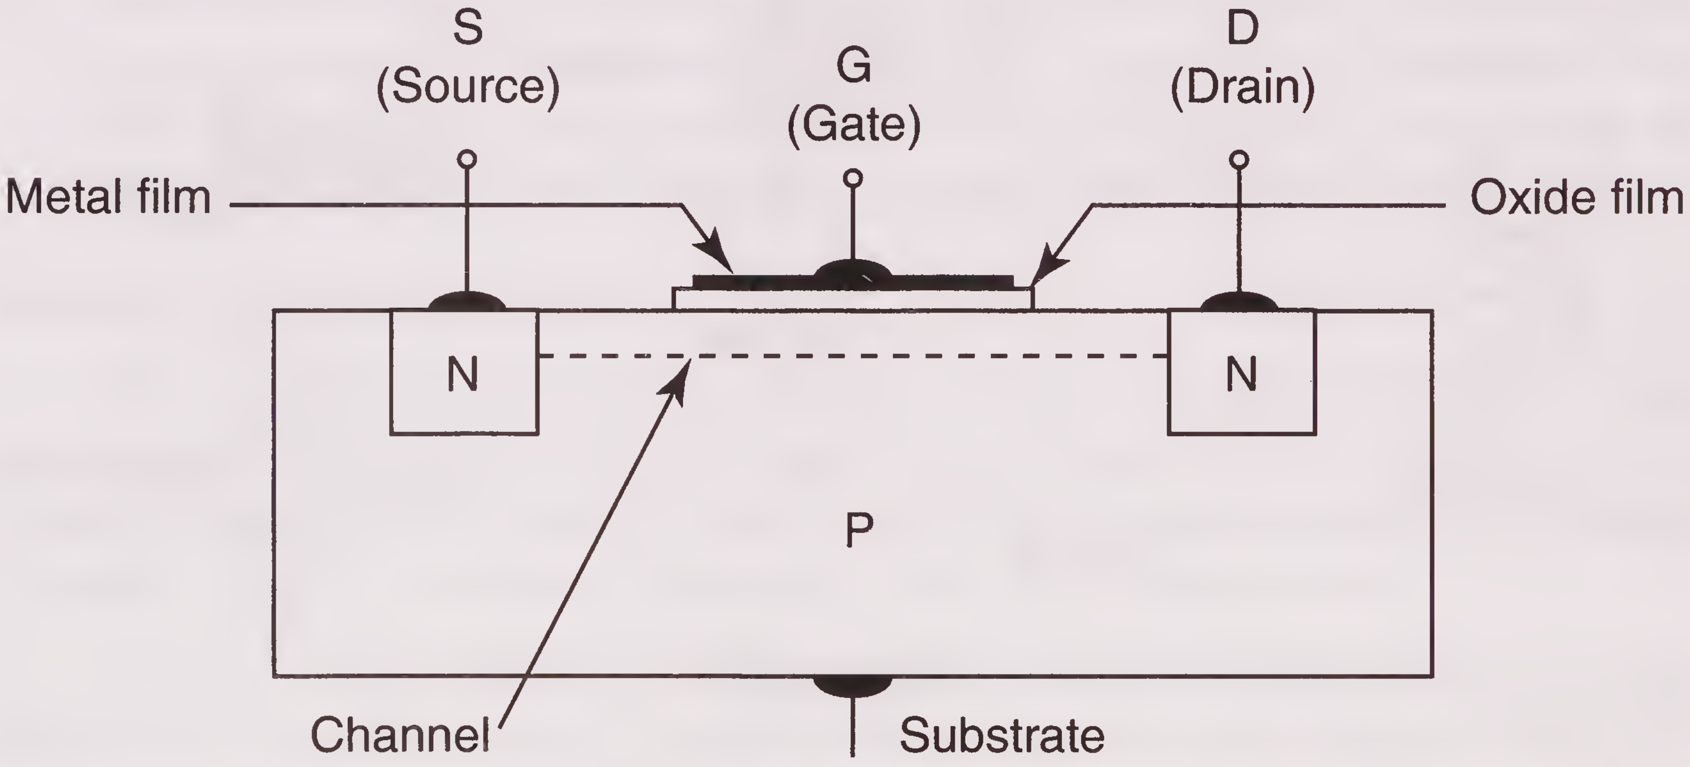

Figure 132

Although there are differences in the structure, the operation of a MOSFET is the same. A voltage applied in the gate can control the amount of current across the device or the current between drain and source. The MOSFET can be used in the same applications where the JFET is found with some advantages. It can be used in signal amplification, signal generation, and many other functions.

Warning: The layer that isolates the gate region from the channel is very thin, making the device extremely sensitive to static discharges. If you have a static charge in your body, touching any terminal of the device can produce a spark between the gate and channel, destroying the isolating layer and the device.

Symbols and Types

Figure 133 shows the symbols of the two types of MOSFETs commonly found in electronic circuits. This figure also shows types of these devices.

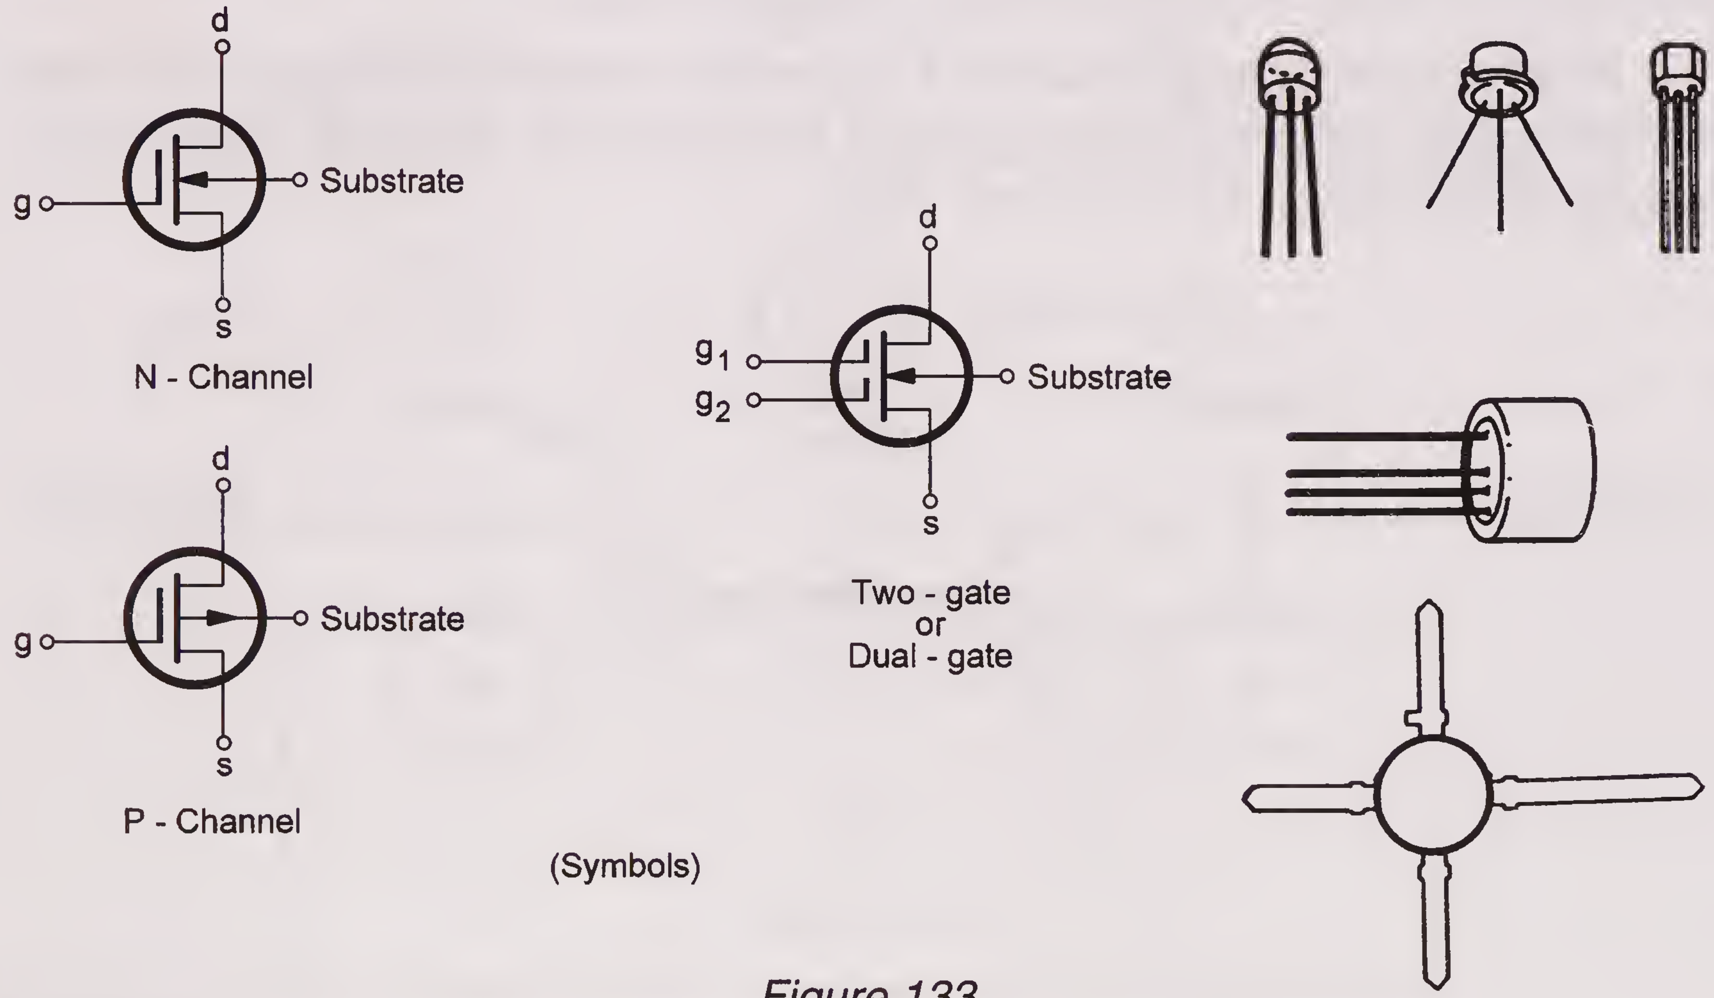

Figure 133

As we can see by this figure, the MOSFET can also be found in a two-gate version (g1 and g2). The amount of current across the device can be controlled independently by the voltages applied to each of the two gates. This device is suitable for applications where two signals must be mixed.

The common MOSFETs are low-power devices and look the same, making it difficult for an electrician to identify them from bipolar transistors. It is necessary to have the schematic diagram, a data sheet with information, or the type (part number on its body).

Specifications

A MOSFET is identified by a part number. By knowing this type number, consulting data sheets, or consulting handbooks it is possible to know its electric characteristics. These characteristics are important in order to find a replacement type. The main characteristics of a MOSFET are as follows:

A. Maximum voltage between drain and source—indicated as Vds (max) or only Vds, this is the maximum voltage that can be applied to the device without burning it. Values between 20 and 50 volts are common.

B. Maximum drain current—the maximum current controlled by the device. In common types this current ranges from 10 to 100 mA. It is also abbreviated by Id or Id (max).

C. Transconductance—in the common JFETs, it is the parameter that indicates the amplification capabilities of the device. It is measured in Siemens (S).

D. Dissipation Power (Pd)—as in any electronic device, the MOSFET converts electric energy into heat. The maximum amount of heat generated by the device and transferred to the area surrounding the device is the maximum dissipation power (Pd) given in watts (W).

Where they are found

The MOSFETs are mainly found in high- and low-frequency power circuits as in the input of audio amplifiers and as sensor amplifiers, or in high-frequency low-power circuits like RF, FI, mixer, and oscillator stages in radios, remote controls, receivers, TVs, walk-talkies, etc.

Today the functions of JFETs and MOSFETs can be included in other devices (integrated circuits) as we will see, but in some cases, depending on the equipment, the electrician may find these components.

Testing

The MOSFET can be tested by measuring the resistance between drain and source and also between the gates and the source (Figure 134). However, the best test can be made using a probe circuit that can easily be implemented on a solderless board (protoboard).

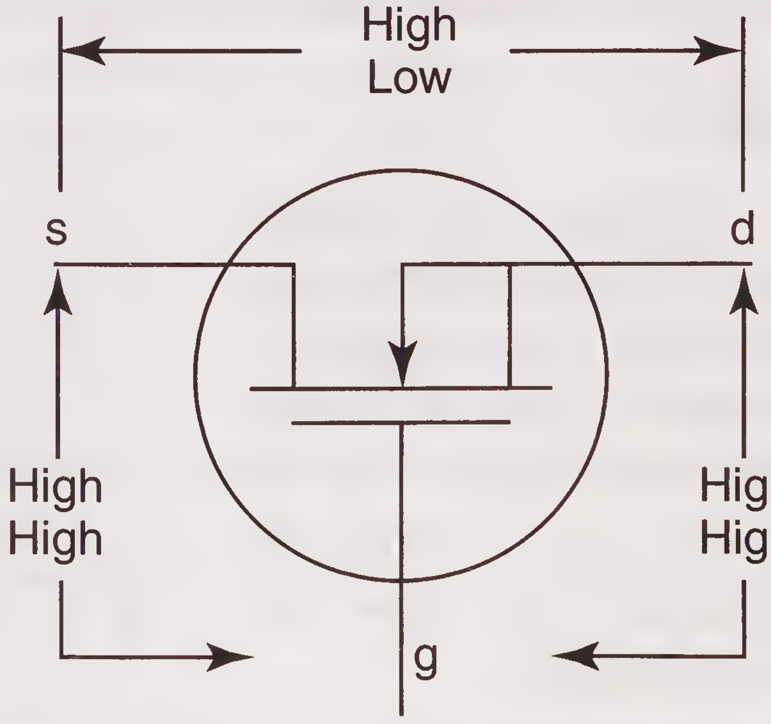

Figure 134

Power FETs

Power FETs are MOSFETs that can be used to control large amounts of current. They are very common today in digital and analog applications replacing the bipolar transistor. Power FETs, or power MOSFETs as they also called, can control currents as large as 50 amperes under voltages of more than 500 volts.

The structure and the operation principle of a power MOSFET are the same as the common MOSFET. The differences are in the size and shape of the silicon chip used when the device is manufactured.

Several technologies are used to produce these devices giving to the POWER-FET transistor names such as VFETs, power FETs, DFETs, and TMOS. The power FETs operate the same way the common MOSFET operates. A voltage applied to the gate can control the amount of current flowing across the device.

High-current devices such as solenoids, motors, electromagnets, relays, heaters, and lamps can be controlled by power FETs in the same kind of stages as the ones that use power bipolar transistors or Darlington transistors. The main advantage found in the use of power FETs is the low resistance presented when conducting a current (called Rds or drain source resistance). Because the amount of heat produced by the device depends on this resistance, power FETs can control much larger currents than the equivalent bipolar transistor while generating less heat.

Symbol

Figure 135 shows that the power FETs can be found in two types—N and P channel. They look the same as a power bipolar transistor because they use the same bodies.

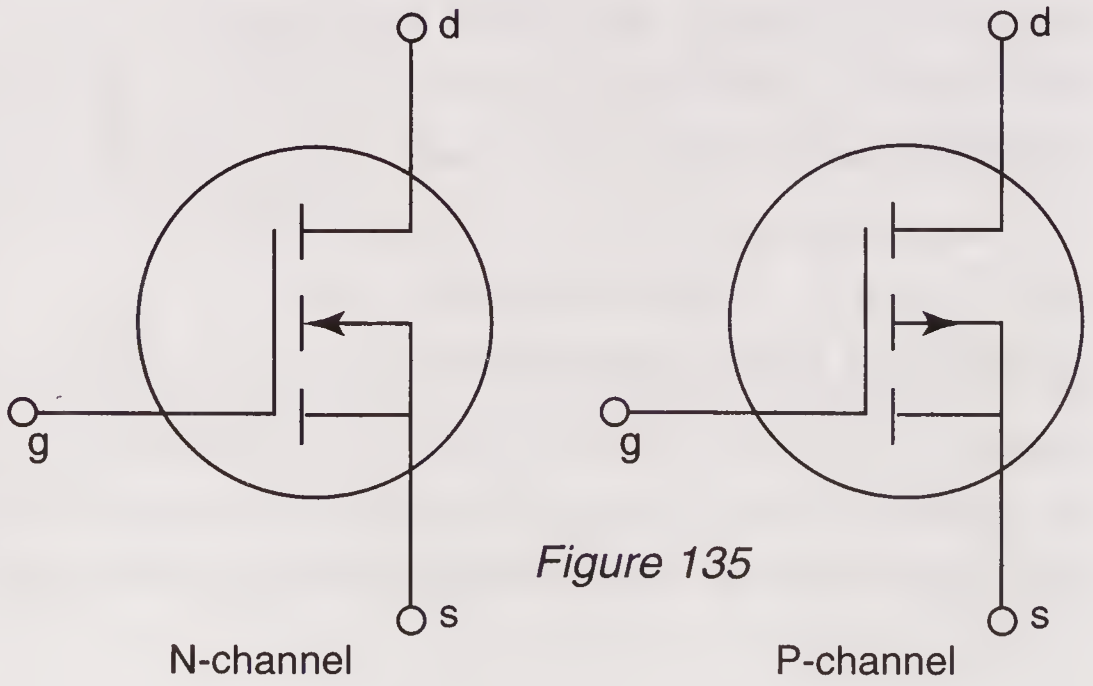

Figure 135

As with any other power transistor, the

power FETs must be mounted in heat sinks to transfer to the all the heat they generate when working.

Specifications

The power FETs are identified by a part number. A popular series of power MOSFETs and produced by many manufacturers including International Rectifier, Fairchild, and Motorola is the IRF series. All devices of this series have part designations beginning with IRF: IRF640, IR720, IRF630, IRF730, etc.

By knowing the name (part number), it is possible to find the electrical characteristics of a Power FET in handbooks or on data sheets. The principal characteristics are as follows.

A. Maximum voltage between drain and source—the maximum voltage that can be applied to the device without burning it. Common types have voltages ranging from 50 to 1000 volts. This specification can be indicated as Vds (max).

B. Maximum drain current—the highest current that can be controlled by the device and can range from 1 to 50 amperes. This specification is abbreviated by Id or Id (max).

C. Dissipation power—the amount of heat that the device can transfer to the surrounding area. It is measured in watts and can range from 10 to 250 watts.

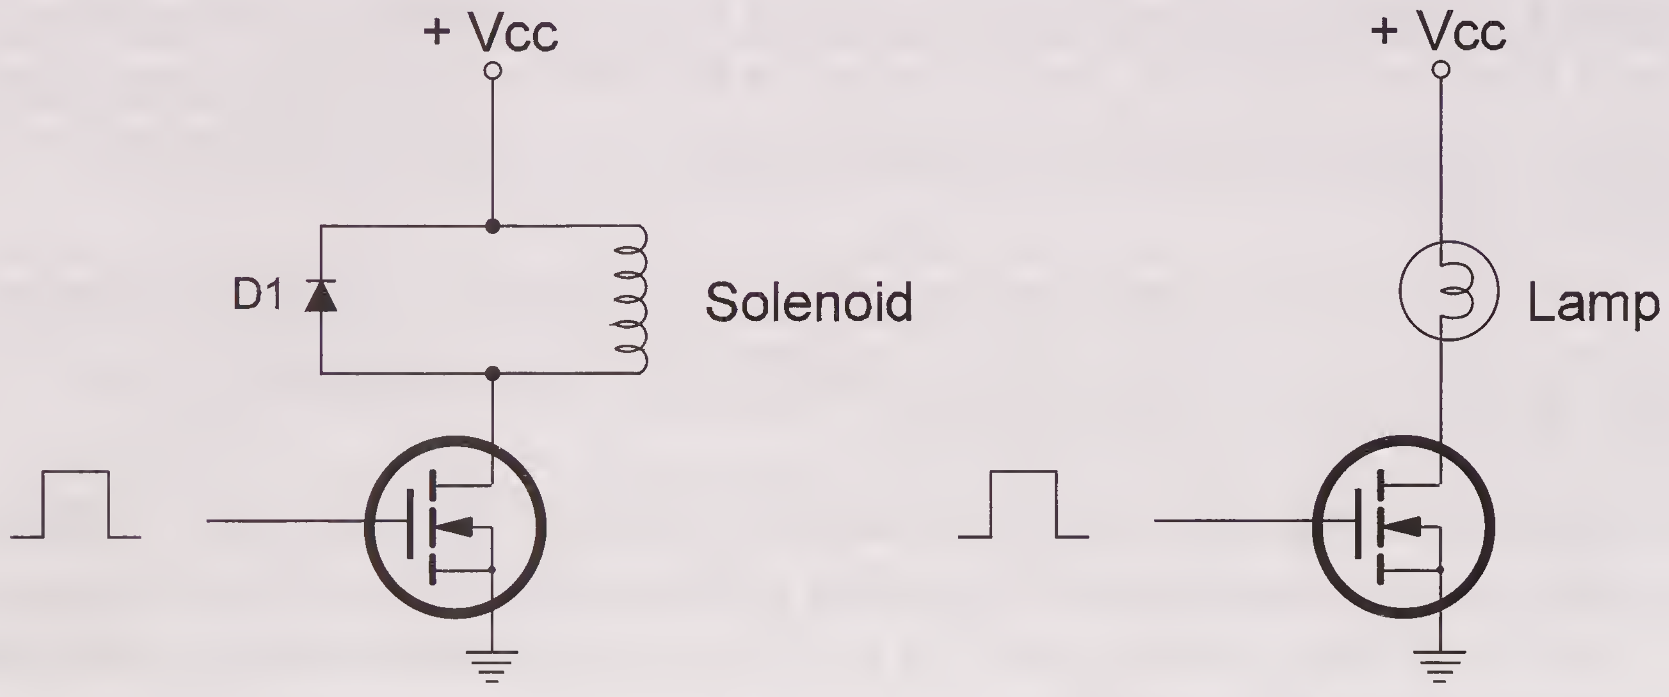
D. Resistance between drain and source in the on state—the most important of the power FET's specifications. The amount of heat generated by the device depends on this resistance as it operates in more of the applications as an electronic switch. The product of this resistance multiplied by the square of the current gives the generated power. It is easy to see that the lower this resistance, the more efficient the device is when controlling high amounts of current and more heat is generated. This resistance used to be less than 1 ohm in more of the common devices. It is also indicated by rDS or Rds and is given in ohms (Ω).

Where they are found

Power FETs are slow devices used to control high current loads but in low- and medium-frequency circuits. Like the bipolar transistors, the power

FETs can be used as a switch (digital mode) or as a signal amplifier (linear mode).

As switches we can find the power FETs controlling solenoids, relays, step motors, and other loads in circuits like the one shown in Figure 136.

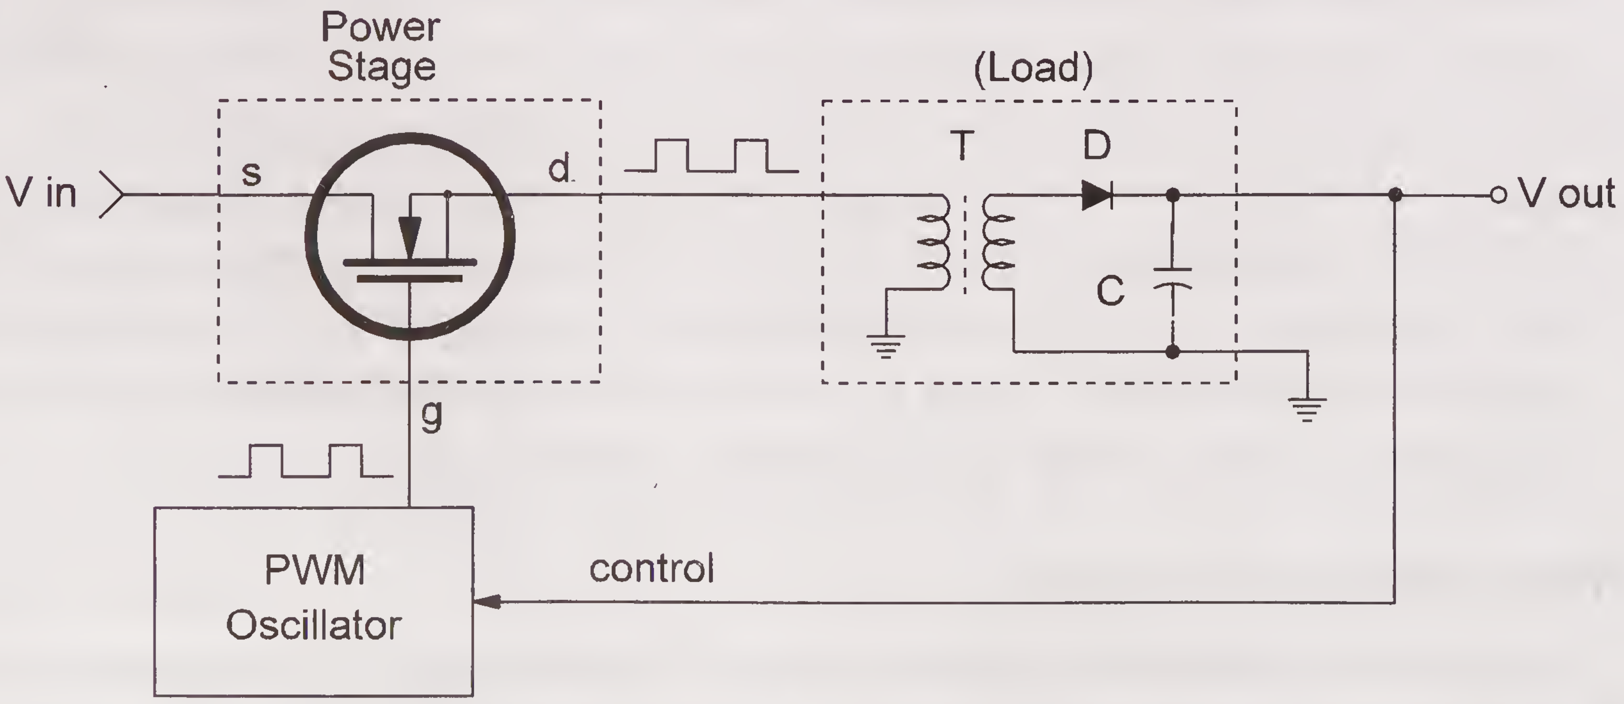


+ Vcc
D1
Solenoid
+ Vcc
Lamp

Figure 136

When a positive voltage is applied between gate and the ground, the power FET (P channel) turns on and the current flowing across the device powers on the load.

Another important application of power FETs is in Switch-Mode Power Supplies (SMPS) like the one shown in a block diagram in Figure 137.



Power Stage
(Load)

s
d
T
D
V out
C
g
PWM Oscillator
control

Figure 137

In this circuit the power FET acts as a switch that opens and closes very fast in a manner so that the pulses of voltage applied to the load can be controlled in frequency and duration.

If the interval or the width of the pulses changes, the amount of energy they transfer to the load also changes, and with them, the average voltage. By using a feedback circuit it is possible to control the width and interval between pulses to keep constant the average voltage applied to a load. So, in an SMPS exists a circuit that changes the voltage output, controlling the pulse width applied to the power FET to compensate the alterations and keep the output voltage constant. This kind of power supply is found in many types of electronic equipment, such as computers, video monitors, and TVs. In the linear mode, power FETs can be used as audio amplifiers or low-frequency signal amplifiers. A circuit where an audio signal is amplified by a power FET is shown in Figure 138.

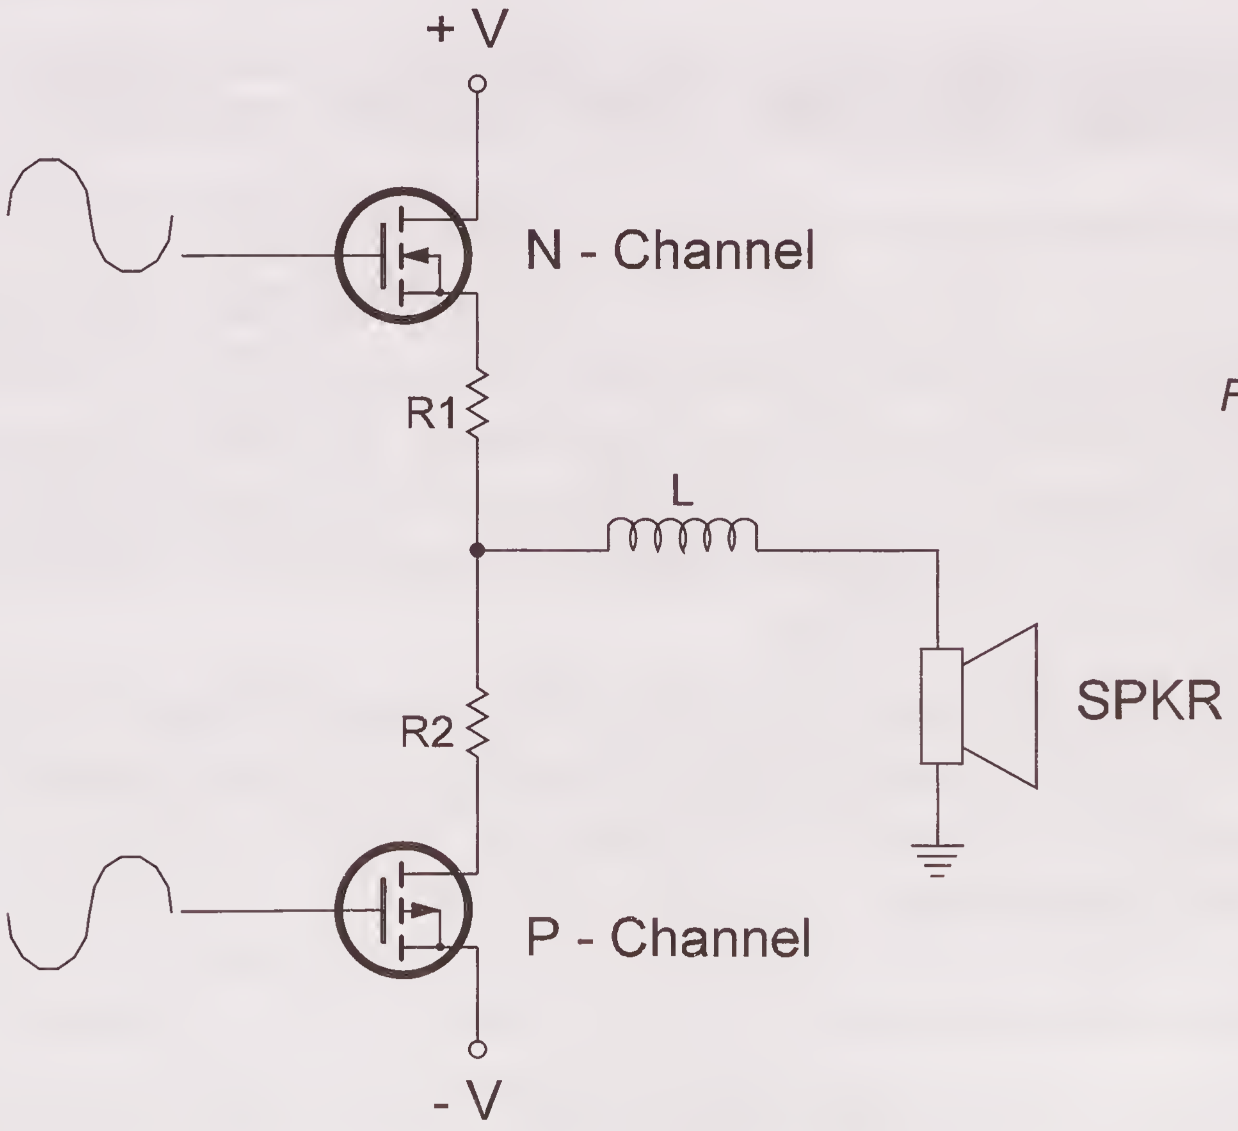

Figure 138

Alarms, which are a common type of audio equipment, can use this type of transistor in their output stages driving the loudspeaker with many watts.

High-fidelity (hi-fi) audio amplifiers that use power FETs are high-quality equipment presenting low distortion levels. The power FETs have characteristics similar to the ones found in the old tubes for amplifying low-frequency signals. Many enthusiasts of the bipolar transistor can't reproduce the sounds with the same quality found in old tube models. But, amplifiers using power FETs can present levels of fidelity closer to those found in the tube amplifiers better than the ones of bipolar transistors.

Testing

A simple multimeter can be used to test a power FET. The resistance between the gate and the other terminals must be very high in a good transistor. If a low resistance is measured the transistor has problems. A low resistance between gate and the other terminals indicates a transistor with losses or a short.

Isolated-Gate Bipolar Transistor—IGBT

The Isolated-Gate Bipolar Transistor or IGBT is a semiconductor device that combines the advantages of a bipolar transistor and a power FET. They are transistors where the main current or controlled current flows between a collector and an emitter as in a bipolar transistor, but is controlled by a gate voltage as in an FET. The advantage is that the device presents very high input impedance and the characteristics of commutation or control of a bipolar transistor.

IGBTs are used in the same functions where power bipolar transistors and power FETs are used, and in some cases they have advantages. They are used in applications where it is necessary to drive a high current load (solenoids, lamps, motors, etc).

Symbol

Figure 139 shows the symbol of an IGBT. As with other transistors, we can't identify an IGBT only by its appearance because it looks the same as bipolar transistors and power FETs. It is necessary have a part number or a schematic diagram of the equipment.

Specifications

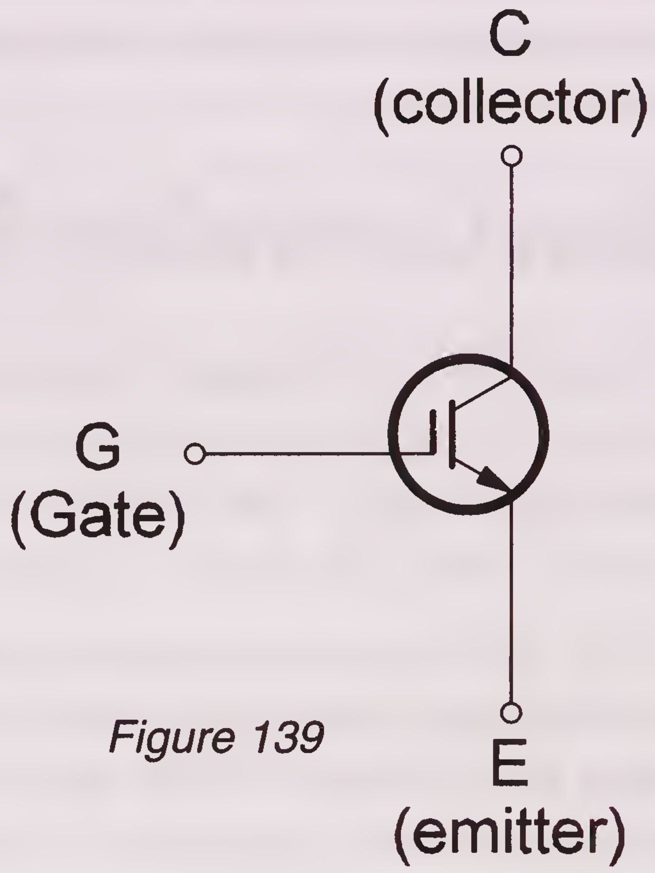

Figure 139

IGBTs are identified by a part number. From the part number, the electrical characteristics can be discerned. The main characteristics are as follows.

A. Maximum voltage between collector and emitter—the maximum voltage that can be applied to the device. It is also represented by Vce (max).

B. Maximum collector current—the maximum current that can be conducted by the device. It is also abbreviated by Ic (max).

C. Dissipation power—the maximum amount of power that the device can convert in heat and transfer to the surrounding area. It is given in watts and abbreviated as Pd (max) or Pd.

Where they are found

IGBTs are components widely found in industrial applications. The advantages of the use of this device in the control of high-current loads in industrial machines, such as motors, solenoids, electromagnets, and heaters, make them very commonly used in these types of equipment.

In many cases, the IGBT can directly replace a power FET or a Darlington bipolar transistor. The most the technician must do in many cases is change the value of some resistors in the circuit.

As IGBTs are new devices they are not very common in electric or electronic applications more than 10 years old. In home appliances, such as dishwashers, clothes washers, and others that use inductive loads, the IGBT can be found as the control element.

Testing

The simplest way to test an IGBT is measuring the resistance between the terminals. The resistance between the gate and the other elements in both directions must be very high. A low resistance in these measures indicates a shorted device or one with losses.

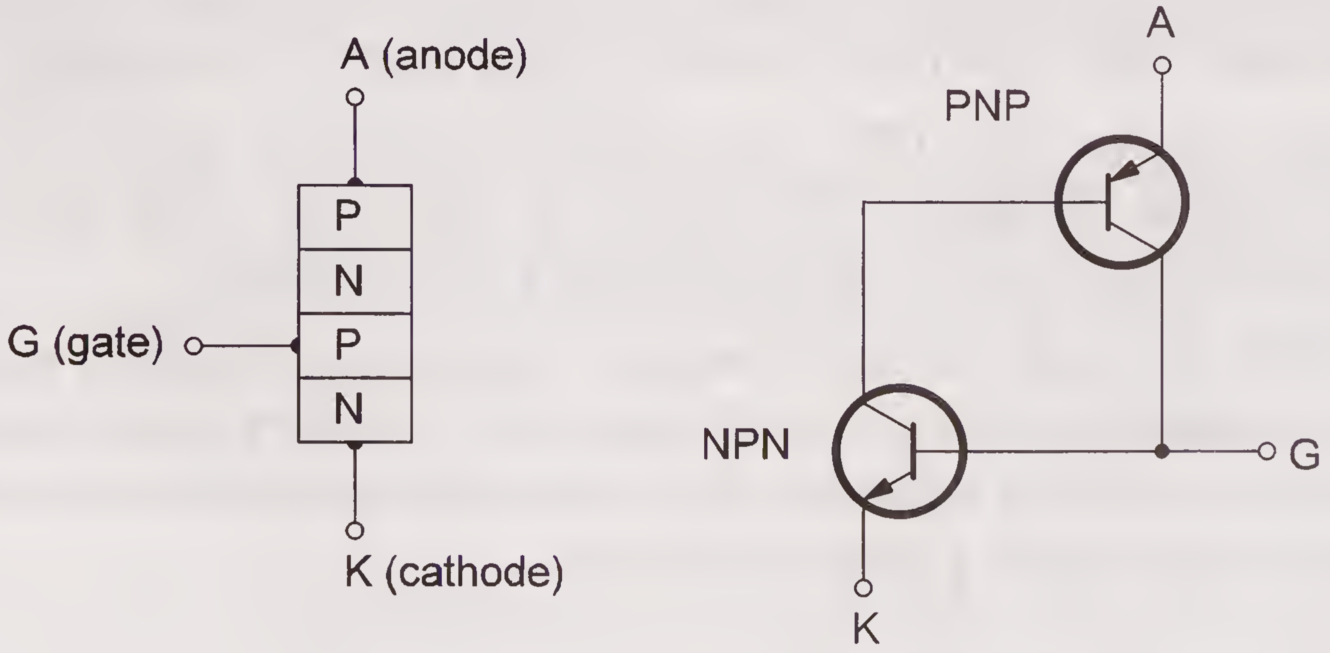
Silicon Controlled Rectifier—SCR

The SCR or Silicon Controlled Rectifier is one of the most important of the electronic devices the electrician will find in electric installations and appliances. In fact, the SCR is made to control devices plugged in to the AC power line in its basic configuration.

The SCR is a member of the thyristor family. Thyristors are four-layer semiconductor devices basically intended for applications of control and AC circuits. They are solid-state switches, can operate at voltages up to many hundreds of volts, and can handle currents up to hundreds of amperes.

As the SCR is very important to the electrician who wants to know how electronics devices are used in electric installations, more space than the usual dedicated to other components is given to their description and applications. So, what is an SCR, starting from its structure?

Figure 140 shows the structure of an SCR and the equivalent circuit formed by two complementary transistors. It is a silicon semiconductor with a PNPN structure.



(a) Structure)

(b) Equivalent circuit

Figure 140

In the basic operation the anode (A) is made positive and the cathode (K or C) negative. The load is placed between anode and the power supply. If no voltage is applied to the gate (G) the two transistors remain off and no current can flow across the load. But, if enough voltage is applied to the gate, it can make the NPN transistor conductive and a current begins to flow between its collector and emitter.

This current is the one that comes from the base of the PNP transistor biasing on this component. The current that now begins to flow by the NPN transistor acts as a feedback to the NPN transistor as it also flows through its base. The feedback makes all the currents in the circuit increase speed and in a few microseconds the circuit reaches a saturated state. The current between the collector of the PNP transistor and the emitter of the NPN transistor is now at its maximum value. After completion of this very fast process, even if the initial voltage that started all this is no longer present, the device remains conductive.

In a real SCR the process is the same: a positive voltage applied in the gate triggers on the device that conducts the current from the anode to the cathode. Even if the voltage disappears once it is triggered, the device is kept in the on state. To trigger it off there are two possibilities:

1. Turn off the power supply for a moment. This makes the device current fall to zero.
2. Reducing the current flowing through the device to a value that cuts the feedback process. A short between anode and cathode, reducing the voltage to zero (Figure 141), can be created to trigger the SCR off.

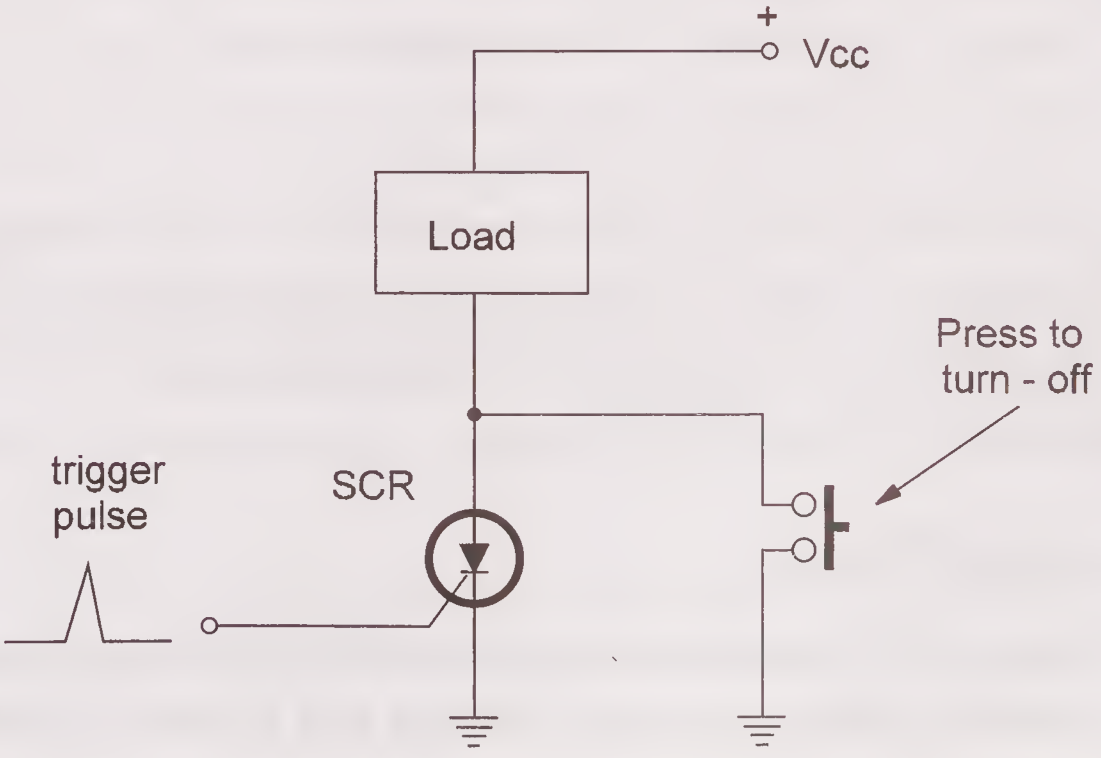


Figure 141

Notice that the SCR acts as a diode that can be made conductive or not conductive because the current flow only can flow in one direction. This explains its symbol—a diode with a gate.

Real SCRs can be triggered by voltages of about 1 volt and currents ranging from 100 microamperes for the most sensitive to some miliamperes for high current types and less sensitive types.

If placed in an AC circuit like the one shown in Figure 142, when turned on the SCR can conduct only the positive semicycles of the AC power line voltage.

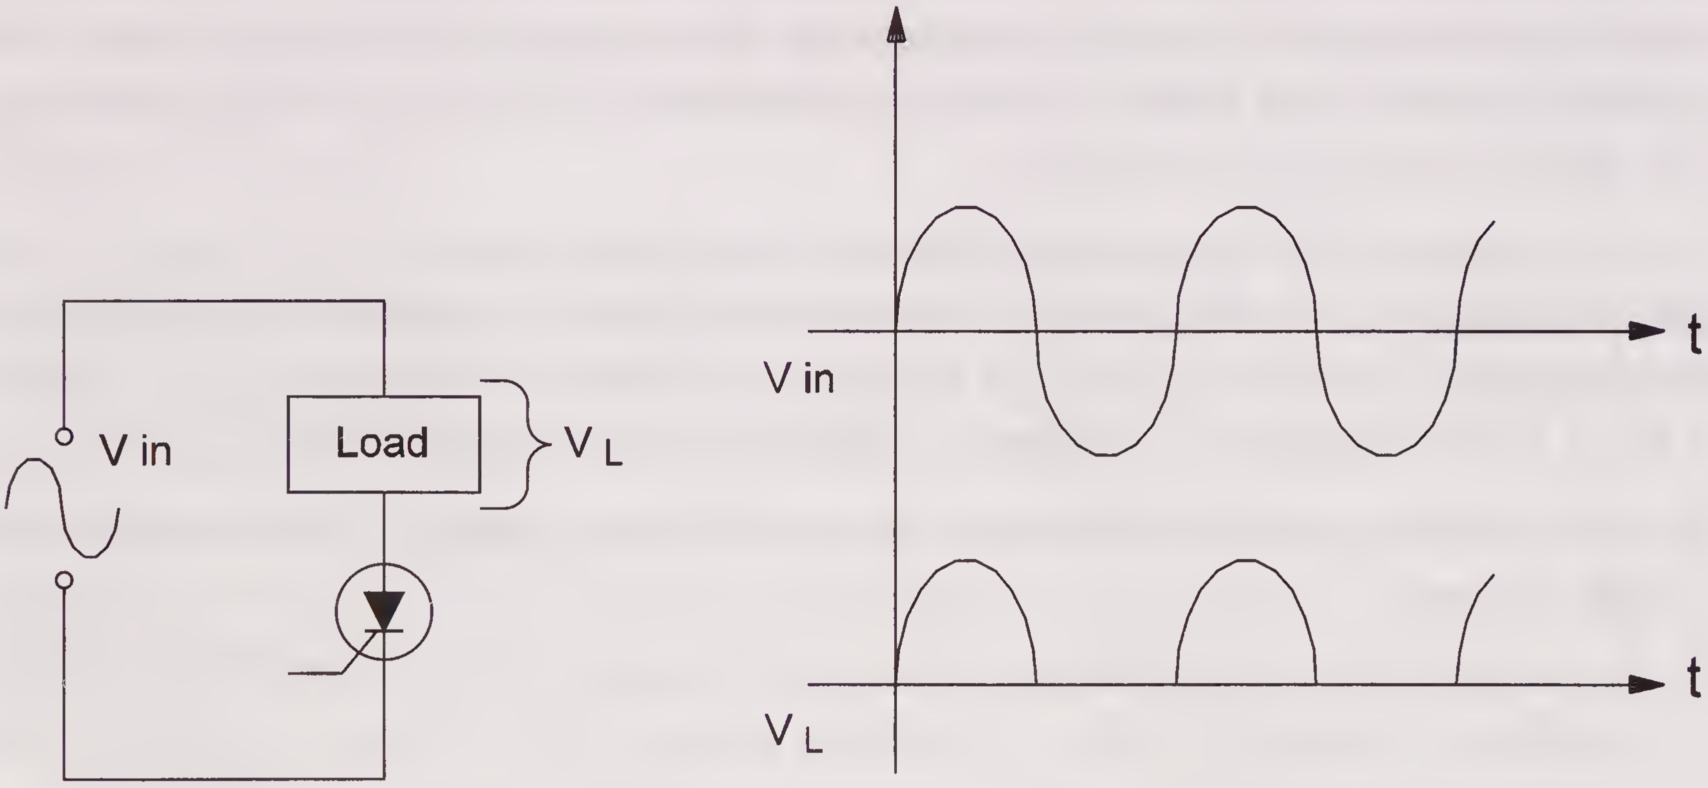

Figure 142

The SCRs can be used to control AC loads directly from the AC power line. The most common types can operate handling high voltages and high currents. This is because this device can be found in many applications related to the AC power line.

Symbol and Diagram

Figure 143 shows the symbol adopted to represent an SCR. The main types found in electronic equipment are shown in the same figure.

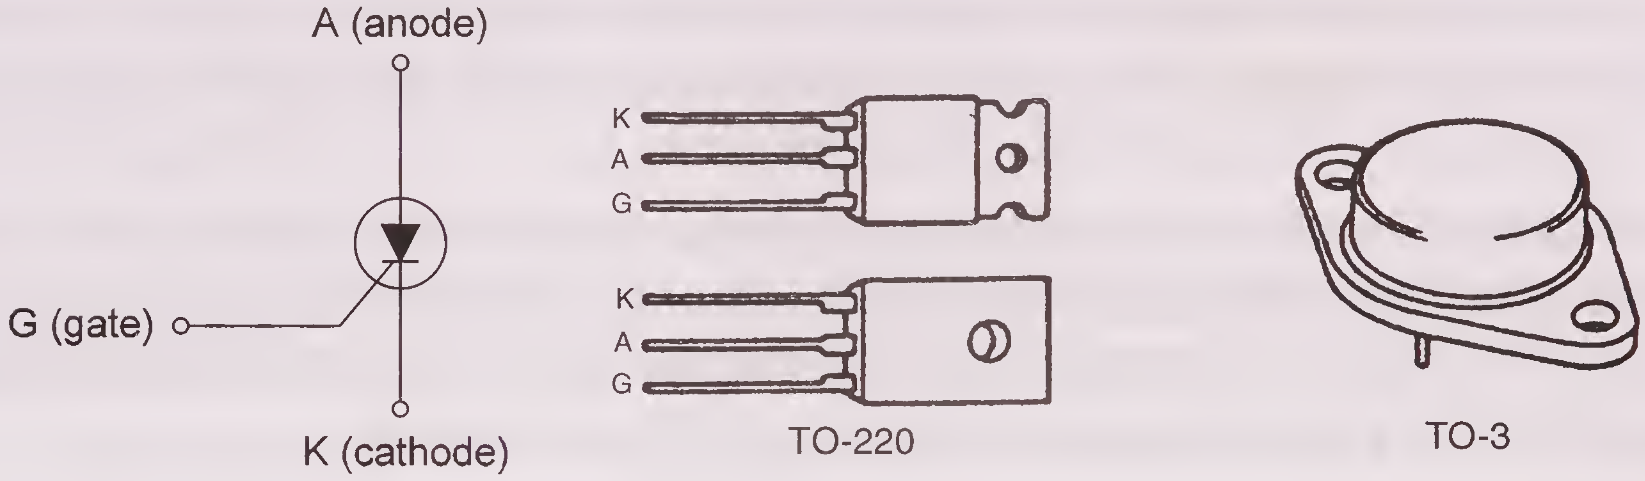

Figure 143

Although small SCRs designed to control low currents still exist, more of them are power devices including resources to place them on large heat sinks. The tab or the metal body of the SCRs used to be connected to the anode terminal.

Specifications

The SCRs are identified by a part number given by the manufacturer on the body. From this part number, looking in a handbook, in a databook, or on a data sheet it is possible to know the electrical characteristics.

When using any SCR it is important to know the following characteristics:

A. Maximum voltage between anode and cathode—the maximum voltage that can be applied to the SCR when it is in the off state. Typical values range from 50 to more than 1000 volts for common types. This specification can also be indicated as Repetitive Peak Off voltage and abbreviated by Vdrm or as Repetitive Peak Reverse Voltage and abbreviated by Vrrm.

B. Maximum current—the maximum current that the SCR can hold when in the conductive state. Common SCRs found in AC-powered appliances are specified to control currents in the range from a fraction of an ampere to more than 50 amperes.

C. Dissipation power—When an SCR is on, independently of the current it is conducting, the voltage between anode and cathode is about 2 volts. The product of this voltage by the current gives the dissipation of the

SCR. The maximum dissipation of an SCR is important to know in order to calculate the size and shape of the heat sink.

D. Holding current—the lowest current that the SCR can conduct without turning off. This current is abbreviated by I_H.

Other important specifications are the speed of the device given by the value referred to as Critical Rate of Rise of Off State Voltage and measured in volts by microseconds. This value shows how fast the voltage applied to the load increases when the SCR is turned on.

Where they are found

SCRs are found in several applications involving AC power control. Some devices where SCRs can be found are motor controls, timers, dimmers, alarms, solenoid drivers, and many home appliances.

The most common application of an SCR as a power control is the one shown in Figure 144.

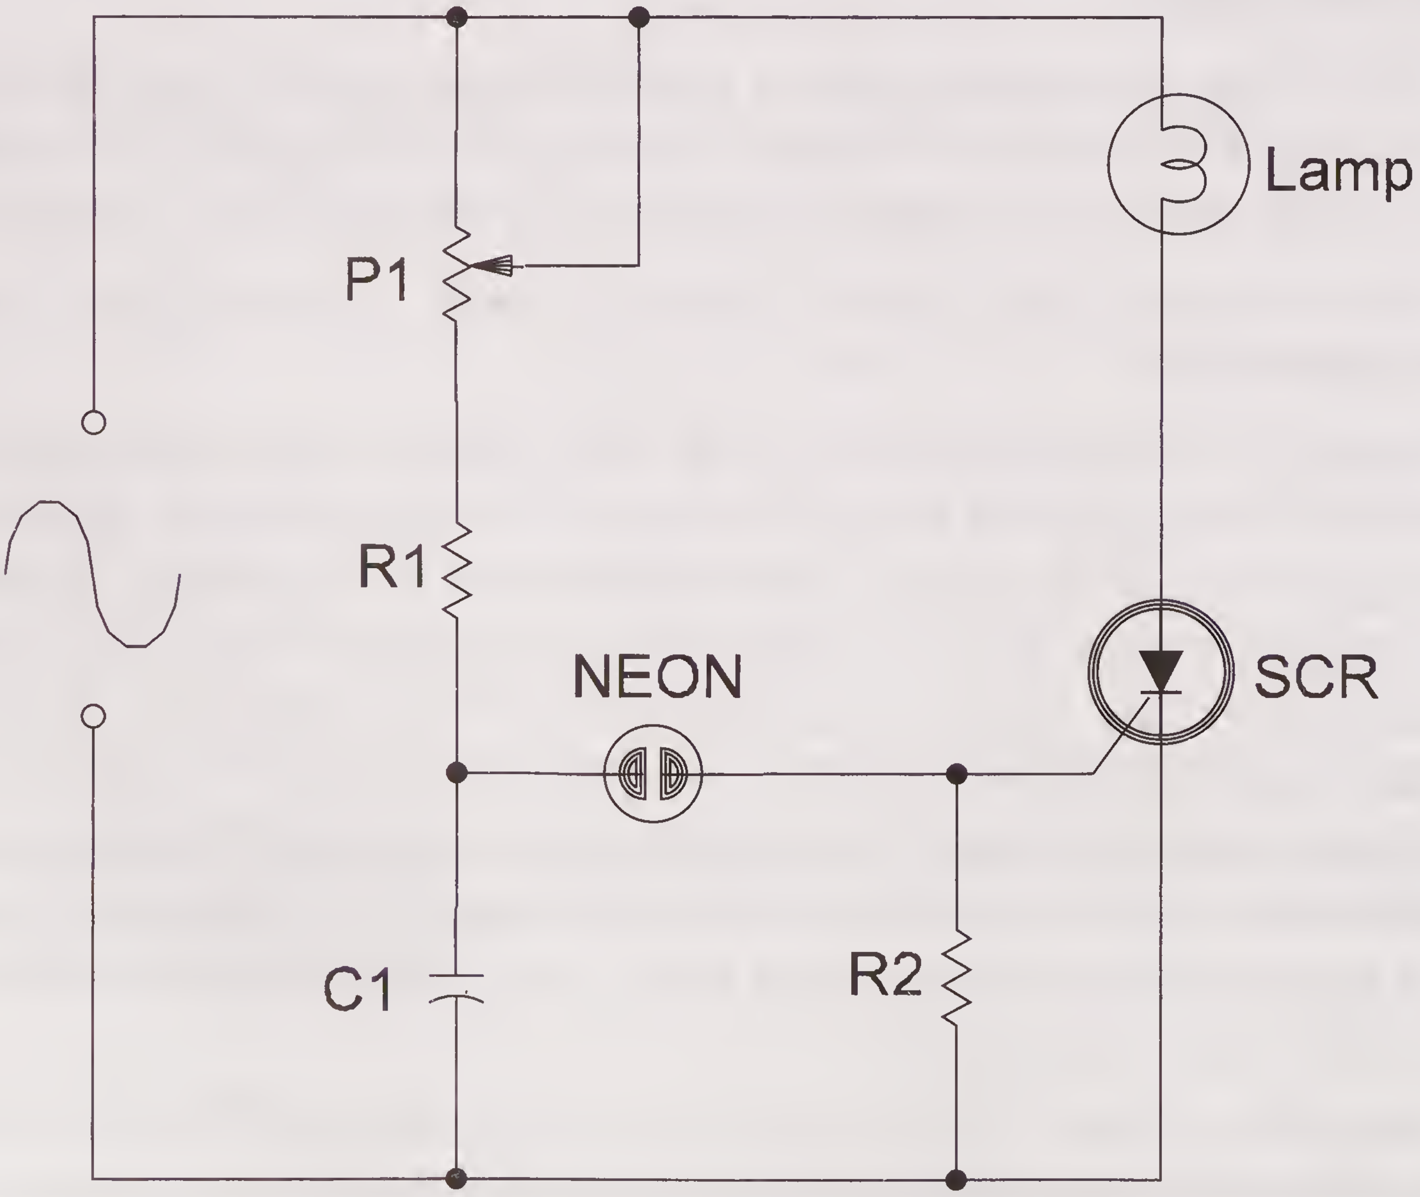

Figure 144

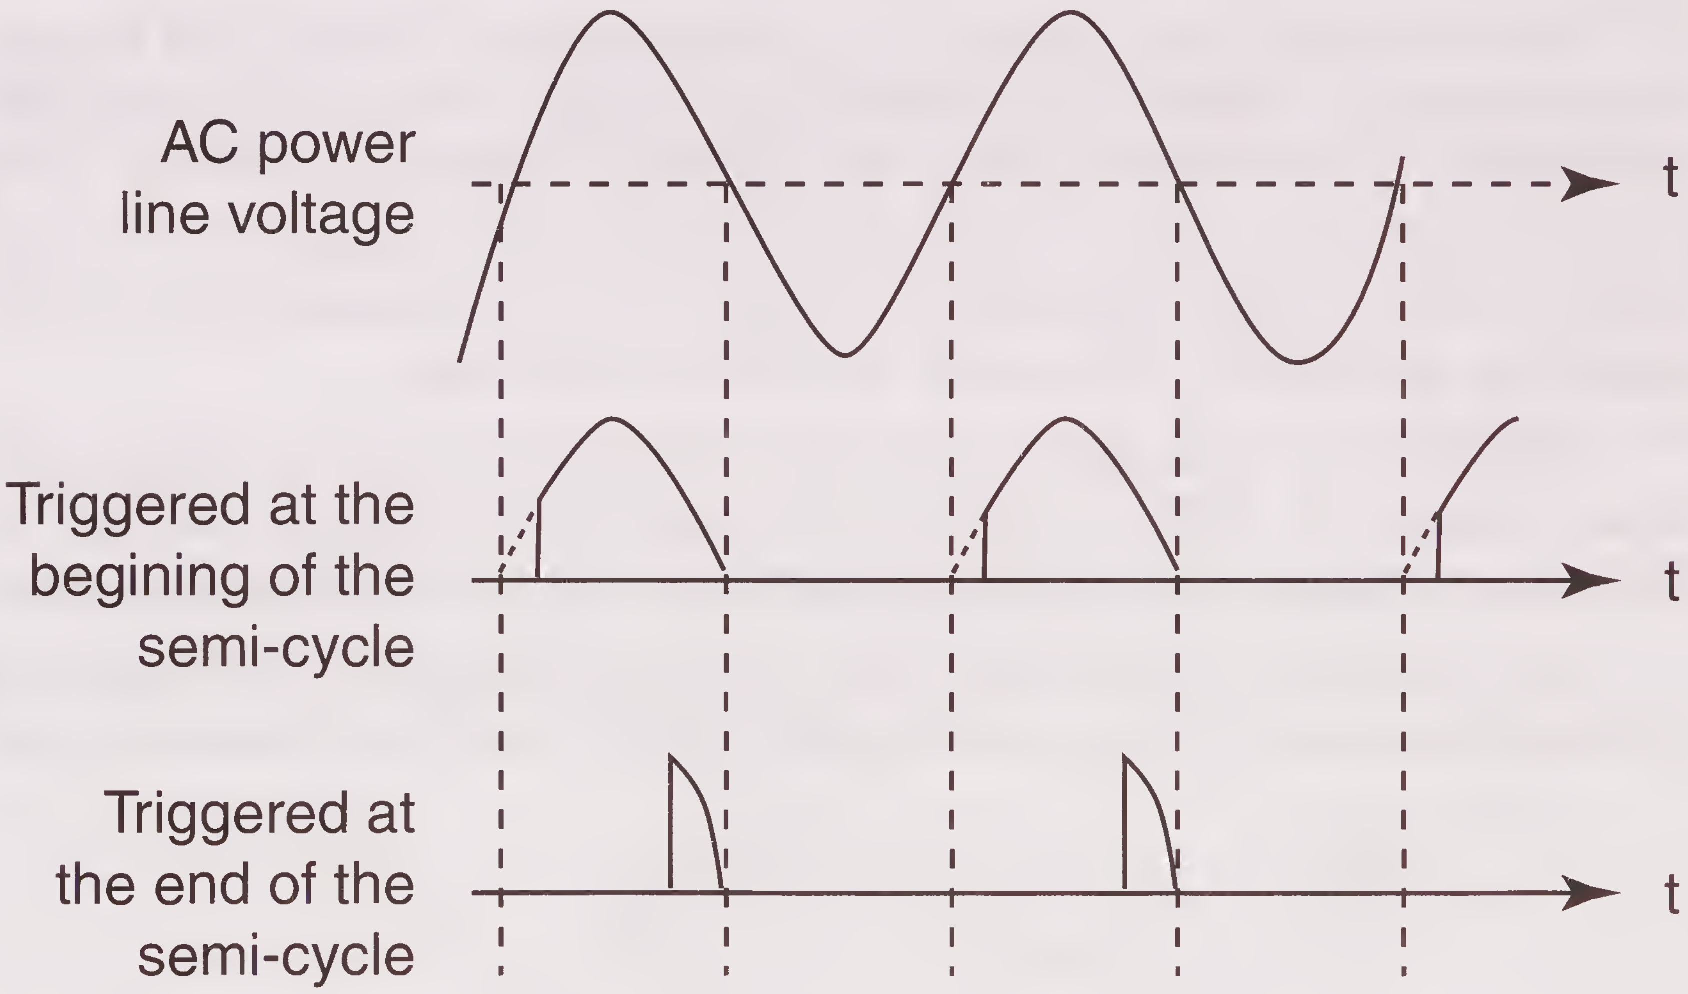
This circuit is found in commercial dimmers like those installed to replace common on/off switches. It is also used to control the brightness of incandescent lamps, in fans as a speed control, and in heaters as a temperature control.

It is very important for an electrician to know how this circuit works because its operation principle is applied to a large number of common electric appliances that have a power (speed, temperature, etc) control.

Look at the waveform of the AC power line voltage shown in Figure 145.



AC power line voltage
t
Triggered at the begining of the semi-cycle
t
Triggered at the end of the semi-cycle
t

Figure 145

The voltage changes make the current flow forward and backward across a load determining the amount of power absorbed by it. This can be reduced if we cut the semicycles of the AC power line voltage in different points.

For example, if the semicycles are cut at the end, only a small part of the AC power line voltage passes and is applied to the load. If it is a lamp it will present a low brightness. If it is a motor it runs at low speed. If it is a heater the temperature is lower. If the semicycle is now cut at the beginning, a larger part of the power passes and is applied to the load. If it is a lamp, the brightness is increased, a motor runs at a higher speed, and a heater is warmer.

Using an appropriate control, we can slide the point where the semicycles are cut from near zero to 100 percent and thus control, with a great precision, the amount of power applied to a load.

The circuit shown in Figure 144 makes this control. At the beginning of a semicycle of the AC power line the voltage applied to the capacitor C increases in speed depending on the value of the component and the value of the resistance adjusted in the potentiometer P1.

If the potentiometer is placed in a low-resistance position, the capacitor charges fast and the voltage necessary to trigger on the SCR is reached at the beginning of the semicycle. More power is applied to the load. If the potentiometer is now slid to a high-resistance position, the capacitor charges slowly and the voltage necessary to trigger the SCR is reached only at the end of the semicycle. Less power is applied to the load.

Notice that in both cases, when the semicycle ends, the voltage falls to zero letting the SCR turn off. As the capacitor discharges through the SCR when it triggers on, in the next semicycle, the process begins again.

By sliding the potentiometer from zero to 100 percent of its resistance it is possible to control the power applied to the load in a range that typi-

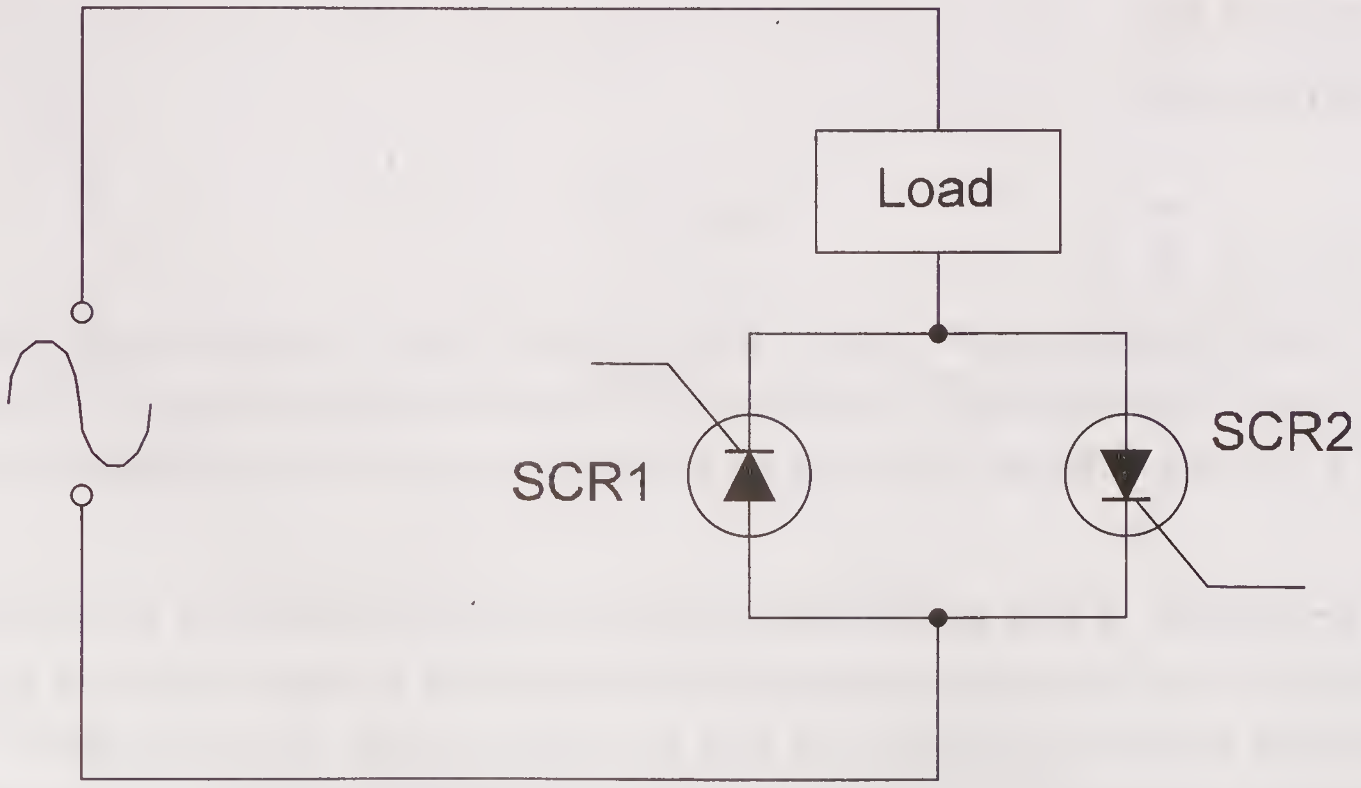


Figure 146

cally goes from near 0 to 95 percent of the maximum power. A little problem must be considered in this circuit: the SCR is a unilateral device and the AC loads must receive both semicycles to reach their normal maximum power. How can this problem be solved?

In some cases the circuit can operate only with the positive semicycles of the AC power supply line, and the SCR can be used. In other cases, two SCRs wired in an anti-parallel mode are used, as shown in Figure 146. One SCR conducts the positive semicycles and the other conducts the negative semicycles of the AC power line voltage.

Another solution to the problem is in the use of a diode bridge (rectifier) that converts the AC power line voltage into a DC pulsed voltage, or a voltage formed only by positive voltage semicycles as shown in Figure 147.

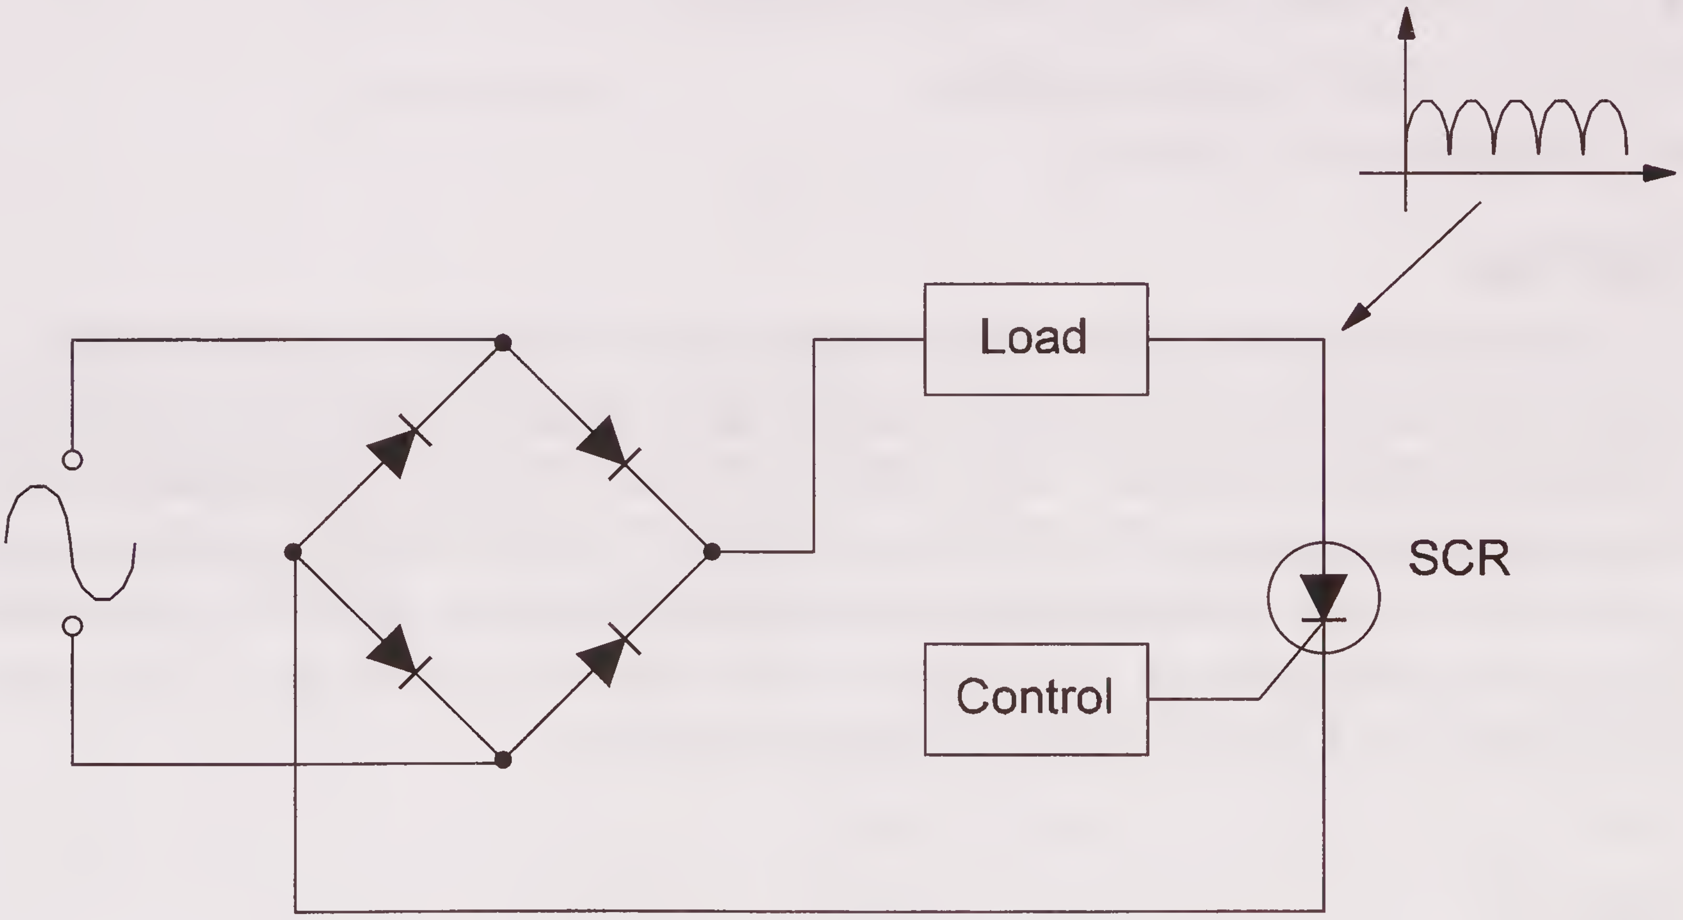

Figure 147

But, the best solution is in the use of another device of the thyristor family—the triac. The triac can be considered as two SCRs inside a unique case that can be used to control both semicycles of the AC power line voltage. The SCR is not used only as a power control. Many other configurations are possible including timers, oscillators, alarms, automatic switches, and protection circuits (crowbar).

The 106 Series

One of the most popular series of SCRs found in many electronic circuits is the 106 series. It is formed by low-cost general-purpose SCRs that can control currents up to 3 or 4 amperes (3.2 volts average for the TIC106) in circuits having voltages in the range between 50 and 1000 volts. The devices of this series are very sensitive; they can be triggered from currents as low as 60 uA (typical). The part number of the SCRs of this series begins with a group of letters identifying the manufacturer followed by 106, and a figure indicating the maximum operating voltage.

Some examples follow.

- MCR106-B (Motorola - the B indicates it is for 200 V)
- TIC106-6 (Texas Instruments for 400 V)
- IR106 (International Rectifier)
- C106 (General Electric)

Testing

SCRs can be tested with a multimeter. In normal conditions the device is an open circuit when the resistance between anode and cathode is measured (the multimeter will indicate infinite). If a low resistance is measured in this condition the SCR is shorted. The other test consists of the verification of the gate-cathode junction that acts as a diode. In one direction a low resistance is found and in the opposite direction a high resistance is found if the device is in good condition.

Triac

The Triac is another important device of Thyristor family. As demonstrated, SCRs are unidirectional thyristors meaning that they can control the current only in one direction—from anode to cathode. Unlike the SCR, triacs are bidirectional and can conduct the current in both directions. Compare a triac to two SCRs connected in inverse parallel (anti-parallel) and placed inside a single three-terminal case as shown in Figure 148.

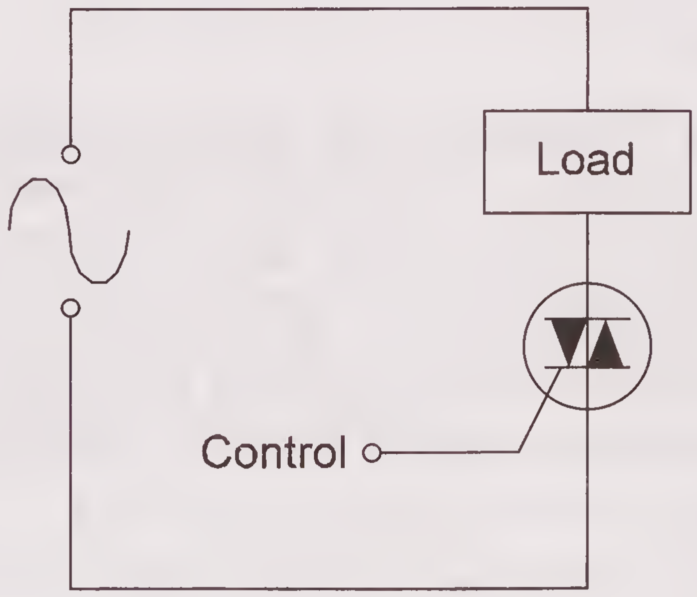
Figure 148

The triac is indicated to applications where AC voltages must be controlled meaning that a large range of applications in domestic and industrial installations includes this component. So, it is another device with a large degree of importance for the electrician. In basic applications the triac is connected in a circuit as shown in Figure 149.



Load
Control

Figure 149

Like the SCR, the triac can be used as a power switch controlling a large amount of alternating current from the main terminals (MT1 and MT2) from a low voltage applied to the gate. Unlike the SCRs that need only positive voltages applied to the gate to be turned on, triacs can be triggered either by a positive or a negative gate signal, regardless of the polarities of the main terminal voltages. This means that the device can be triggered by four modes, indicated as follows:

- I+ Mode = MT2 positive and gate current positive
- I– Mode = MT2 positive and gate current negative
- III+ Mode = MT2 negative and gate current positive
- III– Mode = MT2 negative and gate current negative

The gate sensitivities in the I+ and III– modes are high and in the other modes are lower.

Common triacs need only some miliamperes of current in the gate to be turned on and once in the conductive state, high currents in the range from some amperes to more than 1000 amperes can be controlled.

Symbol

Figure 150 shows the symbol adopted to represent a triac.

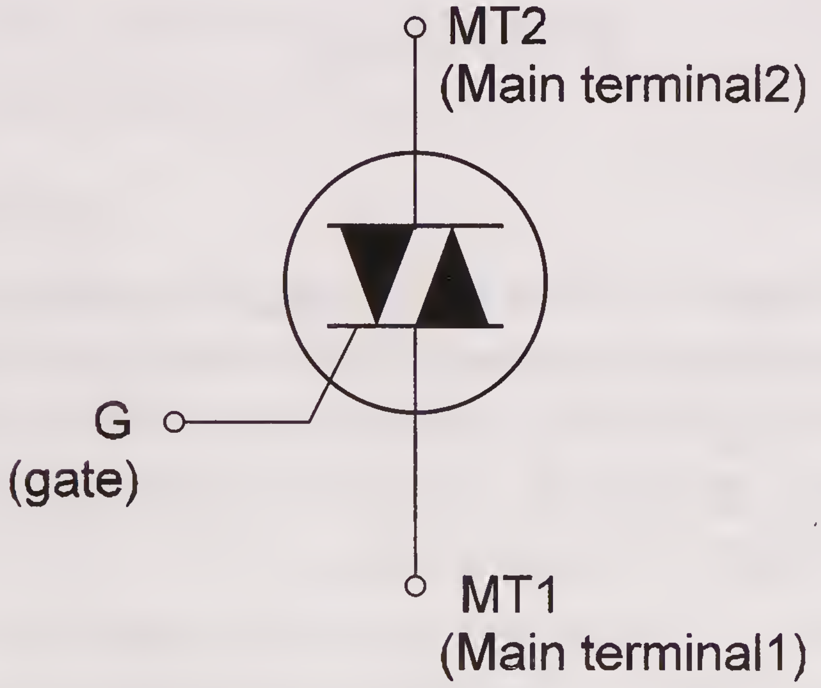


Figure 150

The body is the same as that used by high-power transistors, SCRs, and many other components. Notice that they are basically high-power solid-state switches and must be mounted in heat sinks when handling high currents. The identification of the terminals (MT1, MT2, and G) is made using the information of the data sheet or documents of the manufacturer as it changes from type to type. A general rule is that MT1 used to be connected to the case or to the tab.

Specifications

The triacs are identified by a part number displayed as a figure on the body, the same way the SCRs, transistors, and many other solid-state devices are. From the part number, using a data sheet or other document from the manufacturer, it is possible to find the electrical characteristics of the device. The inverse procedure is valid as well; from the characteristics, it is possible to find a triac suitable to an application by the part number.

The main specifications to be observed in a triac are:

A. Maximum voltage—the maximum voltage that can be applied to the triac in the off state. They are indicated also as the Repetitive Pulse Reverse Voltage (Vrrm) or Repetitive Peak Reverse Voltage (Vrrm) and can be typically in the range between 50 and more than 1000 volts for common types.

B. Maximum current—the maximum current that can be controlled by the device is indicated as the Continuous On State Current or average On State and can be in the range of 1 ampere to more than 100 amperes for common types.

C. Trigger current and voltage—the current that triggers the triac on is indicated as the Gate Trigger Current and abbreviated by Igt. Typically this current is in the range between some microamperes and 100 mA depending on the size of the device. The trigger voltage is also indicated as Vgt and is typically in the range between 0.8 and 1.5 volts for common types.

D. Dissipation power—When the triac conducts the voltage across, it is typically between 1.7 and 2.2 volts. This voltage times the controlled current or the load current gives the dissipation power of the device. The maximum dissipation depends on the device.

Where they are found

Triacs are found in all the modern applications where a speed, temperature, or power control must be made from an AC power line voltage. We can say that triacs are solid- state switches with a large range of applications in AC control.

Dimmers, speed motor control of electric appliances, heaters, and many other circuits use triacs as a central element.

Figure 151 shows a typical power control or dimmer for loads powered from the AC power line using a triac.

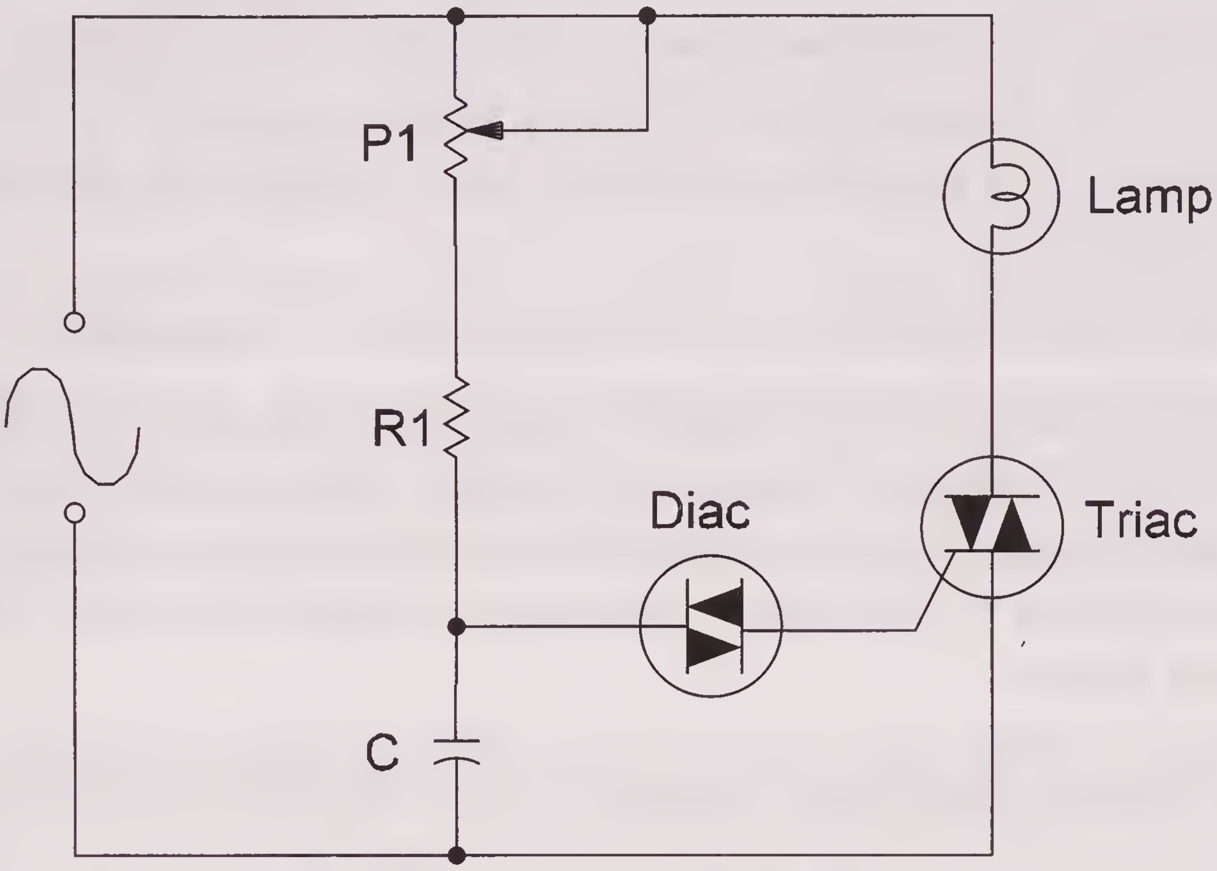

Figure 151

The operation principle is the same as the power control using SCRs previously described. The only difference is that the capacitor charges with both semicycles of the AC voltage and the triac triggers with them conducting both to the load.

The waveforms in the circuit are shown in Figure 152.

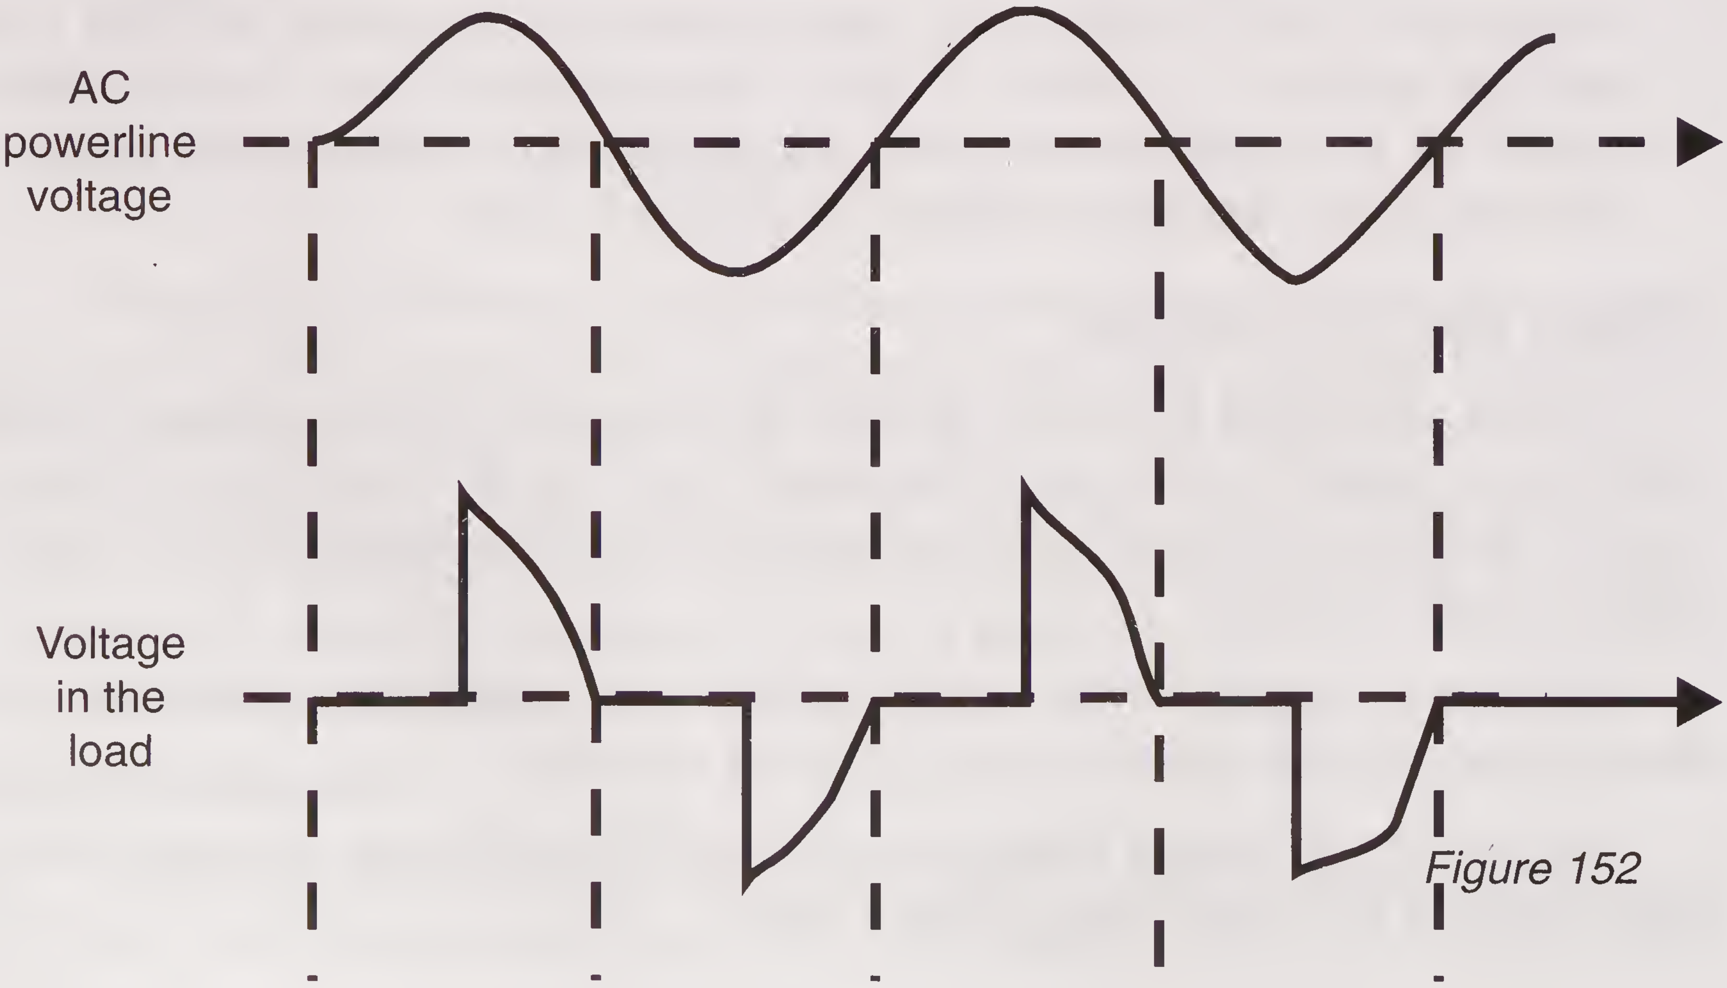

Figure 152

The diac is an auxiliary element used to help the triac trigger with the correct voltage adjusted by the potentiometer. Circuits like this are used in common incandescent lamp dimmers replacing common on-off switches. The speed control of motors used in electric appliances, such as drills and fans, use a circuit like this.

Testing

The best way to test a triac is using an appropriated circuit for this task. The multimeter can only reveal if a triac is shorted. If a low resistance is measured between MT1 and MT2 in a triac out of a circuit it is because it's shorted. When replacing a triac by an equivalent type, the specifications (voltage and current) must be equal or greater than the original.

Electromagnetic Interference (EMI)

Triacs and SCRs are high-speed power switches. Their turn-on and off times are very low, only a few microseconds, and this can cause problems with Electromagnetic Interference.

EMI or RFI (Radio Frequency Interference) is the interference caused by undesirable radio signals produced by devices like thyristors affecting the operation of many sensitive pieces of electronic equipment.

When an SCR or triac is used in a circuit as power control, the high-speed changes of the current in a load result in the generation of a series of harmonically related radio-frequency signals. The magnitude of the fundamental signal is proportional to the magnitude of the controlled current, and in a larger part of the cases, can be great enough to cause interference in AM radios and many other circuits that operate with low- and medium-frequency radio signals.

Specifically, the interference is higher when the SCR or triac controls inductive loads in motors, solenoids, magnets, etc. The snap action of the triac or SCR makes the current oscillate in the circuit generating a strong electromagnetic field.

A protection circuit that minimizes the interference is shown in Figure 153. The capacitor and the resistor form a damping circuit reducing the current oscillation and the electromagnetic interference.

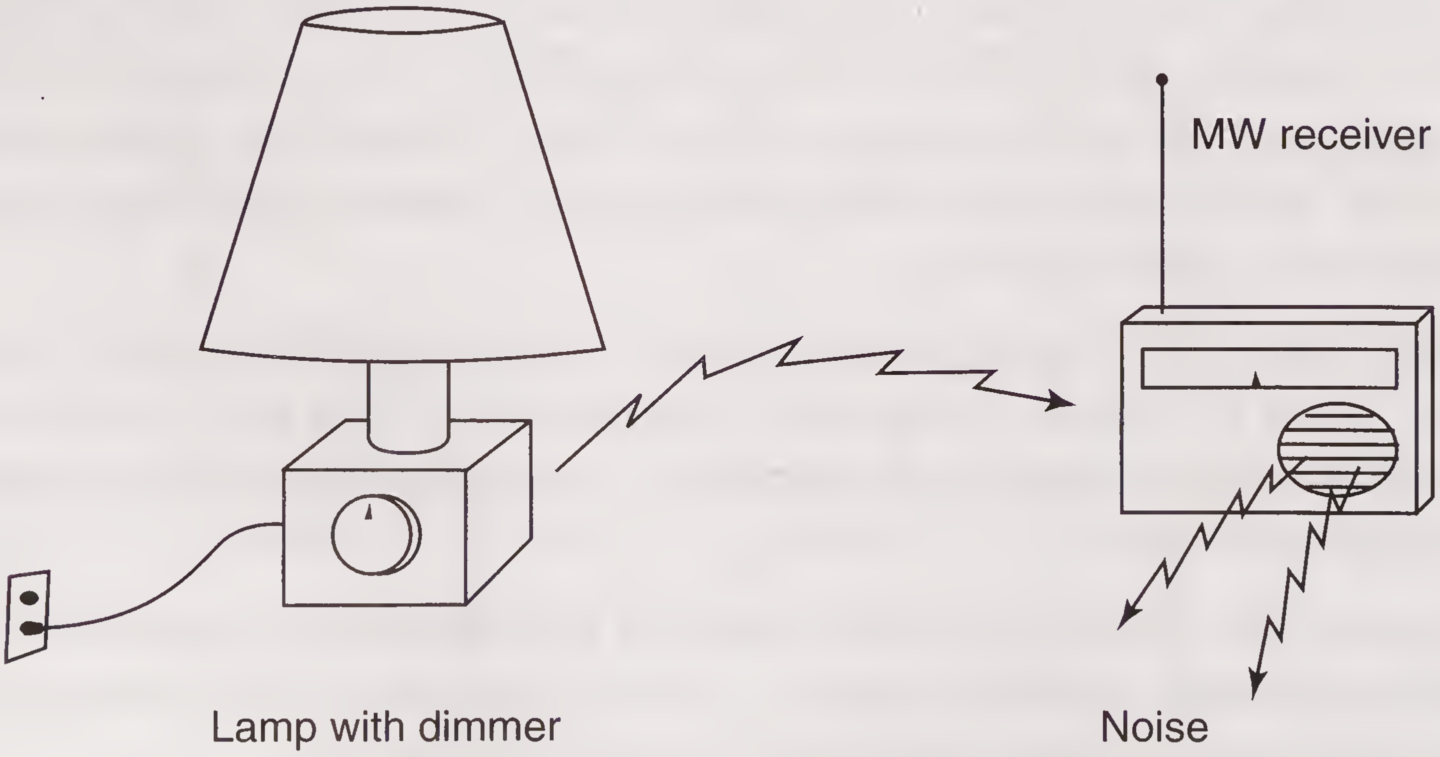
Figure 153

The noise in an AM radio receiver produced when a circuit using triacs or SCRs is turned on or the small dots and points in a TV screen when the same device is turned on are examples of the interference process.

The interference can reach the radio receivers, TVs, or other sensitive devices two ways. The first way is for it to be irradiated directly into the air as a radio signal (Figure 154).



MW receiver
Lamp with dimmer
Noise

Figure 154

The undesirable signal, in general, is very weak and only causes problems if a radio or other type of sensitive equipment is placed near the source of interference. It is also concentrated in the low band of the radio spectrum as shown in Figure 155, interfering much more with power in the LF (low frequency) and MW (medium wave) band.

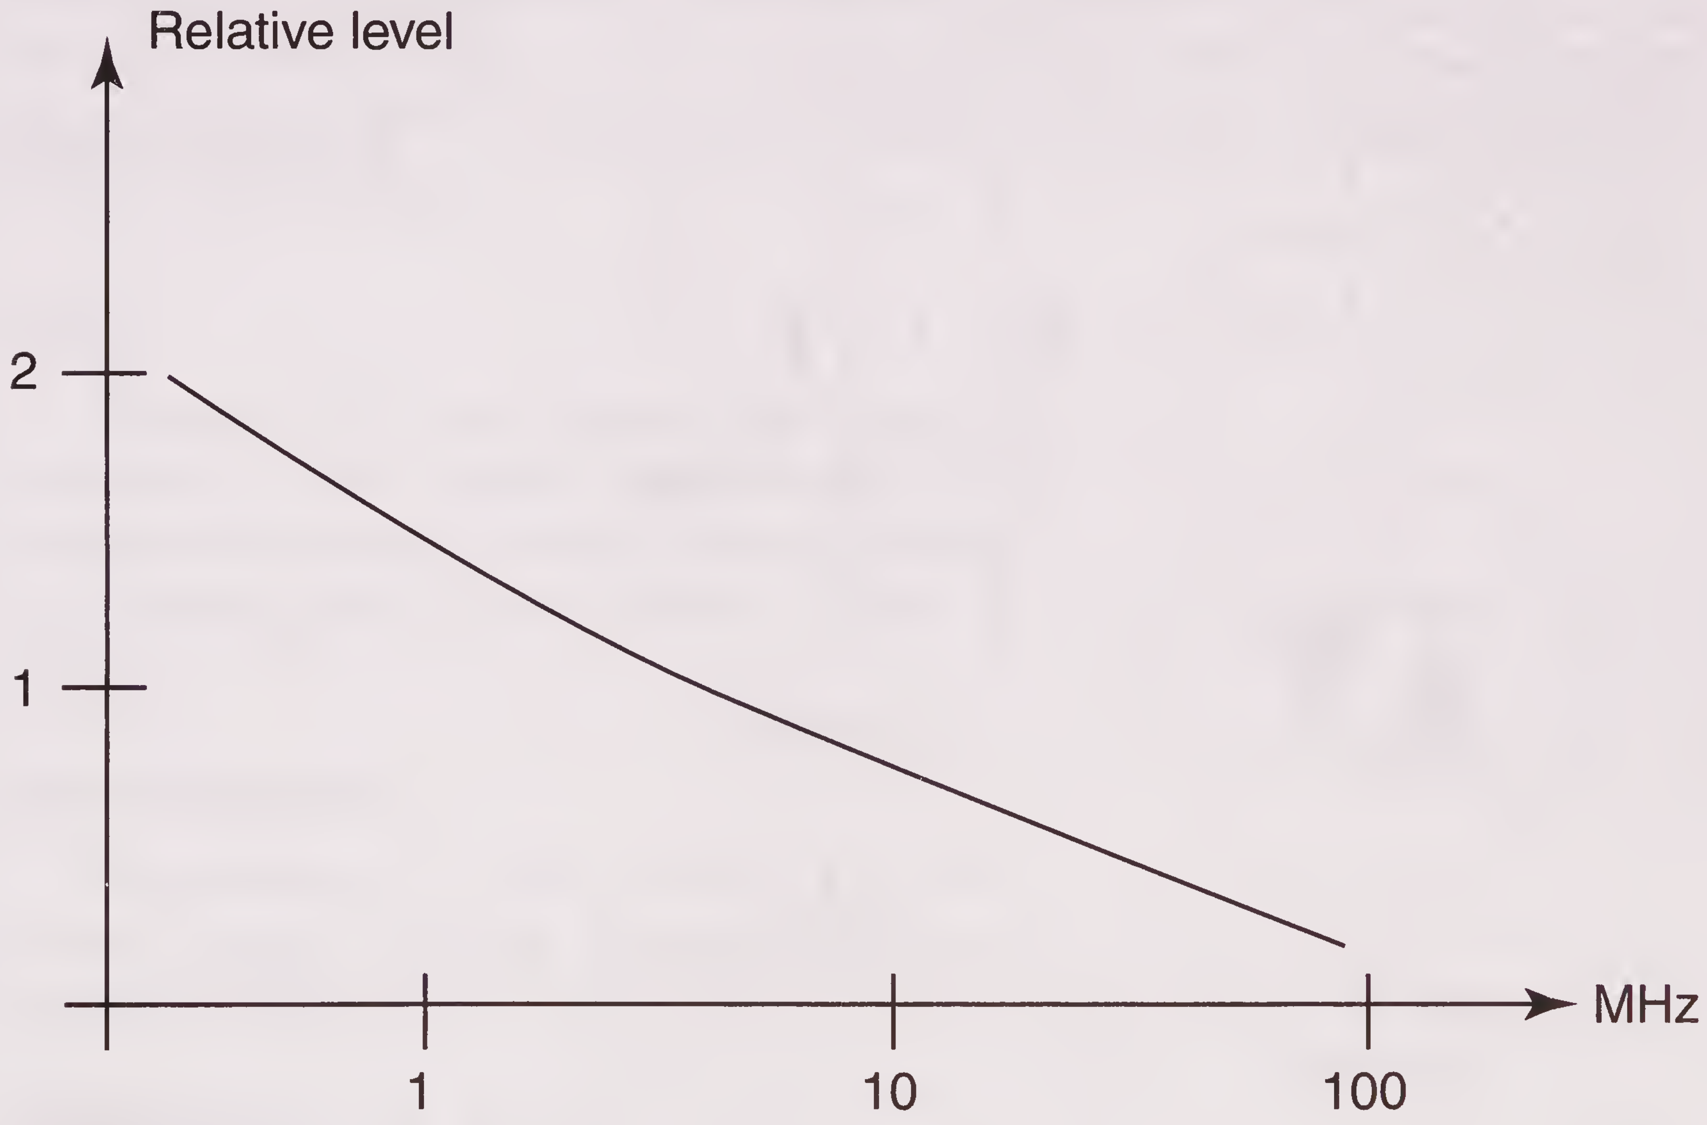


Figure 155

Radio receivers operating at higher frequencies, such as FM receivers, VHF receivers used in remote controls for garage doors, and cellular telephones aren't much affected by this interference not because of lower power concentrated in this band, but also because of their operation principles.

Secondly, the signal reaches the interfered equipment by the AC power line, as shown in Figure 156.

To avoid the interference in this case, use an L-C filter like the one shown in Figure 157.

The electrician can have this problem many times. When installing a dimmer or other device using SCRs and triacs in any domestic electric installation, a TV or an AM radio placed near it or powered from the same

AC power line can interfere. A filter like the one shown in Figure 157 placed between the dimmer or the interfering equipment and the power source can solve the problem or reduce the interference to a comfortable level.

Diac

The DIAC is another semiconductor device of the thyristor family. It is also a four-layer component with special trigger characteristics. The diac is the semiconductor equivalent of the neon lamp. When the voltage across a diac reaches a certain value, the device triggers on, passing from a high-impedance state to a very low-impedance state. The high-speed triggering characteristics of this component make it ideal as a trigger element for circuits using triacs.

Symbol

Figure 158 shows the symbol used to represent a diac. Notice that the diac is a nonpolarized component because the triggering characteristics are the same in both directions.

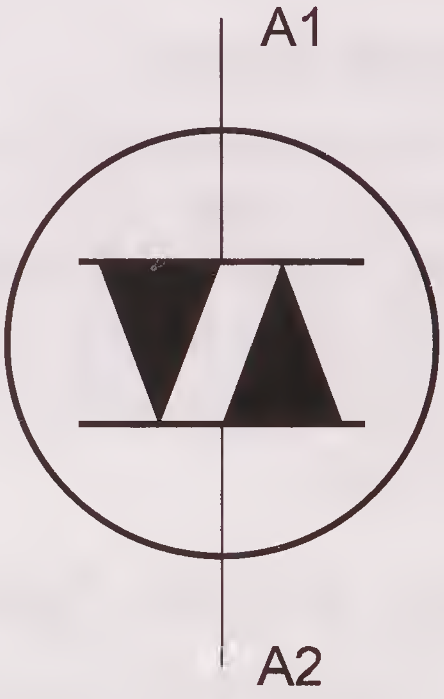

Figure 158

Specifications

Associated to a part number, the diacs have a trigger voltage. Typical values are around 35 volts.

Where they are found

Although many applications exist with diacs as a central element of a circuit, the most common is as a trigger element of a triac as in the dimmer. Speed controls for electric motors and dimmers are examples of circuits of where triacs are found, the triggering devices are the diacs.

Testing

The multimeter can't be used to test diacs as they don't have enough voltage to trigger the multimeter and when turned off, they act as an open circuit. The best way to test a diac is using a circuit. The multimeter can only reveal if the diac is shorted when presenting a very low resistance.

Quadrac

The quadrac is a device formed by a diac and a triac in the same body. It is also used as a power control for incandescent lamps, heaters, motors, and other inductive loads the same way the triacs and diacs are used.

Symbol

Figure 159 shows the symbol of a quadrac. They use the same body as power transistors.

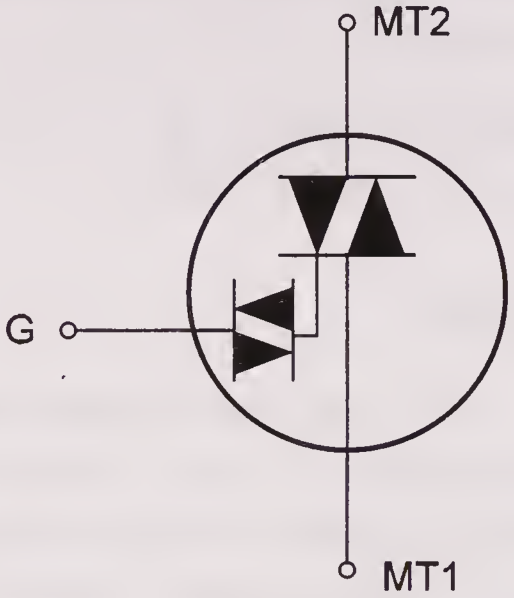

Figure 159

Specifications

The specifications of a quadrac are the same as a triac and a diac. The maximum voltage, maximum current, and trigger point are indicated by the manufacturer. A part number or type number is used to design the component.

Where they are found

Quadracs are not common today. They can be found in old motor controls, lamp dimmers, and some electric appliances where the speed of a motor, temperature, or any amount of power applied to an AC load must be controlled.

The basic application is the same as a triac in power controls as explained before.

Testing

The multimeter can only reveal if the quadrac is shorted. Low resistance between any of the three terminals indicates a problem.

Silicon Unilateral Switch—SUS

The Silicon Unilateral Switch is a device of the thyristor family and is used as a trigger element in circuits using SCRs. The SUS is an SCR with an anode gate and a built-in zener diode, as indicated by the equivalent circuit shown in Figure 160.

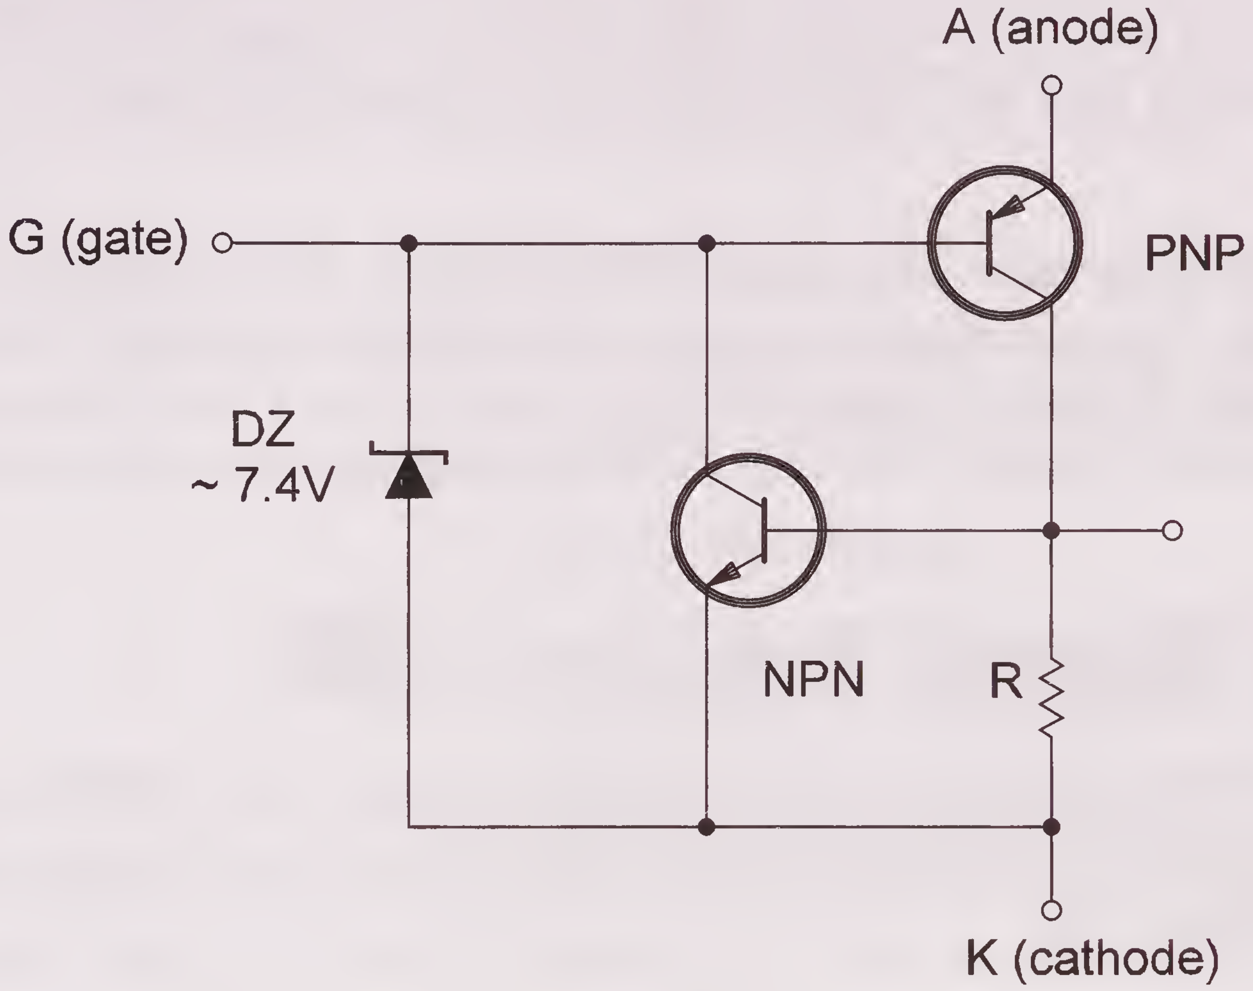

Figure 160

The zener diode determines the triggering voltage, which is normally around 8 V. But, by connecting a lower-voltage zener between the gate and the cathode it is possible to reduce the triggering voltage.

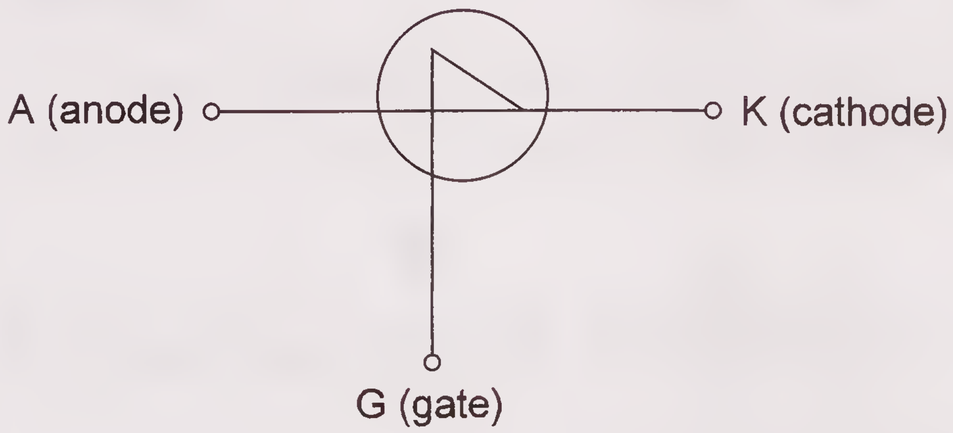

Figure 161

Symbol

Figure 161 shows the symbol of an SUS. It looks the same as a common low-power transistor because they use the same bodies.

Specifications

The main specification of an SUS is the triggering voltage or the internal zener voltage. Other specifications are the maximum current and the maximum voltage supported by the device. Manufacturers identify SUS by part numbers.

Where they are found

Silicon unilateral switches are not common devices today. They can sometimes be found in circuits using SCRs as a trigger element. The applications using only an SUS as core of any project are rare.

Testing

A multimeter can only reveal if the SUS is shorted between anode and cathode. The resistance between gate and anode is low in one direction and high in the opposite direction due to the PN junction between these two points. Ideally, the test must be made using a special circuit.

Silicon Bilateral Switches—SBS

Silicon Bilateral Switches (SBS) are devices of the thyristor family. It can be considered the same as two SBS wired in anti-parallel mode as shown in Figure 162.

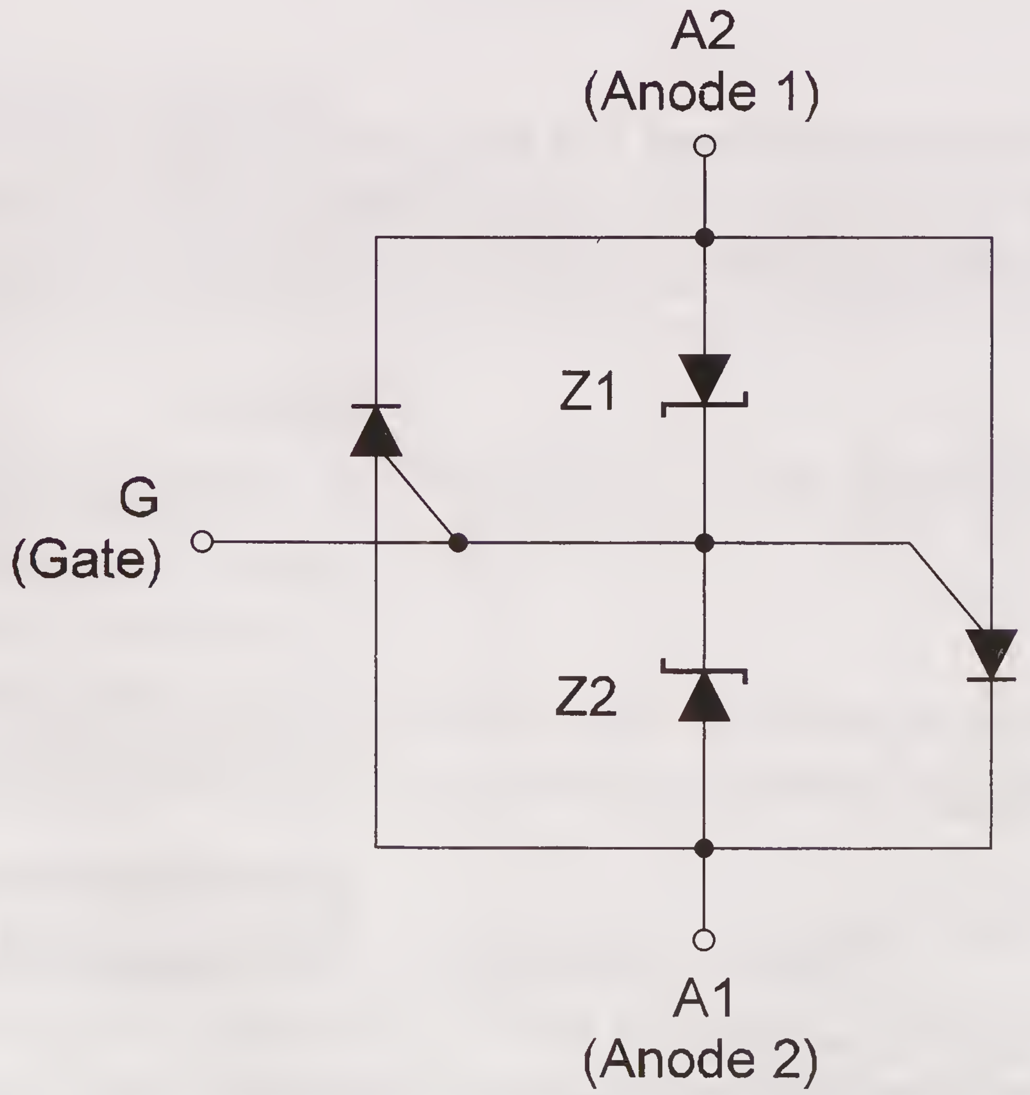

Figure 162

They are used as triggering elements for circuits using triacs. The operation is the same as the SUS; the internal zener diodes determine the trigger point of each SUS and the gate can be used to alter this value. External zener diodes can be wired between the gate and the two other terminals (A1 and A2) to lower the trigger point of the device.

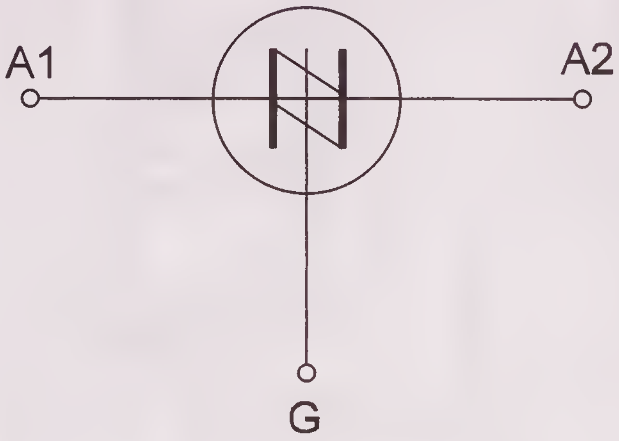

Figure 163

Symbol

Figure 163 shows the symbol adopted to represent the SBS.

Specifications

A part number is adopted by the manufacturer to indicate the device is an SBS. However, only with a data sheet or other manufacturer's document is it possible to access the electrical characteristics of the device, which are the maximum current and voltage between A1 and A2 and the voltage of the internal zener diodes.

Where they are found

The SBS isn't a common device in modern equipment. They can be found in some equipment using SCRs as motor controls, timers, alarms, sensor interfaces, etc.

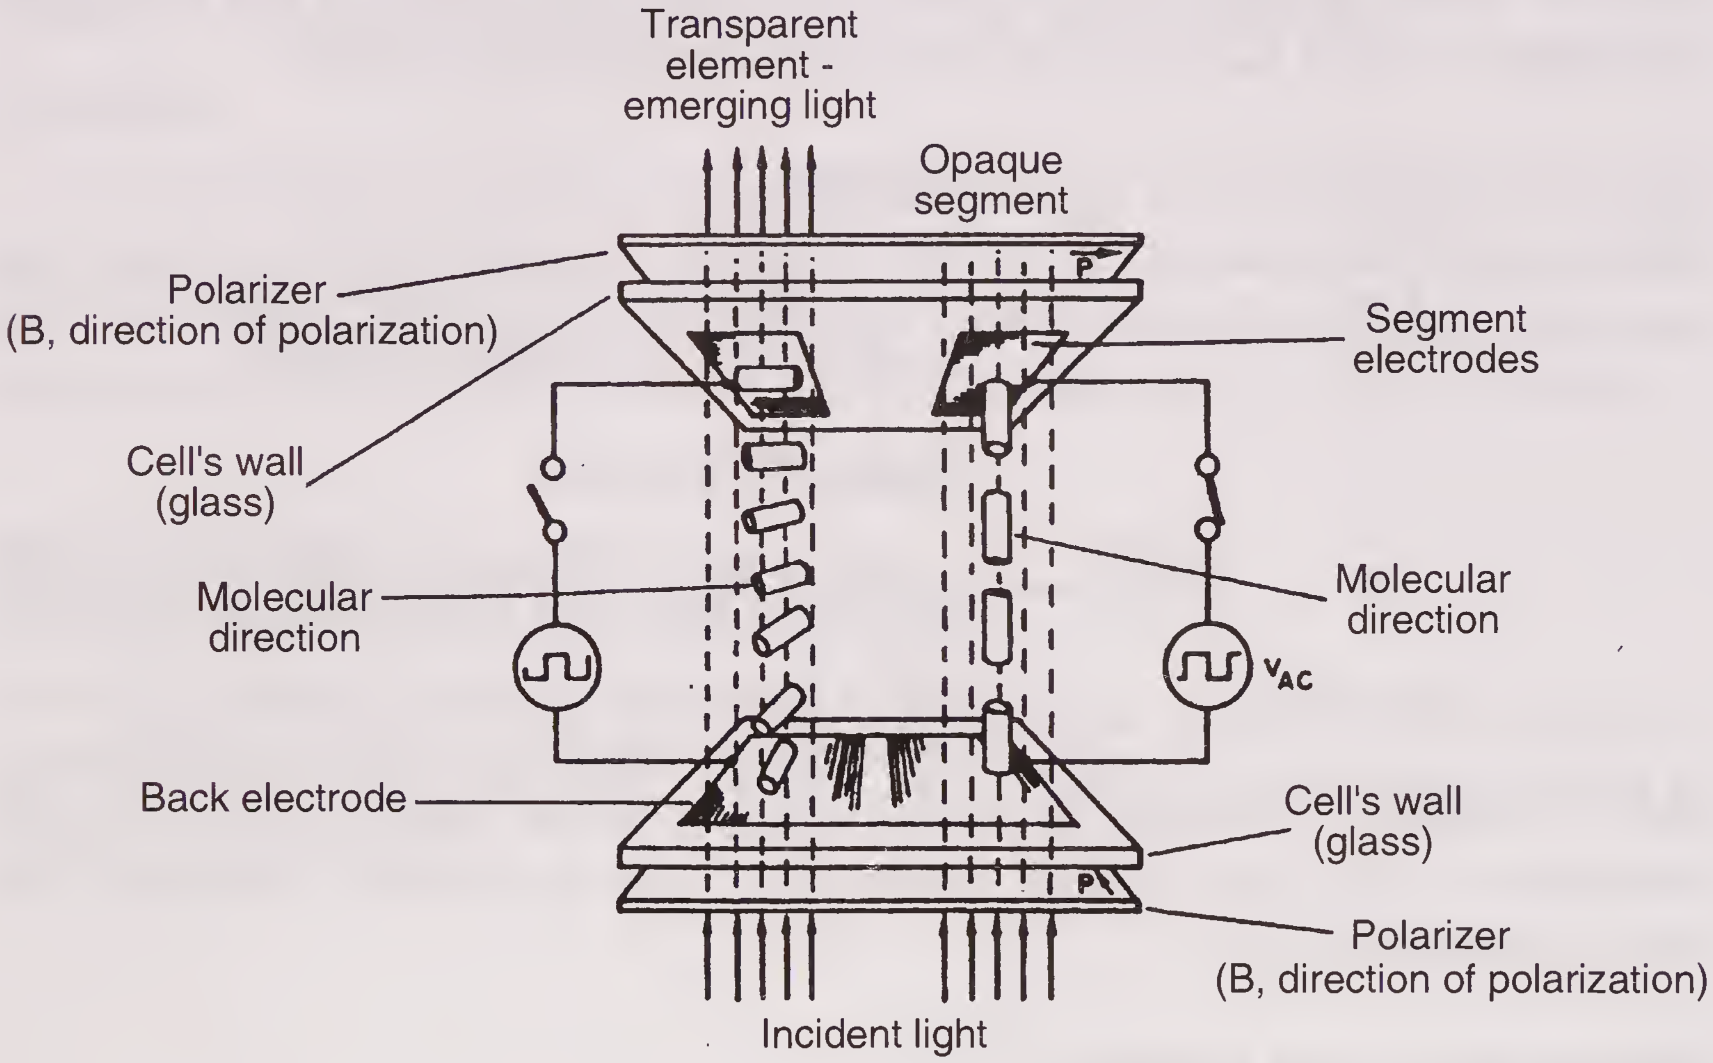
Testing

The multimeter can only reveal if an SBS is shorted. The operation test must be done using an appropriated circuit.

Liquid Crystal Displays—LCD

Liquid Crystal Displays or LCDs are found in a lot of modern electronics. The liquid crystal displays can display information like the results of arithmetic operations in calculators; time in clocks, timers and watches; programmed operations in dishwashers, clothes washers, and microwave ovens, as well as many other modern applications.

The liquid crystal displays use the electrical properties of the molecules of certain substances that can change their positions when an electric field acts on them as shown in Figure 164.



Transparent element - emerging light

Polarizer (B, direction of polarization)
Segment electrodes
Cell's wall (glass)
Molecular direction
Molecular direction
V_{AC}
P
Back electrode
Cell's wall (glass)
P
Polarizer (B, direction of polarization)
Incident light

Figure 164

With no electric field present in the substance the molecules are oriented in a manner that lets the light pass through the liquid. The substance is now transparent. When the electric field is applied, the position of the molecules changes making them cut the light. The substance, under this condition, becomes opaque.

If transparent electrodes with the pattern to be displayed are placed inside a can filled with a liquid presenting this property, when a voltage is applied in any part or electrode, this part becomes opaque projecting the corresponding image as shown in Figure 165.

The simplest LCD display is the seven-segment type used to display numbers from zero to nine according to excited segments. This type of display is found in clocks, watches, calculators, and timers, just to name a few.

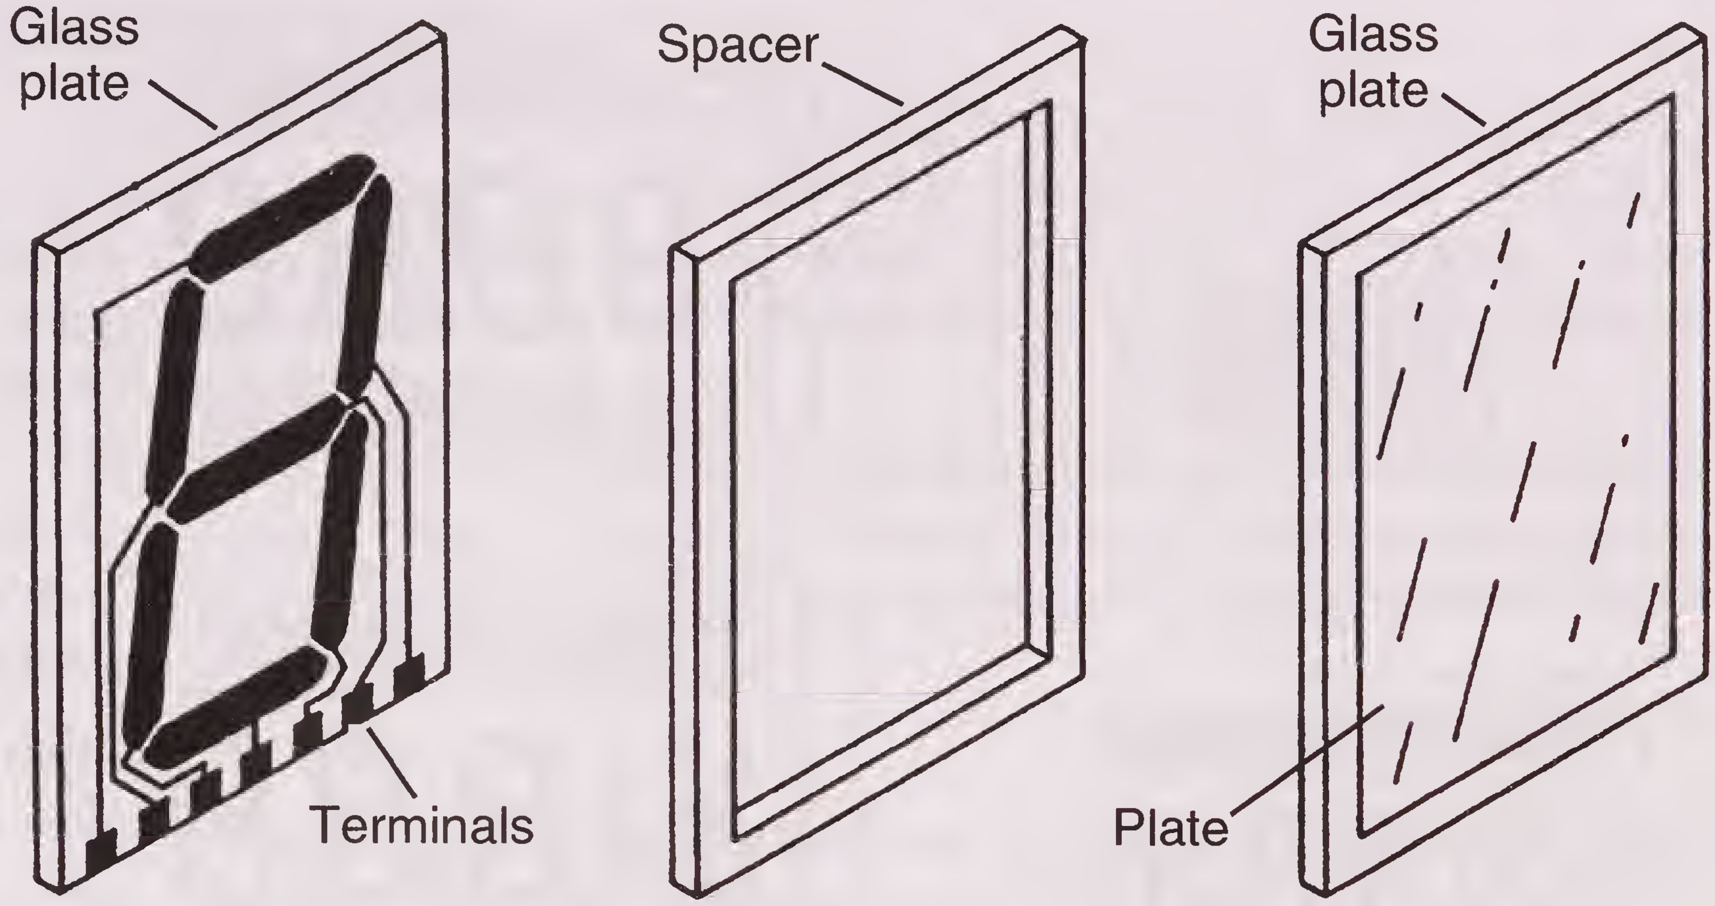

Figure 165

More complex displays include other symbols that can be energized with special signals such as figures in mini games, audio equipment, and radios.

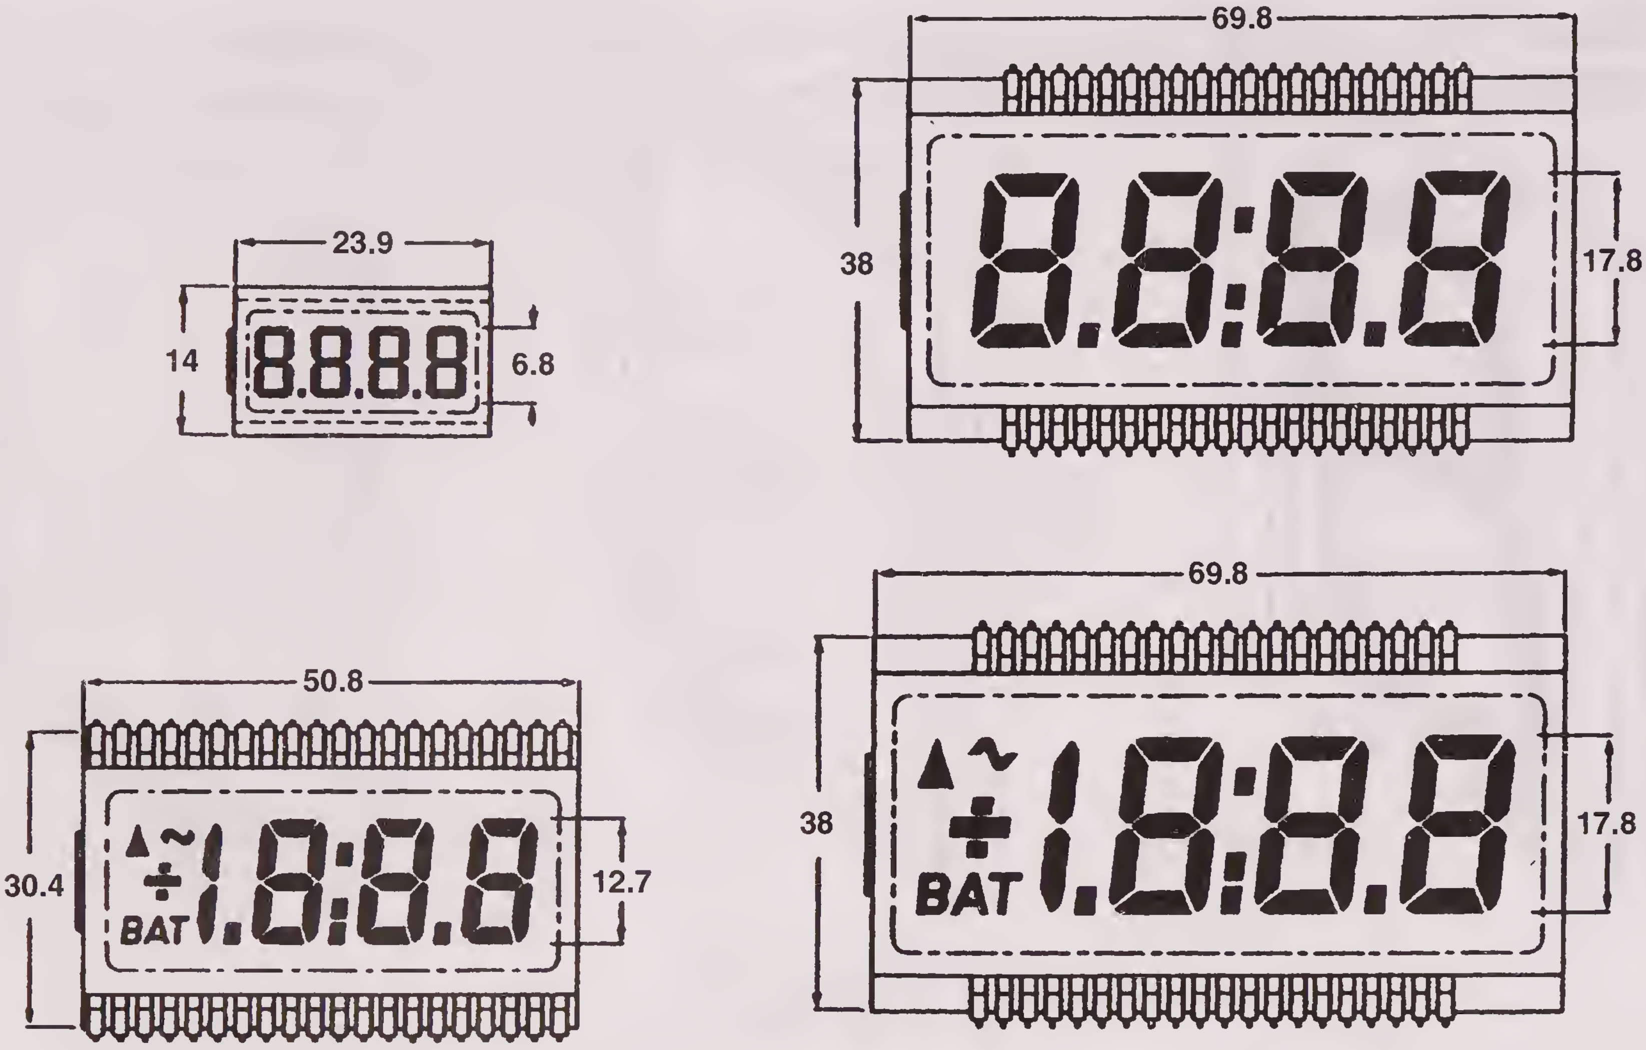
The LCDs need special circuits to become active. The circuit not only recognizes what places of the display must be triggered to show the desired figure, but then also applies an AC voltage. If a DC voltage is used, an electrolysis phenomenon can occur causing the deterioration of the LCD.

The LCD drivers have special characteristics and are included in the group of the ICs (integrated circuits) described later.

Symbols and Views

Figure 166 shows the symbols used to represent an LCD. The same figure shows views of some of these displays.

There isn't any special symbol because many variations can be found in this component based on the application. Normally a representation that corresponds as near as possible from the final end is adopted and easily recognized by anyone who is reading a schematic diagram or working with the circuit.



Dimensions in mm

Figure 166

Specification

The LCDs are indicated by a part number in most cases. We can separate LCDs in two groups: general-purpose types and special or custom types.

General purpose are those that present generic symbols (normally seven segments or matrix types) that can be used to present information for the projection. The same type of display can present several types of informational messages.

Specific types or custom types are those that are prepared for a determined manufacturer that creates a special configuration of information for a product. For example, the displays that have the symbol of a company or a figure representing the parts of equipment that are activated at any given time, are examples of these displays.

The electrical characteristics are not so important in this case as they always are driven by a special circuit (usually an integrated circuit).

Where they are found

LCDs are found in any application where numbers, alphanumeric information, or another type of information must be displayed. Watches, clocks, timers, microwave ovens, radios, telephones, car panels, industrial machine control panels, and facsimile machines are examples of places where LCDs can be found.

Some important information to know about the use of these devices is that they have a power consumption many times lower than the equivalents using LEDs so they are especially suitable for battery-powered applications.

Testing

No simple practical electrical test can provide any information about an LCD. The best way to test is using a specific circuit.

Tubes

Although integrated circuits (IC) and transistors are replacing the tubes in most modern applications, there is still old equipment in use today based on these components. To understand how the tubes work and are used, it is interesting to start from the simplest type: the diode.

A vacuum exists inside a glass tube with some electrodes. In the case of a diode, a tungsten filament is placed inside (in some cases near an electrode called a cathode). Also nearby (without touching) is another electrode called an anode. To put the tube to work a positive voltage is applied to the anode, the cathode is connected to a negative voltage, and the filament is heated by a low-voltage source as shown in Figure 167.

When the filament and cathode are heated, electrons are emitted causing current flows between the filament (cathode) and the anode. If the anode is negative and the filament is positive no current can flow across the tube. In a tube like this, the current can flow only in one direction, such as in a semiconductor diode.

If we now place a metallic grid (Figure 168) between the anode and the cathode we can observe new electrical properties in the device.

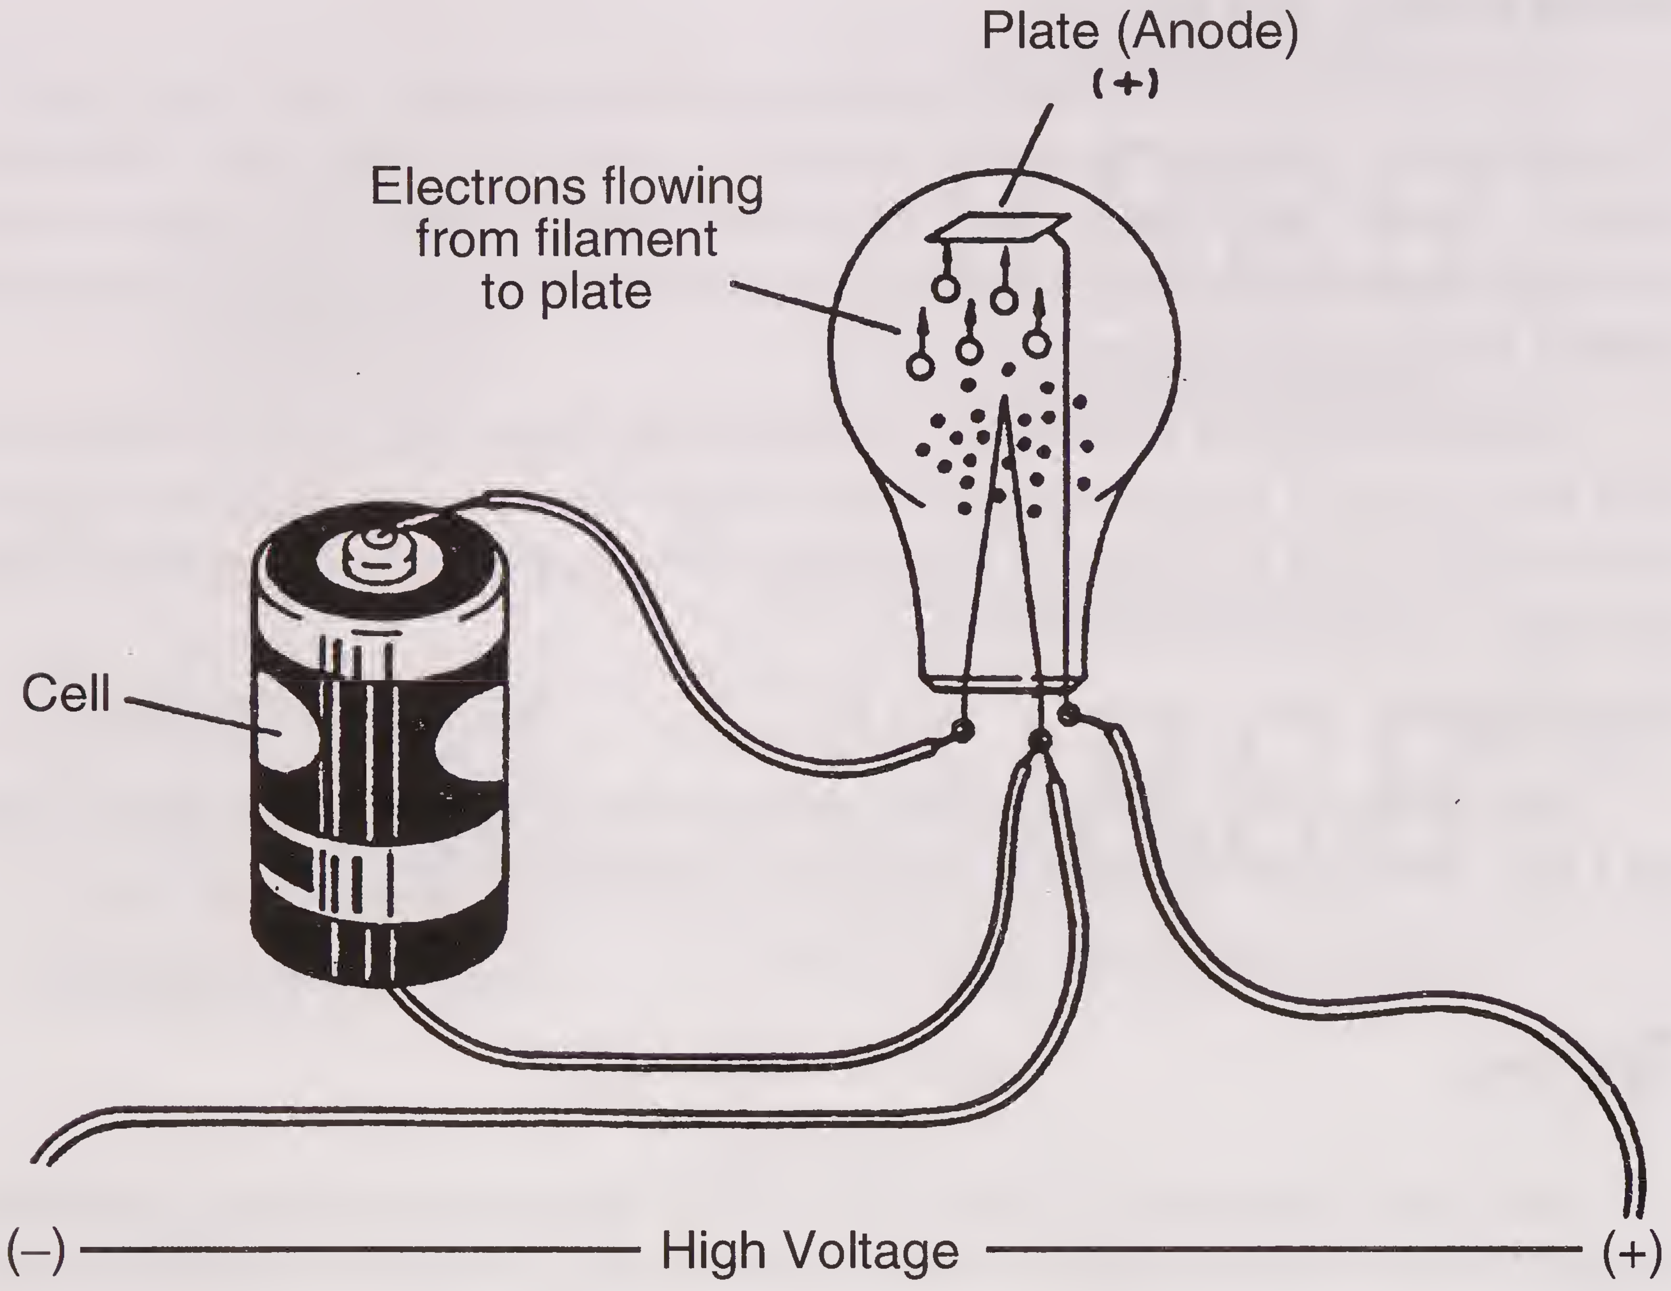


Plate (Anode)
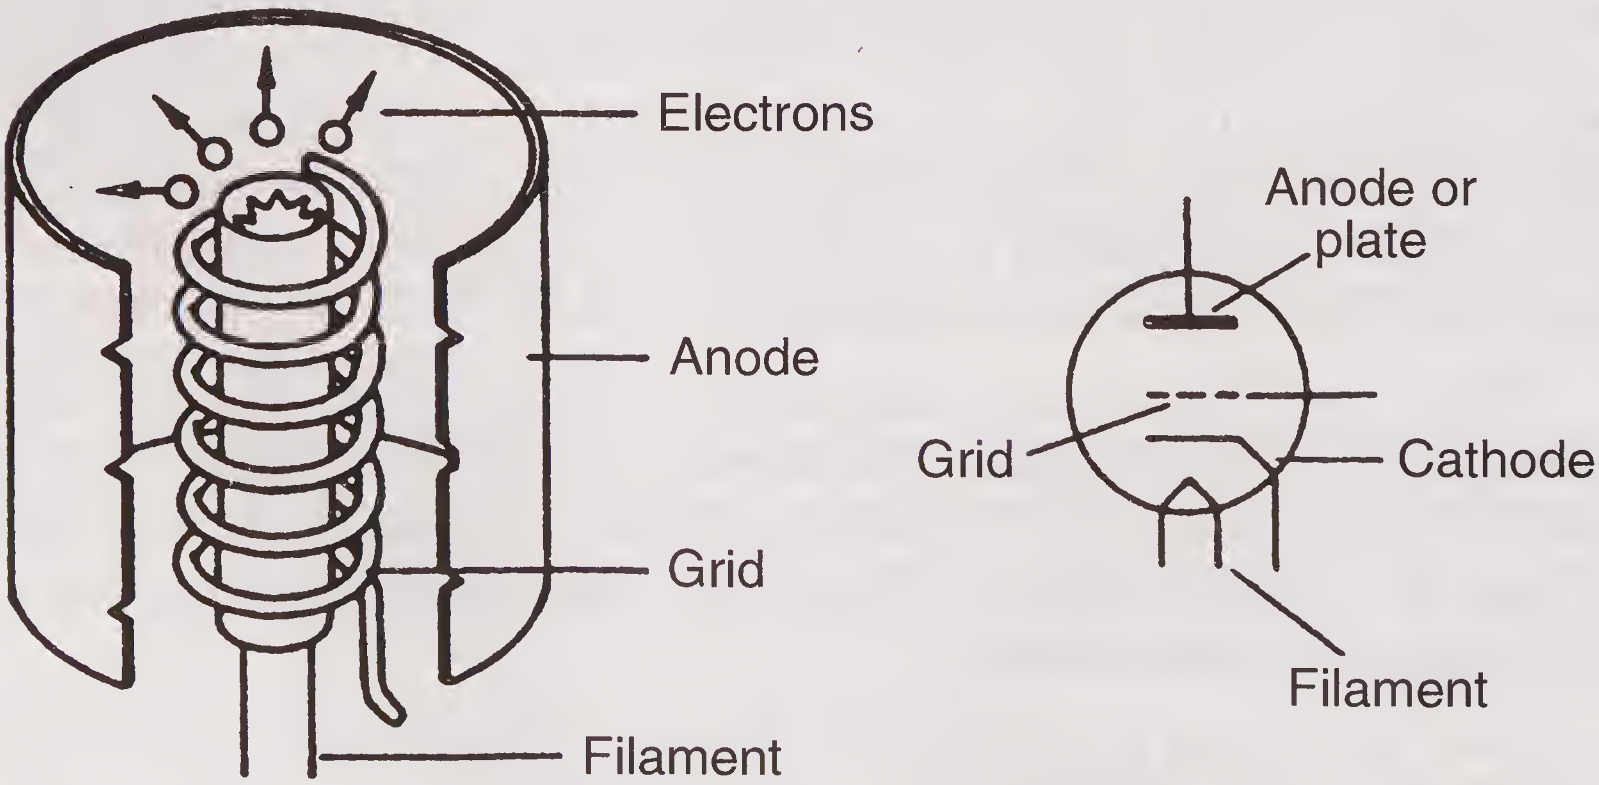
(+)
Electrons flowing from filament to plate
Cell
(–) High Voltage (+)

Figure 167



Electrons
Anode
Grid
Filament
Anode or plate
Grid
Cathode
Filament

Figure 168

A voltage applied to this grid can control the electron flow between cathode and anode. For example, if the grid is made negative the electrons are repelled and no current can flow. On the other hand, if the grid is made positive, the electrons are attracted and accelerate to the anode.

The amount of current between anode and cathode can be controlled with precision by the voltage applied to the grid. This device, called a triode, can be considered as an equivalent of the transistor and is used for the same purposes—as a switch or an amplifier.

New tubes were developed from the triode configuration by adding new internal elements. The tetrode (four elements), pentode (five elements), hexode (six elements), and heptode (seven elements) are all examples of tubes that can be found in old equipment like radio receivers, audio amplifiers and TVs.

Although the tubes are very efficient in some applications and even used in some of them until recently, they have some disadvantages when compared with the equivalent modern solid-state devices like transistors.

The tubes need to be heated to operate and this implies the consumption of large amounts of energy. Another problem is that all the heat can be transferred to the surrounding area. The tubes also need high voltage for their operation. Although common solid-state transistors operate with low voltages ranging from 1 to 30 volts in typical applications, in the same applications, the tubes need voltages in the typical range between 150 and 800 volts! Portable equipment using tubes is almost totally impractical.

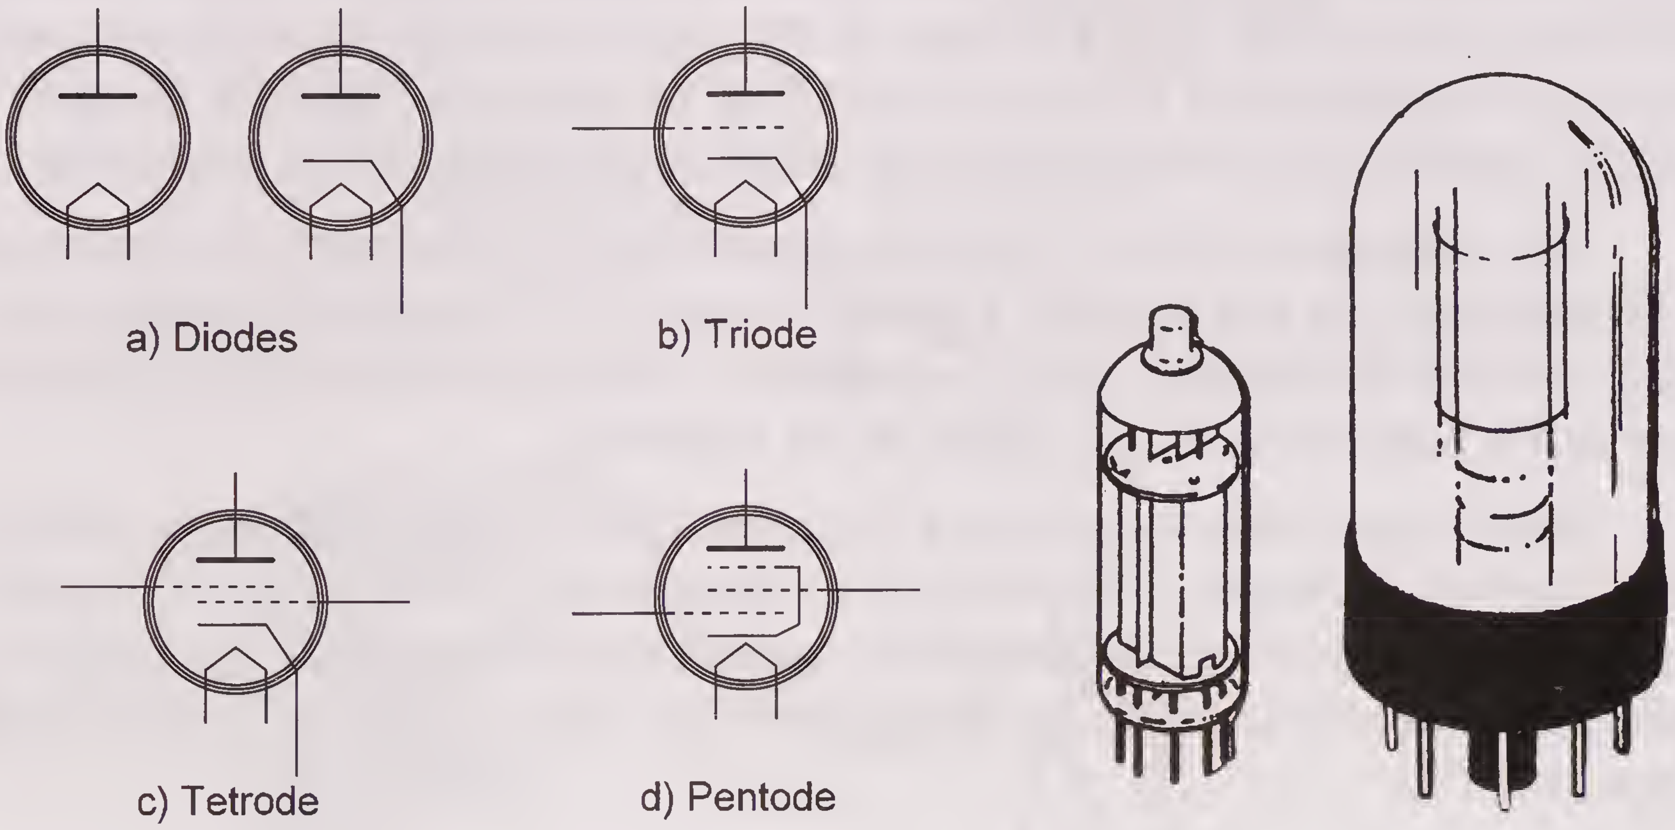
Symbols and Examples

Figure 169 shows the symbols for many types of tubes found in old equipment (and even some modern) and two examples.

In the old types found in some military equipment, metal enclosures replaced the glass and the multiple tubes containing more than one configuration inside a body (a triode and a pentode, for example).

Specifications

The tubes are identified by a part number. There are two main codes used in their specifications. One of the codes uses a number followed by a



a) Diodes
b) Triode
c) Tetrode
d) Pentode

Figure 169

group of letters and another number. The first number is the filament voltage, or the voltage that must be applied to the filament to heat the tube. The second and third figures indicate the specific function. For example, a 12AX7 is a double triode tube that has a 12 V filament.

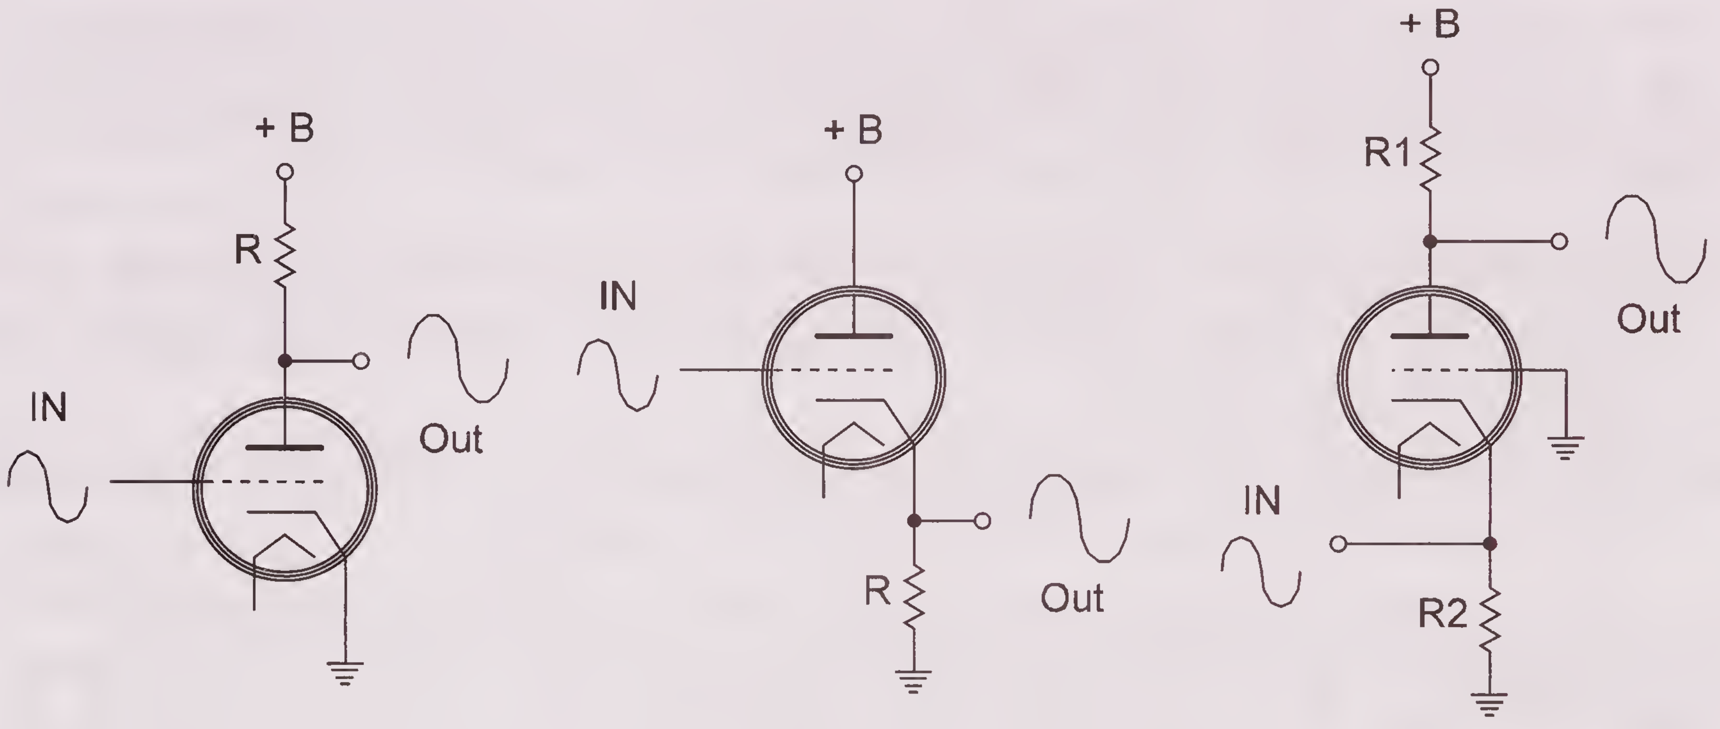
Another way of identification is the European code, where a group of letters indicates the function of the tube and the final number the specific type. For example, the tube ECC83 is a double triode (CC) (equivalent to the 12AX7!).

The best way to identify each tube is by consulting a manual. (Prompt® Publications has an excellent replacement guide for tubes, *Tube Substitution Handbook*, Sams 61036, ISBN 0-7906-1036-1.)

Where they are found

The electrician will not often find tubes in modern electric installations. The tubes can be found in older electronic equipment, especially radios and TVs. The tubes can be used in the same configurations as the transistors, as shown in Figure 170.

Notice the tubes need, in addition to the low voltage to heat the filament, a high-voltage source for the anode. This high voltage ranges from 150 to 800 volts in common equipment.



a) Common cathode b) Common anode c) Common grid

Figure 170

Although in some cases it is not a good idea to try to restore old tube equipment, if you like it (perhaps for sentimental value), many dealers have all types of old tubes for replacements.

Testing

When the filament is open (burned out), the tube doesn't function any more. In most of the cases, the malfunction of any piece of tube equipment is caused by this problem. The advantage of the tubes for the technicians is that it is easy to see if a tube is burned out because when the equipment is turned on, there is no orange or red light emitted by its filament. A visual inspection can reveal problems in this case. But, this is not conclusive; some equipment exists where the filaments are wired in series. So, if one of them burns out, all the others are not powered and all the tubes are off.

A multimeter can be used to test the filament of a tube. The operational test needs special circuits or test equipment.

Integrated Circuits

The Integrated Circuit can't be considered a component, but a collection of components housed in a single chip and installed inside a unique case. The basic idea originated from these questions:

1. Why do we have to manufacture all the components of a circuit in a separated process and then assemble them together to create the desired configuration?
2. Why not make them together in a unique silicon chip to perform the basic circuit for equipment using a single process?

The answer to these questions resulted in the integrated circuit or IC. The integrated circuit consists of a tiny silicon chip that houses a determined number of components, such as transistors, resistors, capacitors, and diodes, interconnected by conductive paths that act as wiring. The components and paths are formed by a complex process that includes diffusion, photo printing, and etching.

Figure 171 gives an idea how the many components can be created on a silicon chip.

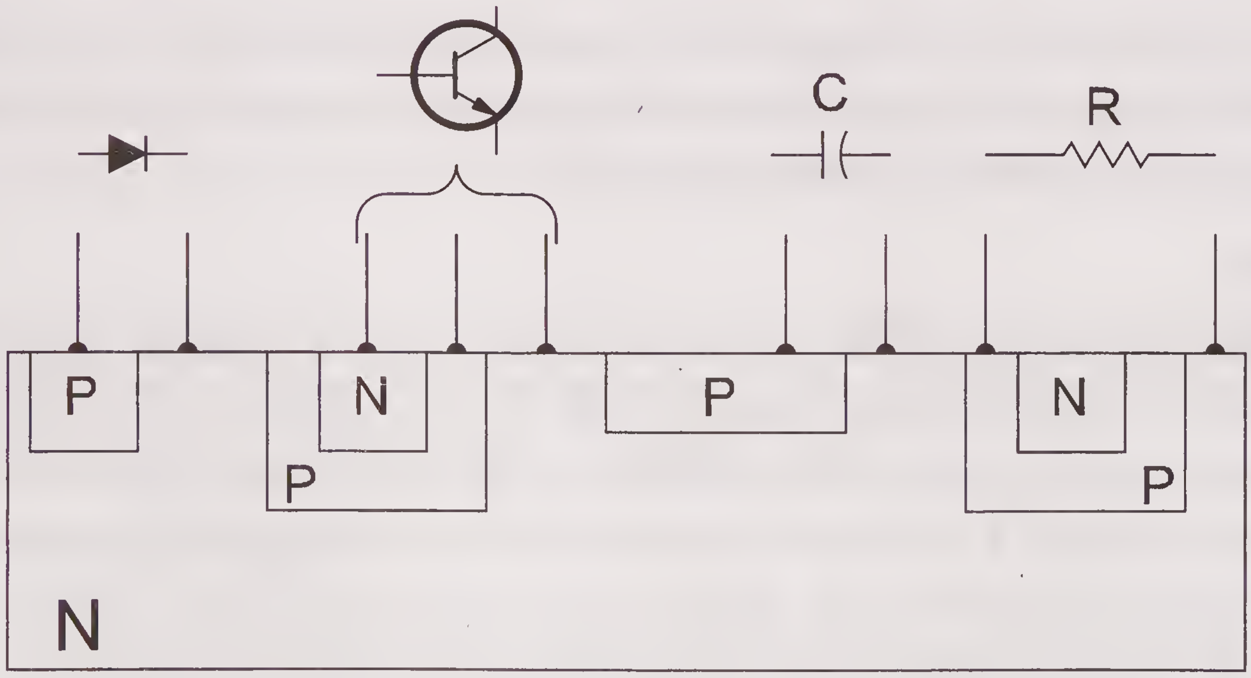


Figure 171

In an N substrate, P regions are created forming a diode. If in the P region of a diode, another N region is formed, a transistor will be created. A capacitor can be formed by a large P region. Having a reverse bias at the junction to create a capacitor, the junction will act as the dielectric and the PN regions as places similar to the varicaps. A resistor can be formed by a P channel formed in the N region. The width and length of the channel determine the resistance of this resistor. The number of components, their disposition in the chip, and the wiring are planned to perform as a complete circuit such as an amplifier, a voltage regulator, or even a computer.

It is possible to house in a single chip, circuits with few components for simple functions to circuits containing more than 7 million components, such as in modern microprocessors used in personal computers. Even a complex integrated circuit with millions of transistors has a tiny footprint measuring only in millimeters.

The principal advantage of the integrated circuit is that the circuit can be manufactured almost complete, needing only a few complementary support devices to perform in the desired equipment.

For example, it is possible to create an IC containing a complete audio amplifier that needs only the input jacks, the power supply, the volume control, and the loudspeaker to perform the complete equipment. The integration has some limits. Some components exist that can't be easily integrated on a silicon chip. For instance, large-value capacitors and inductors are components that can't be found in integrated circuits. So, when planning a complex integrated circuit, if large-value capacitors are needed, they must be external, and the common traditional discrete type must be used.

Although the integrated circuit is very important as a simplified solution for projects it can't form a complete piece of equipment or circuit in many cases, needing completion with external components as capacitors and inductors.

Since an IC can contain practically any configuration with any number of components, they exist in a very large number of types and functions.

Symbol and Types

Figure 172 shows the common symbols adopted to represent an integrated circuit and its various types.

At the side of the IC's symbol or inside, an identification figure allows the technician to identify it.

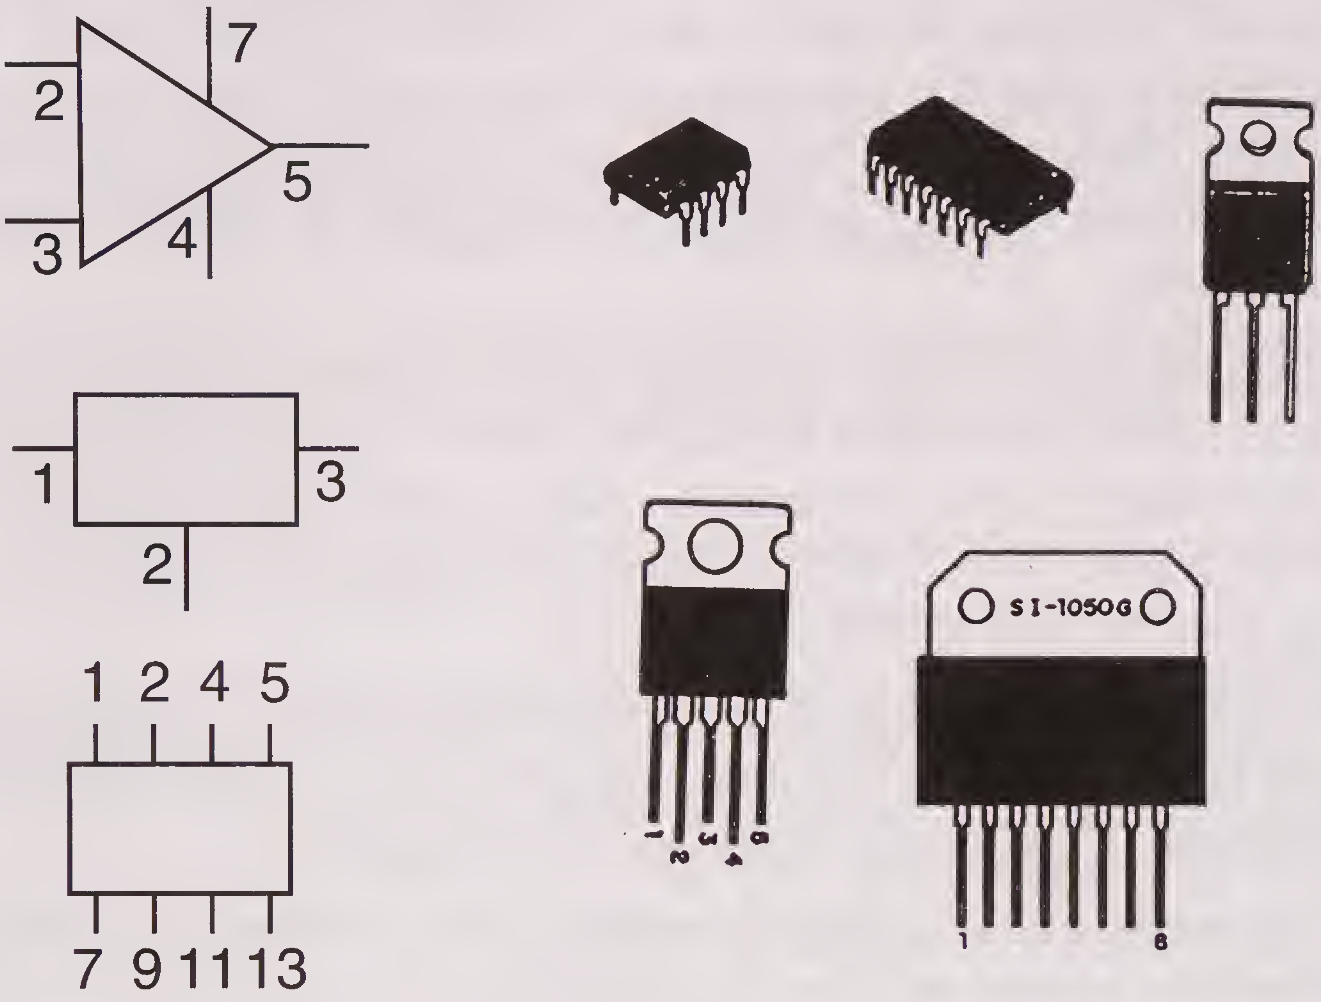

Figure 172

The number of terminals varies according the function. Types with number of terminals ranging from eight to more than 40 are used in common functions. Types with more than 200 terminals are found in special applications such as computers.

Figure 172 shows the most common types of ICs, found in many pieces of electronic equipment that use DIL (Dual In Line) and SIL (Single In Line) cases. See the number of the terminals starting from a mark or point in the case. The identification of the terminals is very important when replacing an IC with another or when trying to troubleshoot. Voltage measurements must be made in these components. Some integrated circuits that perform high-power functions like motor controls, voltage regulators, and audio amplifiers are equipped with tabs or resources to allow them to be on heat sinks.

Specifications and Types

Today we can say that there exist millions of different types of integrated circuits. They are identified by a part number. Only with specific information about the part number is it possible to know what an IC is and what it does. The electrician who wants to work with electronic components doesn't need to have complete handbooks or manuals of all the integrated circuit as it is impossible.

Common functions

Some integrated circuits contain a configuration simple enough and useful enough to allow them to be used in a large number of applications. So, these circuits act as basic blocks in many projects and can be found not only in one kind of application, but in a large number of applications. For example, an integrated circuit that contains a simple low-frequency stage with some transistors and some other components can be used in an audio amplifier, a low-frequency oscillator, an alarm, a motor, and many other circuits.

Many types of these general-purpose or common-function integrated circuits were created and many of them became popular and are used in all the applications we can imagine. Electronics magazines that give projects to hobbyists indicate those ICs in their projects as they can be found in any electronic parts shop and can be handled easily.

The common functions found in ICs are divided in two other groups:

Analog

Analog integrated circuits are the ones that work with DC and analog signals, such as audio, video, AC, and others. We define as an analog quantity, one that can assume any value between two limits. An AC voltage is an analog quantity as its amplitude can assume any value between zero and the maximum amplitude. On the other hand, a digital quantity can assume only determined values between two limits. A byte can assume only the integer values between 0000 0000 and 1111 1111.

In the group of analog ICs we can find some functioning as voltage regulators, operational amplifiers, comparators, audio amplifiers, video amplifiers, timers, PLLs, etc. It is interesting to give a brief description of each of these ICs as they are very common in many appliances and will be found by the electrician in electric installations and in many AC-powered appliances.

Voltage regulators

The purpose of a voltage regulator is to maintain constant the voltage in a circuit. The power supplies of many pieces of equipment use this type of IC to have a regulated output supply voltage. Today a three-terminal, 1-A voltage regulator, such as the 78XX and 79XX series or family (where the XX is replaced by a number indicating output voltage), is very common in appliances. For example, the 7806 furnishes a 6 V output under 1 A of current (maximum). Another type of voltage regulator is the one used in SMPS (Switch-Mode Power Supplies) and the ones found in computers, video monitors, and many other modern appliances.

The operation principles of these regulators are different from the linear regulators as they acts as oscillators, producing a voltage that depends of the frequency and pulse width of the output signal.

Symbols and Types

Figure 173 shows the symbols and some types of this IC. Notice that many of the ICs used as voltage regulators have resources to be mounted on a heat sink. Observe also that other ICs can have more than three terminals.

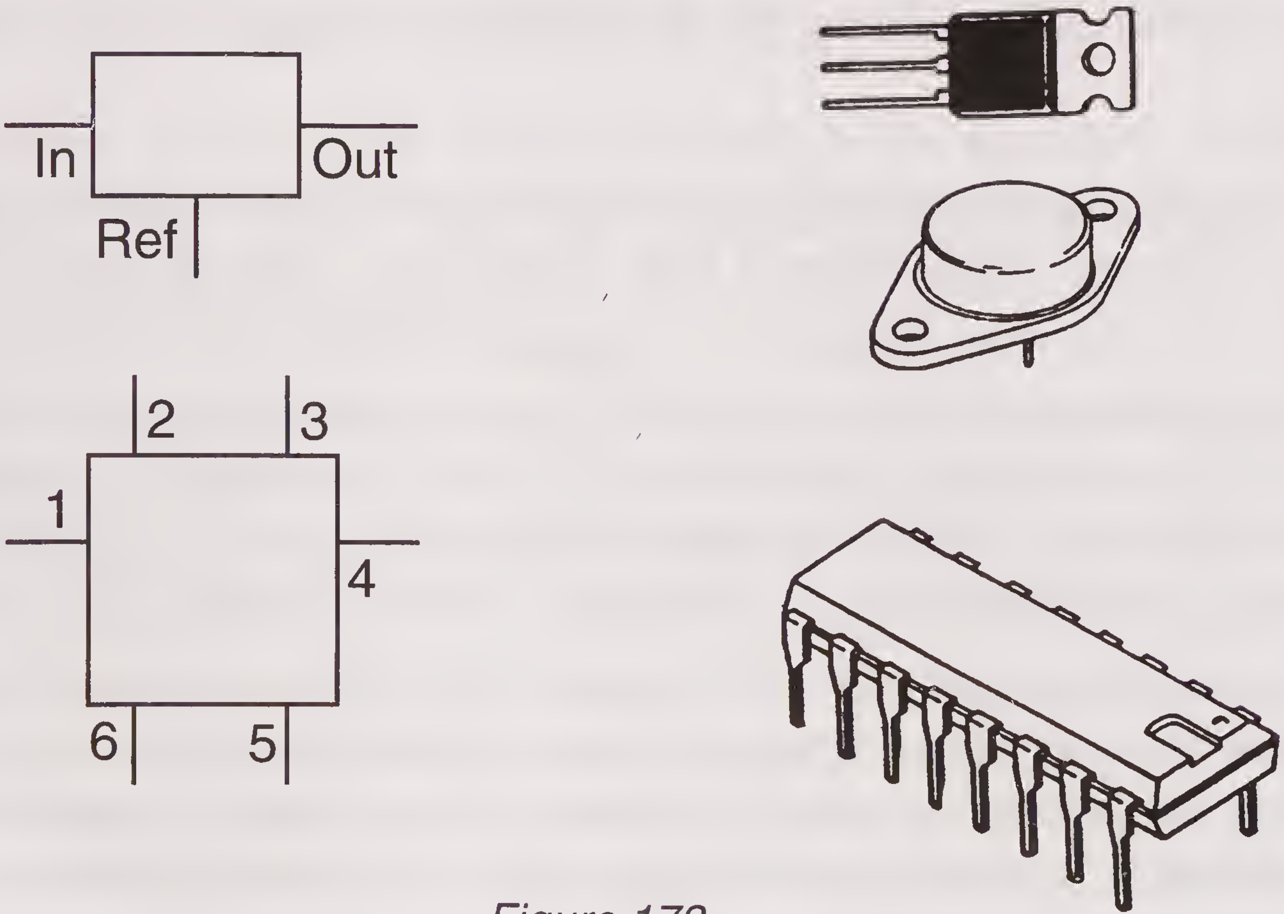

Figure 173

Specifications

The ICs used as voltage regulators, like any other IC, are specified by a part number. The electrical characteristics are found in data sourced by the manufacturer. The main specifications of these kind of IC are:

A. Input voltage range—the range of voltages that can be applied to the input. In the documentation it can be abbreviated by Vin.

B. Output voltage or range (Vout)—Some ICs are fixed voltage regulators. They have an internal zener that fixes the output voltage. Other have resources to be programmed by an external zener or resistors to a determined output voltage. Figure 174 shows a circuit, the LM350, which is an adjustable voltage regulator for a large range of voltages and output currents up to 3 A.

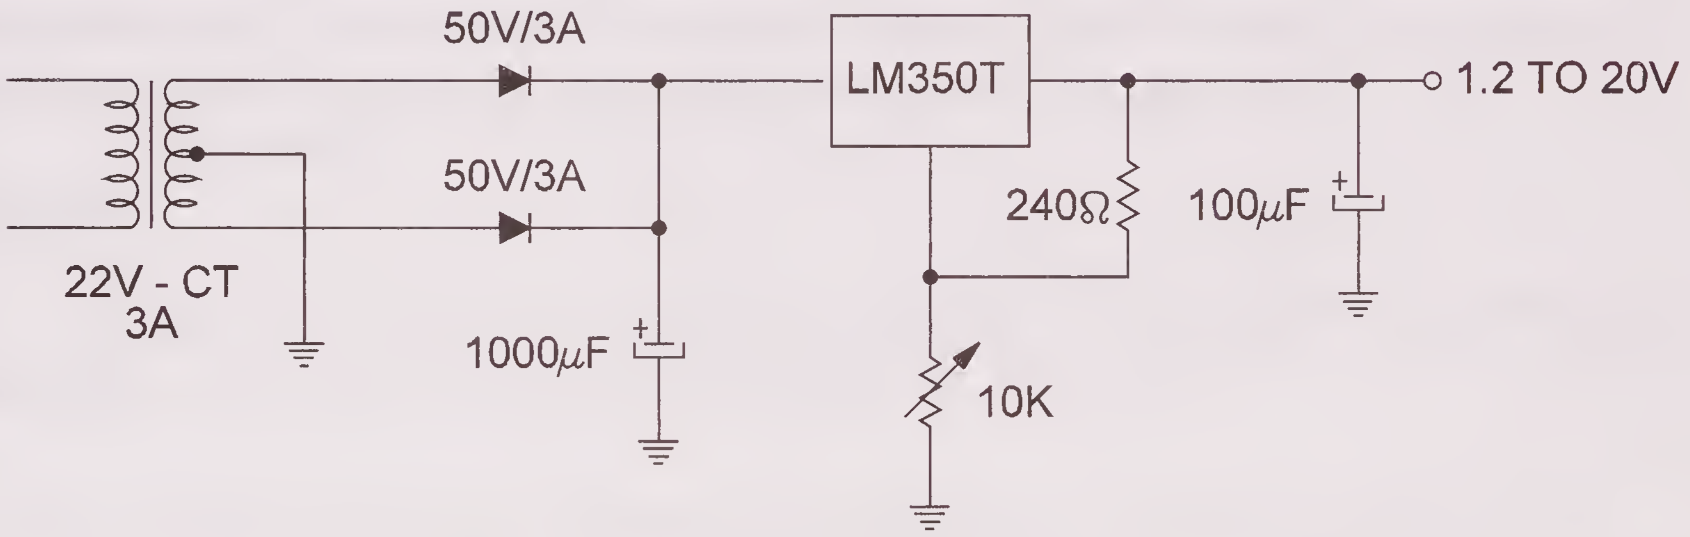

Figure 174

C. Output current—the maximum output current that can be regulated by the IC is an important parameter to be observed when using this kind of IC.

Where they are found

Voltage regulator ICs are present in almost all equipment plugged to the AC power line and even in battery-powered circuits acting as voltage reducers. After rectifying and filtering, they convert the AC power line voltage in one or more DC voltages necessary to power the electronic circuits. These ICs are present in the first stage of any equipment or "power supply" stage.

Testing

The simplest way to test this kind of circuit is measuring the input and the output voltages. The multimeter is the instrument recommended for this task.

Operational Amplifiers

Operational Amplifiers (AO) are general-purpose amplifiers originally designed to perform mathematical operations in analog computers. An operational amplifier has a noninverting input represented by a (+) and an inverting input indicated by a (–). The signals applied to the inverting input appear in the output with the phase shifted, as shown in Figure 175.

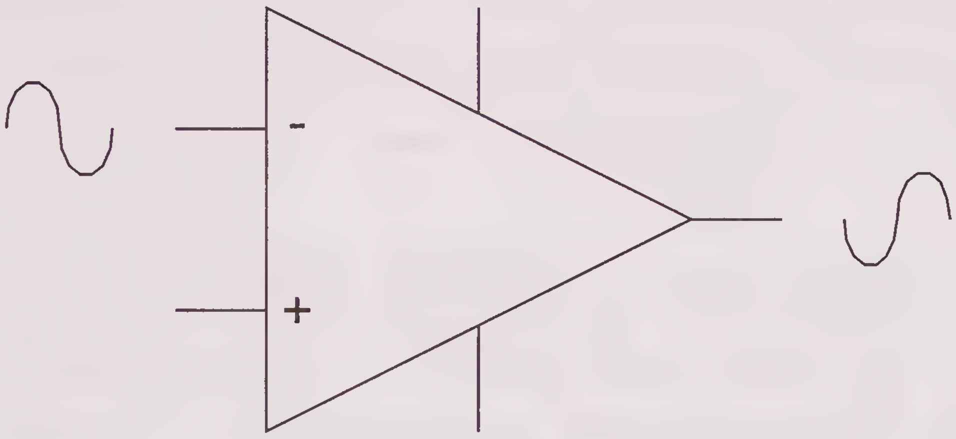

Figure 175

The ideal operational amplifier has an infinite input impedance and a null output impedance. The real types have a very high input impedance of many megohms and a very low output impedance (some ohms to hundreds of ohms).

The gain of an operational amplifier or the number of the times the output voltage is higher than the voltage applied to the input can be programmed by a feedback circuit as shown in Figure 176.

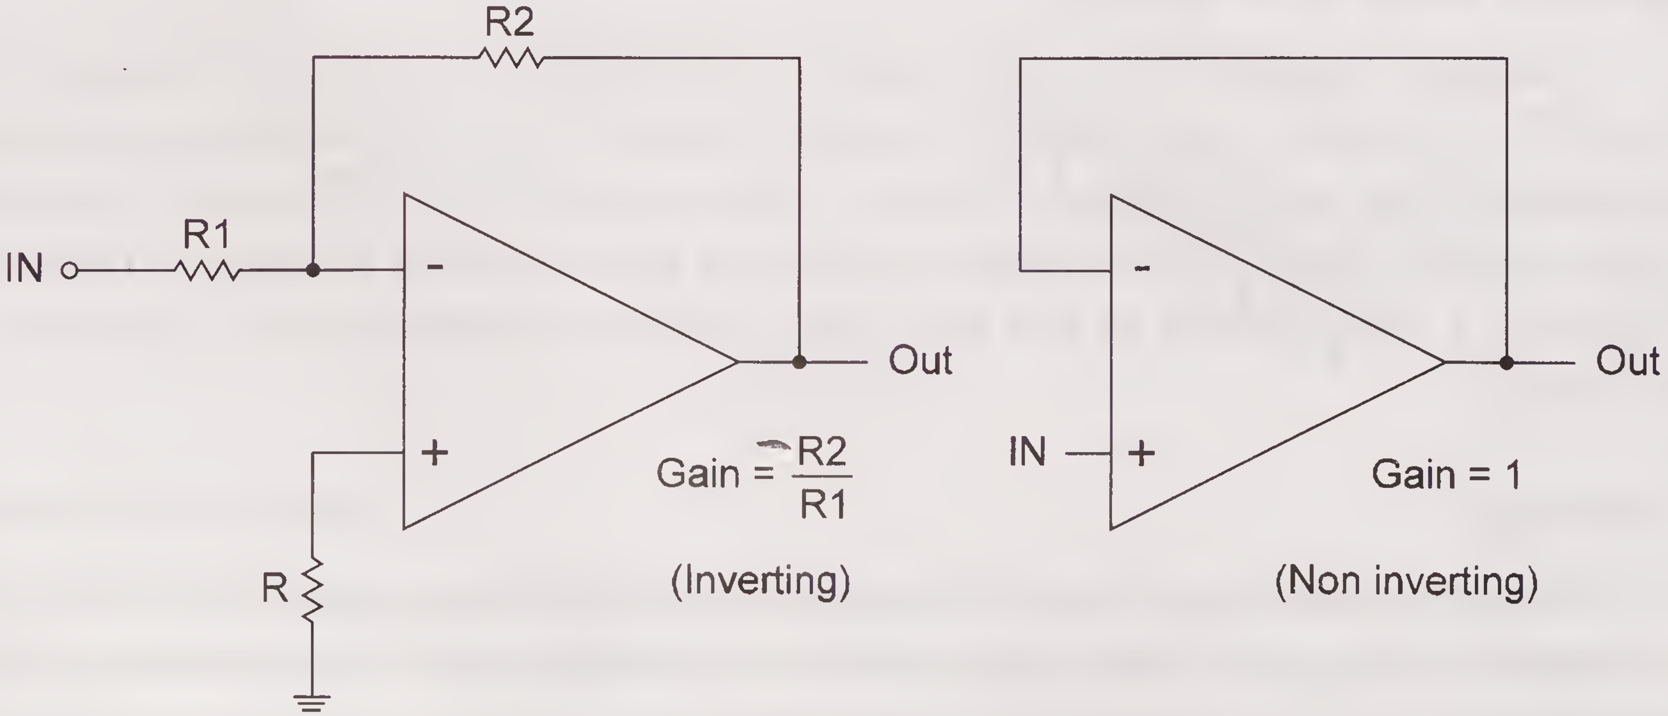

Figure 176

The higher gain is achieved when the feedback is infinite and typically ranges from 10,000 to 1,000,000 in the common types. The lowest gain is achieved when the feedback loop is a zero ohm resistance and is one.

The configuration with a voltage gain of one is called voltage follower. In a voltage follower the output voltage is the same as the input voltage. Despite this, the difference in impedance between the input and output makes the circuit an amplifier with a very high current gain.

Operational amplifiers can be found in a large number of types, sizes, and presenting a large range of electrical characteristics (input and output impedances, power supply voltages, gains, type of transistors found inside as FETs or bipolars, operation frequency range, etc.).

Symbol

Figure 177 shows the symbol adopted to represent an operational amplifier. They generally look the same as other ICs.

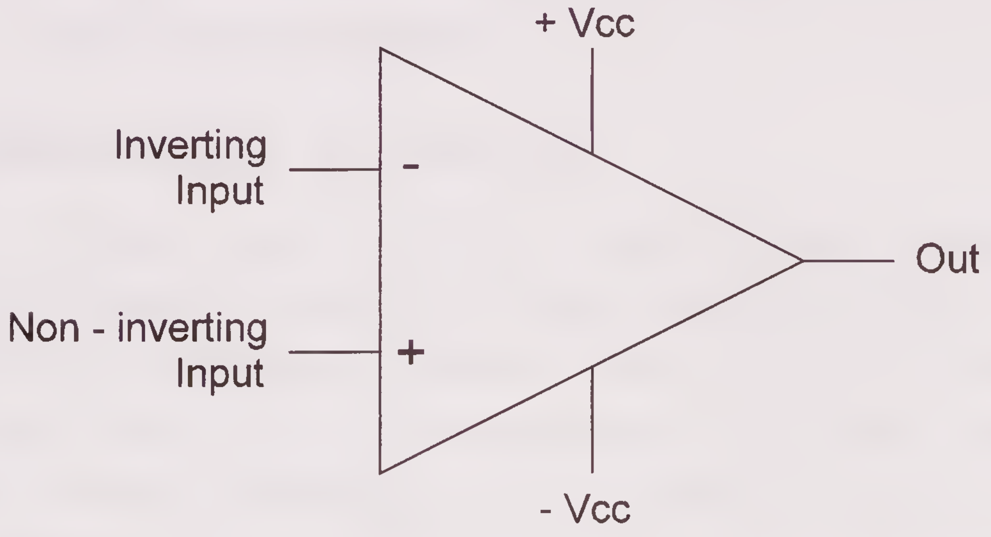

Figure 177

Notice that some ICs exist that contain two or more operational amplifiers. In some cases we can also find terminals where additional components are plugged. These external components are used to add special characteristics to the circuit such as frequency compensation.

Specifications

The operational amplifiers are indicated by a part number according to a code adopted by the manufacturer. Normally a group of letters is used to identify the manufacturer—MC = Motorola, SN = Texas Instruments, LM = National Semiconductor, etc.

From the part number or consulting data sheets and/or handbooks it is possible to access the electrical characteristics of each device. These characteristics are:

A. Open loop gain—The gain is determined by the internal circuit and is specified the maximum gain or the "open loop" gain where no feedback is used. The values can range from 1000 to 1,000,000 in common types. The gain of an AO can be abbreviated by G.

B. Power supply voltage range—This specification indicates the range of voltage that the operational amplifier needs for correct operation. It can range from 1.5 V to more than 40 V.

At this point it is interesting to observe that in many applications the AO needs a symmetrical or double power supply. It is a power supply where a positive and a negative voltage referred to the ground (0 V) must be generated as shown in Figure 178.

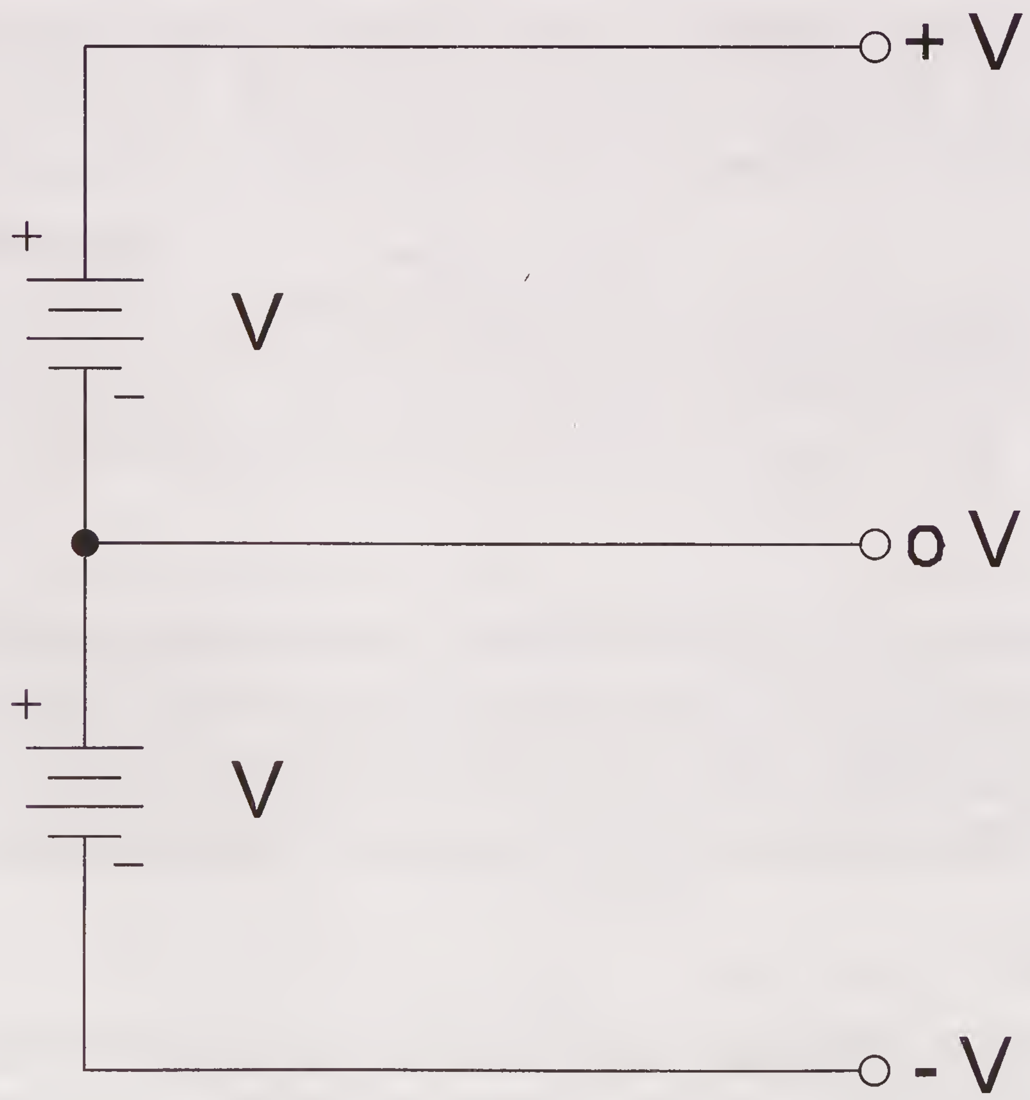

Figure 178

In some documents, data sheets, and diagrams it is common to refer the power supply voltage for an AO as 6-0-6 V, +6, -6, 0 V, +6/-6/0 V or 6+6 V if it needs a symmetrical supply as the one shown in Figure 178.

C. Gain x Bandwidth—The gain of an operational amplifier falls at the same time the signal frequency increases. The frequency band is limited by the point where the gain falls to one; this determines the gain bandwidth product. Common operational amplifiers can operate in frequencies from 1 or 2 MHz to up to some hundreds megahertz.

D. CMRR—If two signals with the same amplitude and phase are applied, one to the inverting input and the other to the noninverting input of an operational amplifier they must be cancelled and the output will be zero. In practice, due to small differences in the internal components, this is not possible and some part of the signal is not cancelled, which then appears in the output. How efficient is the AO when canceling a signal in this operation mode is given by a specification called Common Mode Rejection Ratio or CMRR. This specification must be as high as possible and is indicated in decibels (dB). Common types have CMMR as high as 90 dB and more.

Where they are found

Many appliances use operational amplifiers in the integrated circuit form. They normally are common types such as the 741, CA3140, TL080, TL081, and many others that are easily found in any electronic components shop. Special operational amplifiers can be found driving step motors or other devices, but in general, they can be found at a dealer by part numbers, too.

The basic function of an operational amplifier in many circuits is the amplification of signals coming from sensors, transducers, or other sources, driving them to powerful output stages or circuits that must work with signals having a larger amplitude.

Testing

In many applications the operational amplifier can be tested measuring the voltages in their pins. If the voltages are altered, and the components plugged into it are good, the problem will be certainly in the OA. Another way to test is using a special probe circuit.

Audio Amplifiers

Complete audio amplifiers with output powers ranging from some milliwatts to more than 100 watts can be found in the form of a linear integrated circuit. These integrated circuits consist, in some stages of amplification, of the preamplifier, driver, and output stages interconnected to perform as an audio amplifier.

The high-value capacitors necessary to many of the stages are connected to the circuit by external pins. In many cases, the manufacturers can use the circuit with a minimum of external capacitors.

Many audio amplifiers can have resources to program the gain or the frequency response by some external components. In the simplest types we have an input where the volume control is placed, an output where loudspeaker or headphones/earphones are connected, the power supply pins, and some other necessary parts, such as capacitors (coupling and decoupling) and resistors (to program gain). Many manufacturers have types containing two amplifiers in one case, making the project of stereo equipment easier.

Symbol and Example

Figure 179 shows the basic symbol adopted to represent an audio amplifier. The cases are SIL or DIL or another type based on the output power.

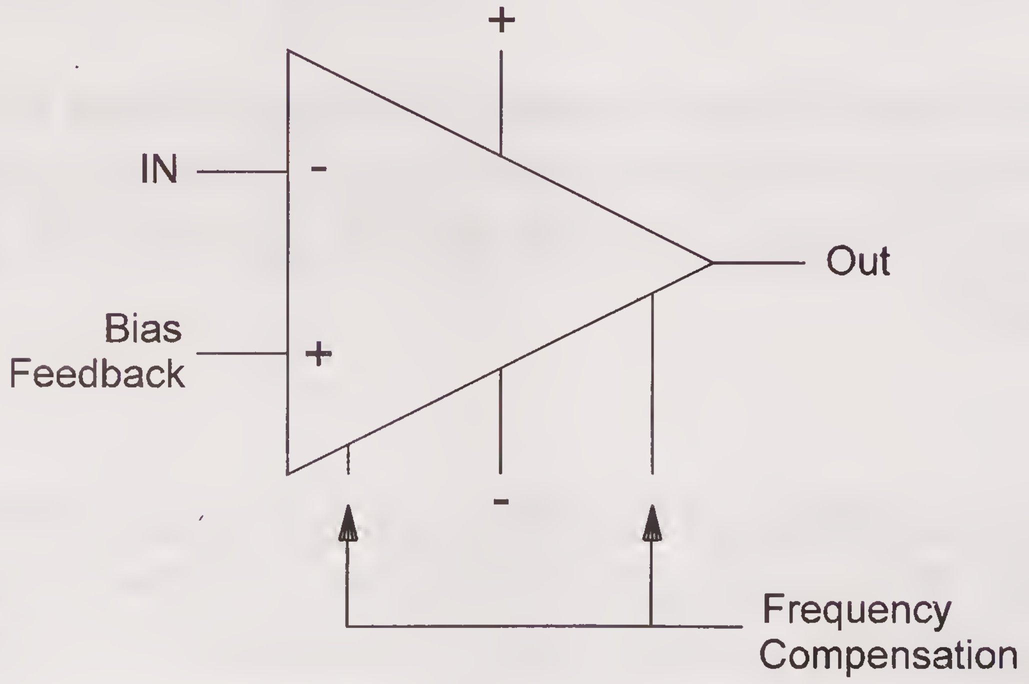

Figure 179

Specifications

The ICs of this group are also identified by a part number according to the manufacturer. The electric specifications of an audio amplifier in the form of an integrated circuit are the same for any other audio amplifier.

A. Output power—the amount of power that the circuit can drive to a loudspeaker. It is indicated in watts (W) and in some cases abbreviated by Po or Pout.

B. Power supply voltages and current—important when designing the power supply for the circuit. It is given in volts.

C. Output impedance—characteristics of the loudspeakers/earphones connected to the output of any audio amplifier are very important to not overload. Impedance is given in ohms and typically is between 2 and 16 ohms for types designed to drive loudspeakers and higher for earphone/headphones amplifiers.

D. Input impedance—given in ohms.

E. Gain—how many times the amplitude in volts of the output signal is higher than the amplitude of the input signal. This specification is important for the input impedance to determine the sensitivity of an amplifier.

F. Operation curves and other specifications—performance of an audio amplifier according to the signal frequency is given by curves. These response curves show how the fidelity of an amplifier is when working with signals of the audio spectrum. These specifications are important when making a project. For the technician who needs information to find a replacement, the part number is enough. It is important to call the reader's attention to the fact that amplifiers with the same power in the cases can be different in disposition of pins and the external components meaning that they are not interchangeable.

Where they are found

Audio amplifiers are found in every part and a large quantity of common AC-powered appliances, embedded in electric installations, or even powered from batteries, but all related to applications in the electric installation. For instance, intercoms, alarms, doorbells, wireless telephones, wireless intercoms, baby monitors, and ambient sound sources can use an audio amplifier (or several) in the form of an integrated circuit to drive an earphone or one or more loudspeakers.

When creating the equipment the designer must instead use a dedicated integrated circuit where all the functions are embedded in a unique device and can use some common integrated circuits in some functions as the audio output.

Testing

The best way to test a common integrated circuit, such as an audio amplifier, is by measuring the voltages in their pins. It is recommended to do this measurement only after verifying if the associated components (external capacitors, resistors, etc.) are good. For this, it is important to have an idea about the magnitude of voltages to be found or to have the schematic diagram of the equipment where the voltages are indicated.

Timers

Another important group of the linear integrated circuits family is the one formed by timers. These are circuits that can be used to generate a signal or to count a time interval. Basically, they are circuits that can be used in two operation modes: monostable and bistable.

In the monostable mode, once triggered, the circuit produces a signal during or after a time interval triggering something or controlling something as suggested in Figure 180.

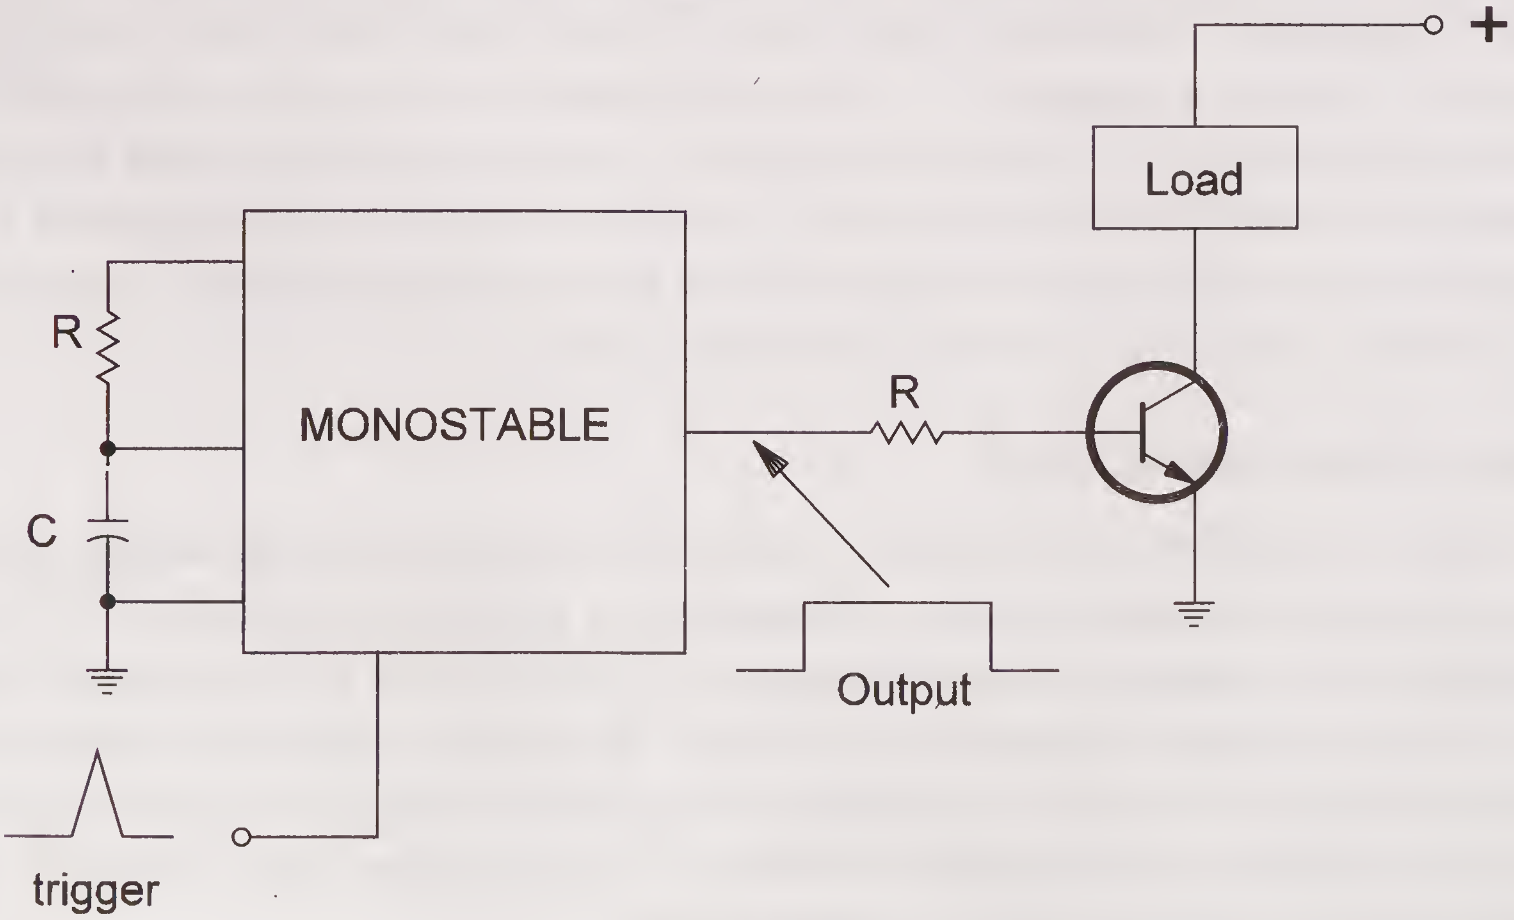

Figure 180

In the unstable mode, the circuit generates a square signal with a frequency dependent on some external components, normally an R-C network as shown in Figure 181.

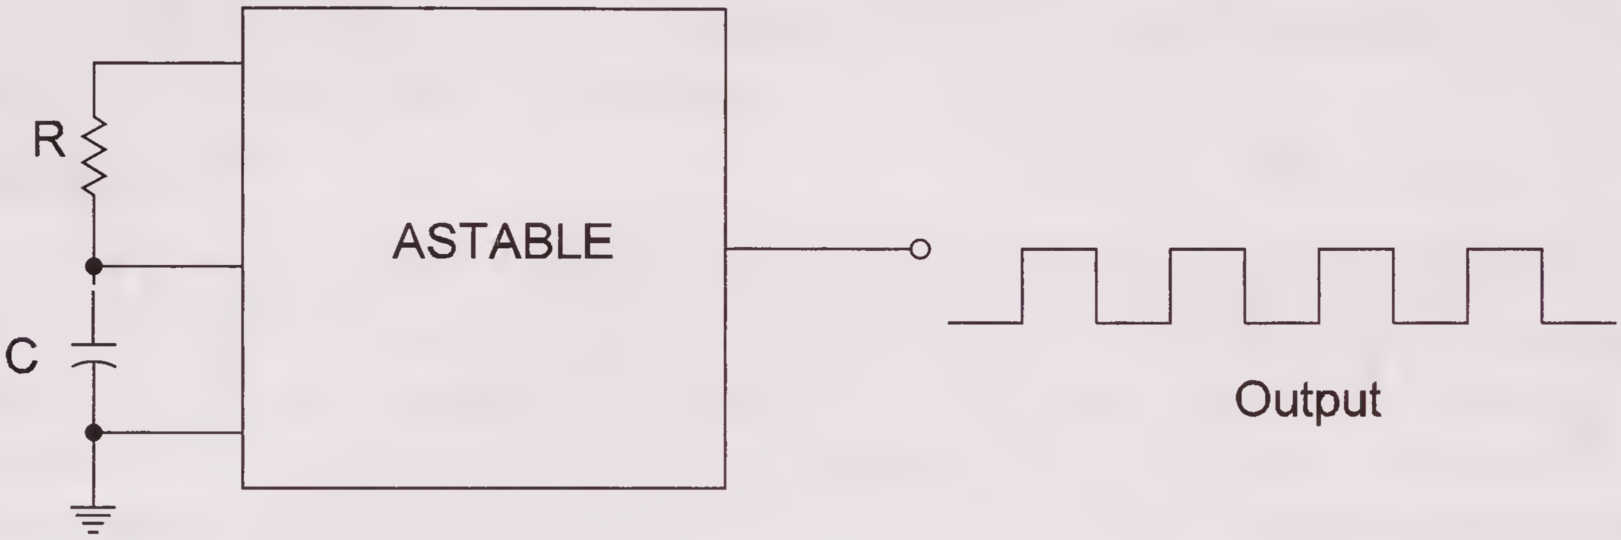

Figure 181

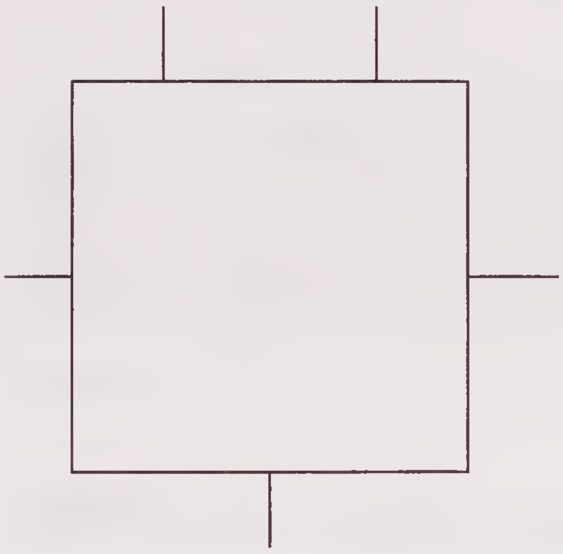

Figure 182

Symbol

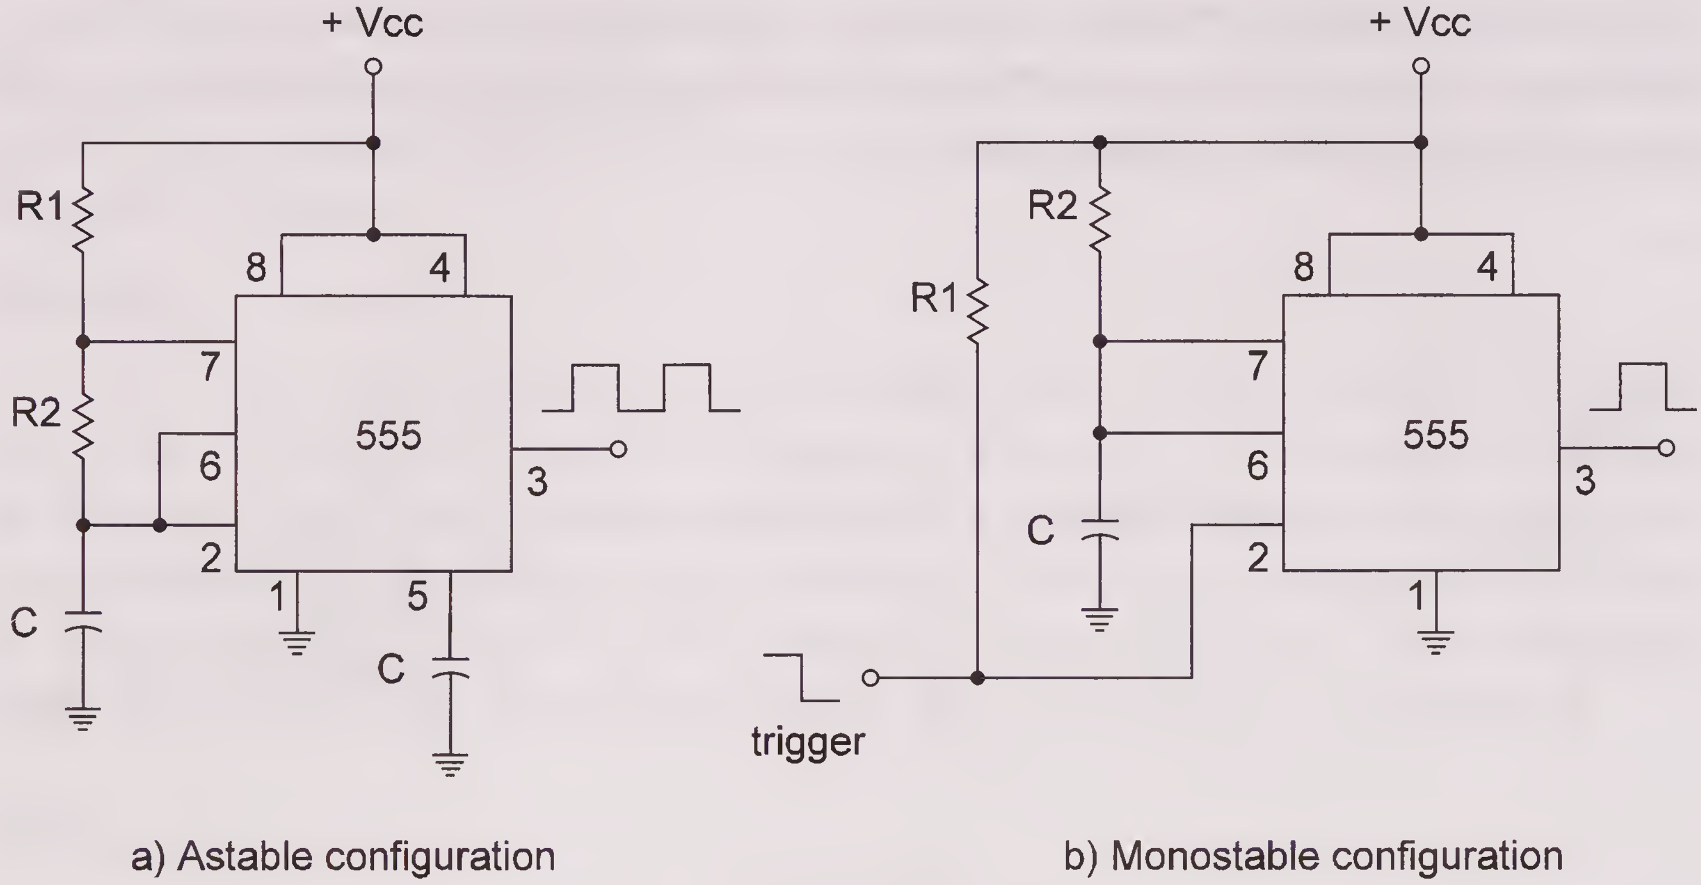
Figure 182 shows the symbol used to represent this function. The ICs of this family are found in DIL cases and others.

The 555

The most common of the timers is the 555 that can be found with manufacturer designations such as NE555, TLC7555, LM555, and MC555.

This integrated circuit can operate in two modes: unstable and monostable depending only on the way some external components are connected as shown in Figure 183.

The bipolar version (where the internal transistors are bipolar types) can provide time intervals up to one hour and oscillate in frequencies up to 500 kHz. A version using JFET transistors (TLC7555) offers larger time intervals and produces higher frequencies with lower current consumption. The meaning of 555 to electronics can be evaluated by a recent report that said that more than 1 billion units of this device type were sold since it launched.



a) Astable configuration b) Monostable configuration

Figure 183

Specifications

The timers in the form of integrated circuits are specified by a part number just as others. The electrical characteristics can be found in the manufacturer's documentation or the schematics of the equipment where they are being used.

The main electrical specifications are:

A. Power supply voltage—the given power supply voltage range where the circuit can operate.

B. How to calculate the time interval or frequency—In the applications, the external components (R and C) determine the operation frequency. A formula or curve allows the designer to find the correct value for the components to any application.

C. Output current—This is an important piece of information, as it says what can be controlled from the IC and how it can be done. In some cases, a transistor stage must be used to control something with a large current consumption .

D. Operation modes—Many timers have different operation modes. They are given in the specifications with information about the way the external component must be connected to perform.

Where they are found

There are many small devices found in electric installations that are based in timers like the 555, TLC7555, and many others. When you press a pushbutton in the wall and the lamp stays on for a certain time interval, most likely the circuit controlling this includes a timer integrated circuit like the 555 or one of the same family.

Testing

As in many other integrated circuits, there isn't a special procedure to test them. Any integrated circuit is a different circuit and specific procedures should be developed to make an effective test. The best way to know if the IC is good is by reading the voltages at its pins. Start with the idea that all other components are good, and compare voltages with specifications or indications in a diagram.

Phase Locked Loop—PLL

Phase Locked Loop, or PLL, are circuits that can be used in many important applications related to electric installation, home appliances, and cars. A PLL is a circuit that can recognize a signal of a determined frequency acting on a relay or other device. If the signal is modulated in frequency, the PLL can also be used to extract the modulation signal. Many types of PLLs in the integrated circuit form are found.

Symbol

Figure 184 shows the symbol of a PLL. The body is not different from any other linear function described here. The only way to know if the IC is a PLL is by its part number displayed as a number on the component's body.

Specifications

As any other IC, the PLLs are indicated by a part number. Using the part number, it is important to know some electric specifications when using a PLL or when trying to find a replacement type. The main specifications are:

A. Power supply voltage range—the voltage range in which the device functions.

B. Frequency range—a very important specification as it indicates the maximum frequency of a signal that can be recognized by a PLL or generated by it when operating as oscillator. Common general purpose PLLs, such as the 556, can operate at frequencies up to 500 kHz.

C. Sensitivity—the minimum amplitude of a signal that can be recognized by a PLL.

D. Output current—this speci-fication indicates the amount of current the device can source or drain when driving a load.

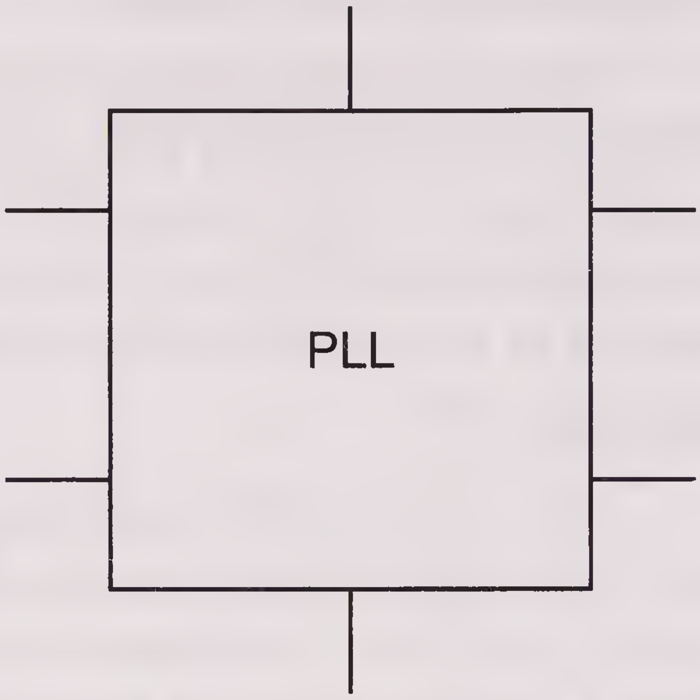


Figure 184

Where they are found

In many modern applications, the PLLs are included in more complex ICs. But, some exist that are for a simple application made by small manufacturers, or even made by amateurs that use the PLL as a single chip. In these case some common types, like the 4046, LM567, and others, can be found.

The next applications can give to the reader of how useful are the PLLs.

A. Remote control—used to recognize a tone sent by the transmitter (using a radio signal or IR) and act on a device (the motor of a garage door, or a function of an electric or electronic appliance)

B. Intercoms—Some types use the AC power line to send the sounds. The sound picked up by a microphone is used to modulate a circuit producing a frequency-modulated signal that is applied to the AC power line. A PLL in the receiver detects this signal and applies it to an amplifier.

C. Alarms—a tone is produced by a circuit and applied to a PLL via sensors. If any sensor is activated the PLL detects the absence of the tone and triggers the alarm.

Testing

The same procedure as recommended for others ICs is valid here: measure the voltage at the pins and compare it with the expected values.

Other Linear Functions

Many other functions can be found in linear ICs. Besides those described before, the reader can find ICs containing video amplifiers, comparators, voltage references, radio receivers, etc. There isn't a specific symbol for these functions and their aspects are the same found in other ICs.

Digital

The digital integrated circuits form a special group of devices with a large range of applications in modern electronics. The basic idea comes from digital electronics. Some fundamentals of digital electronics are important to know to expand information about the devices of this important group. Digital electronics start from the idea that any quantity can be represented by zeroes and ones (0 and 1).

Using only two digits to represent any quantity results in a numeration system named binary. Figure 185 shows how a number in the decimal system can be converted to the binary system.

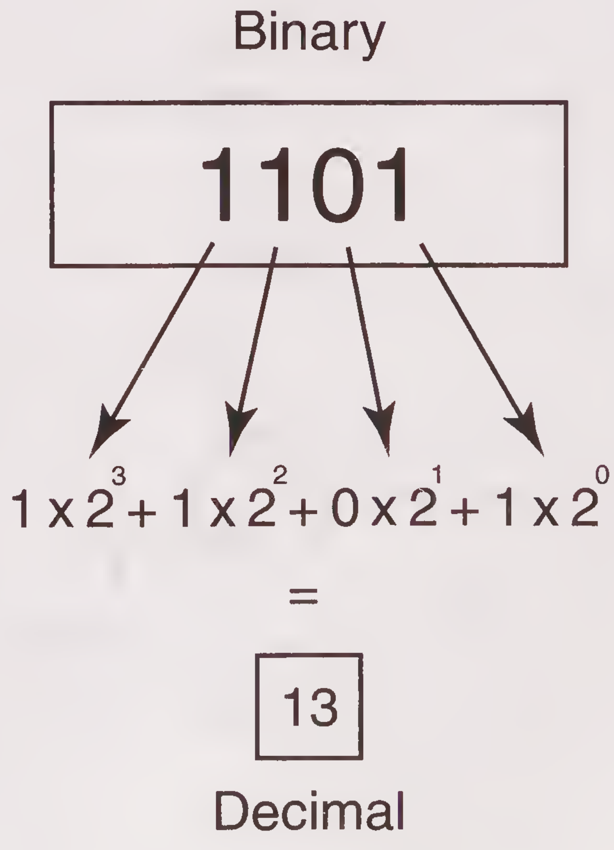

Figure 185

The advantage of the use of binary representation of any quantity is that it can more easily be handled by electronic circuits. In the simplest form, an open switch can be used to represent a zero and a closed switch can be used to represent a 1 as shown in Figure 186.

Working with opened and closed switches it is possible to make any mathematical or logic operations with numbers. The rules that command these operations were first established by Robert Boole two centuries ago. Moving now to the idea that a transistor (and some other components),

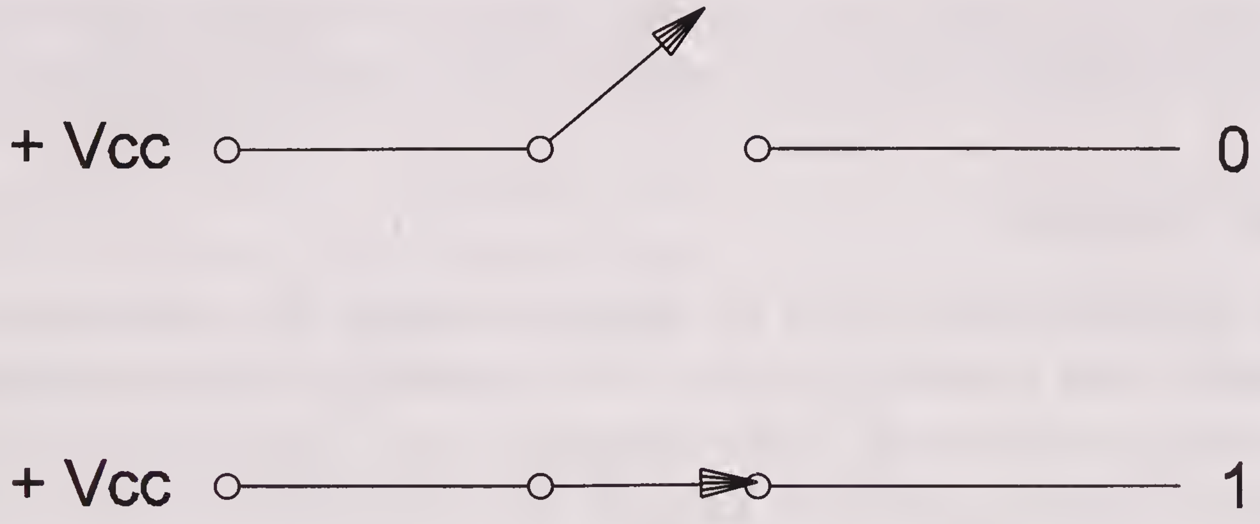

Figure 186

also act as a switch, it can be used not only to represent a zero or a 1 but to execute operations with binary numbers.

As shown in Figure 187, if a transistor is switched to a saturated state (conducting) the voltage in its collector falls to zero or a value near zero, allowing it to represent a low logic level or zero.

R1
R2
0V
(0)
S1
current
+ Vcc
+ Vcc
R1
R2
+Vcc
(1)
S1

Figure 187

On the other hand, if the transistor is switched off (cut), the voltage in its collector rises to a value near the power supply value. This voltage can be used to represent a high logic level or a 1.

Using many parallel transistors any complete number can be represented, and commanding them with appropriate signals, we can execute mathematics or logic operations.

A single digit, 1 or 0, that is used to represent a binary number, is called a bit and a group of eight bits is called a byte. A group of four bits is also called a nibble. A byte can be used to represent any quantity or decimal number between 0 (0000 0000) and 255 (1111 1111).

Thousands, and even millions, of transistors wired as switches can be placed in a chip in configurations that can perform any operation with binary numbers processing the bits to perform final bytes. They are digital circuits like the ones found in computers, microprocessors, microcontrollers, etc.

A certain number of basic functions are used in the projects of digital circuits. These functions are represented in Figure 188.

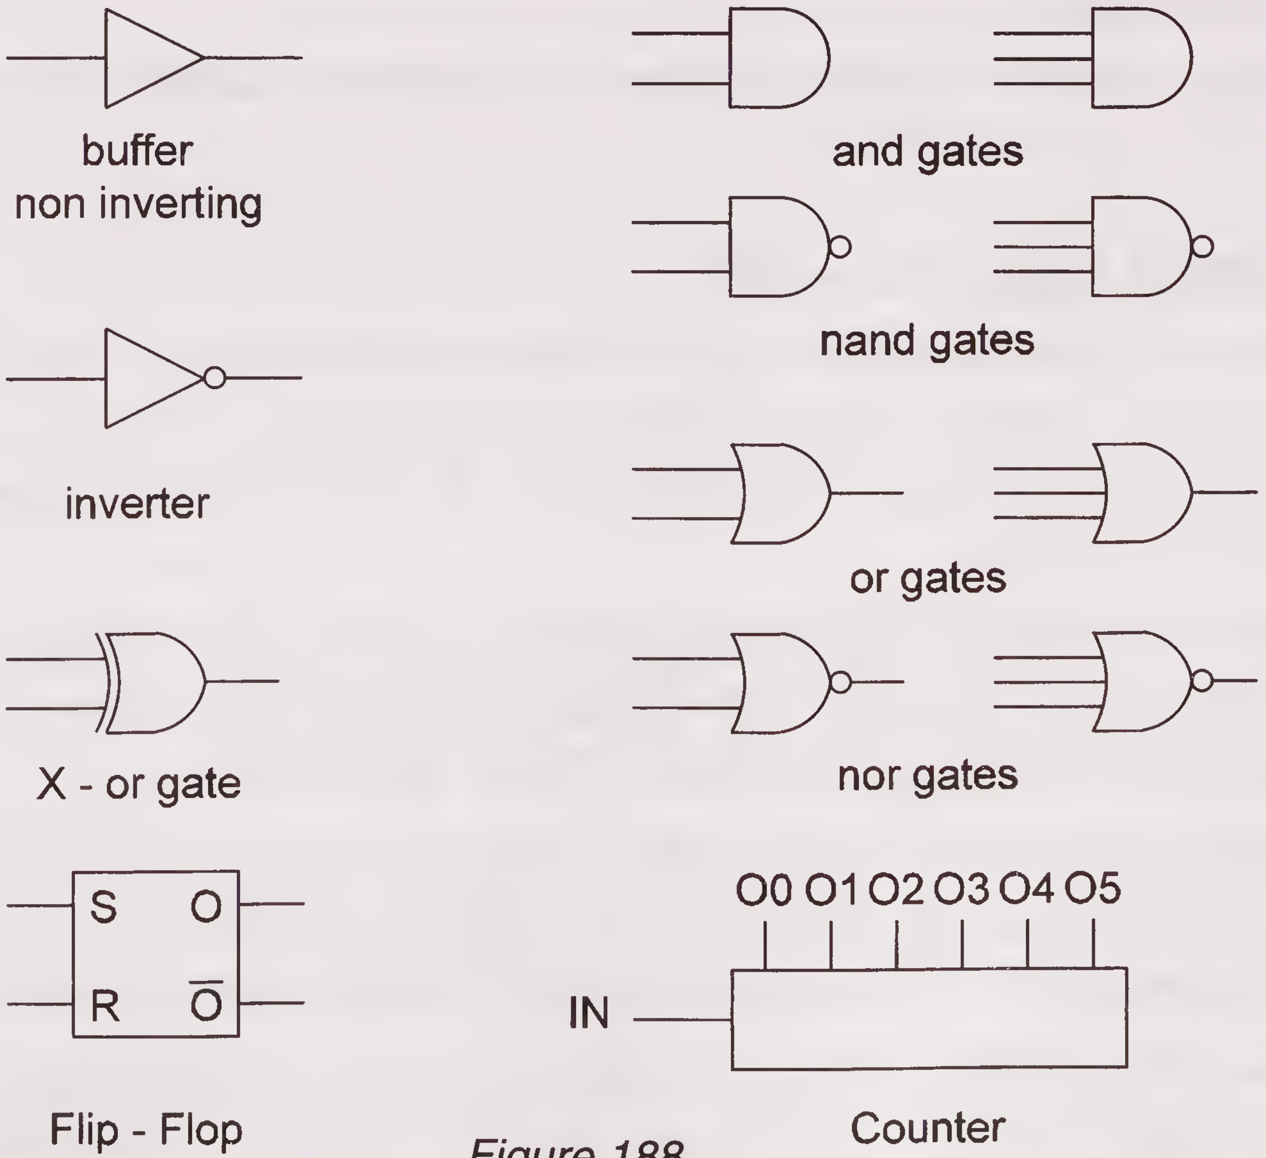

Figure 188

In the first group of basic functions are the gates. Gates are circuits that combine two or more logic levels or digital signals given as a result of logic level or signals determined by rules. The rules follow the mathematics created by Boole. In the second group are more complex functions such as flip-flops (that can store a bit), multiplexers, counters, and decoders. The readers who want to know how a computer and digital circuits work must study digital electronics and Boolean algebra.

In the first computers, like the ENIAC (1942), operations with the bits were done by circuits using tubes. Some time later, the tubes were replaced by transistors. The next step was the use of a large quantity of integrated circuits, each containing many transistors, placed in boards. Now almost all the circuits are inside a chip (one integrated circuit) forming processing units called microprocessors.

Although all the digital circuits are now inside the chip of a microcomputer or other advanced digital circuit, there are applications where integrated circuits performing simple operations or functions must be used. These circuits form families of digital integrated circuits were they all have matched characteristics allowing for interconnection directly to form more complex devices.

Today, a lot of equipment uses integrated circuits of two main families, the TTL and the CMOS.

Transistor Logic IC—TTL

The TTL or Transistor Logic IC family is formed by a large number of devices (near 1,000) with common characteristics. They are all powered from a 5 V power supply and the output of one can be plugged directly to the input of another.

The standard or normal family of TTL devices comprises a large number of functions as gates, flip-flops, counters, decoders, multiplexers, demultiplexer (MUX and DEMUX), PLLs, and timers.

Some subfamilies add to this group of ICs' special characteristics, such as the low-power Schottky (LS) that is compatible with the circuits found in computers adding to the devices' low consumption and high speed.

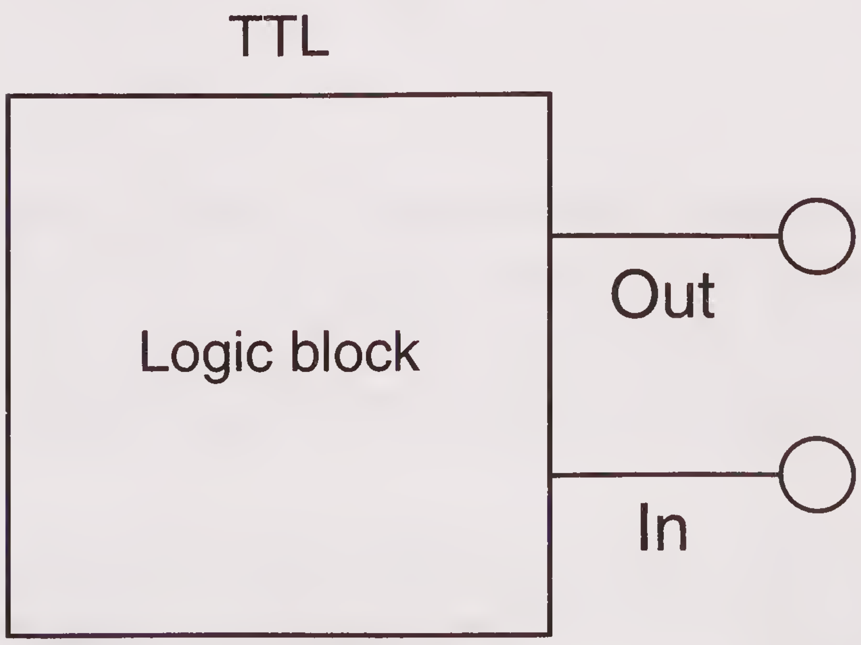
The TTL devices are easily recognized by the designation "74" beginning their part number. Sometimes the TTL family is also called 74 family or 74xx. Almost all devices in this family are designated by a 74 followed by a number according to their function (7400, 7492, 7191, etc.). The subfamilies are recognized by a letter or two after the 74. For example: 74LS04 (low-power Schottky), 74H93 (high power), 74S121 (Schottky), etc.

CMOS

The other important logic family of ICs is the one formed by the CMOS integrated circuits. These circuits perform the same functions found in the TTL but with different electric characteristics. They can be powered from supply voltages ranging from 3 to 15 volts or 3 to 18 volts. They are not as fast as the TTL, but their consumption is lower and their input impedance is very high.

The devices of this family are designated by a "40" followed by a number that says what the device does. So, we find designations like 4004, 4017, 4093, and 40121. Some CMOS subfamilies use the same designation or number of the equivalent TTL function. These devices are indicated by the 74 code but with a C to indicate it is a CMOS (i.e., 74C00).

When working with TTL or CMOS circuits, the technician needs a digital CMOS or TTL handbook or databook to reference what the function of the IC is. The important fact to be observed when working with logic circuits is that all of them work with pulses or logic levels. If the circuit operates with logic levels in the nonsynchronized mode, in the inputs and outputs you will find only two possible voltages: 0 V or the power supply voltage (5 V in TTL or between 3 and 15 V in CMOS circuits), as shown in Figure 189.



Logic level	Voltage
0	0
1	5v

Figure 189

If the circuit is synchronized by a clock, the signals are square pulses as shown in Figure 190.

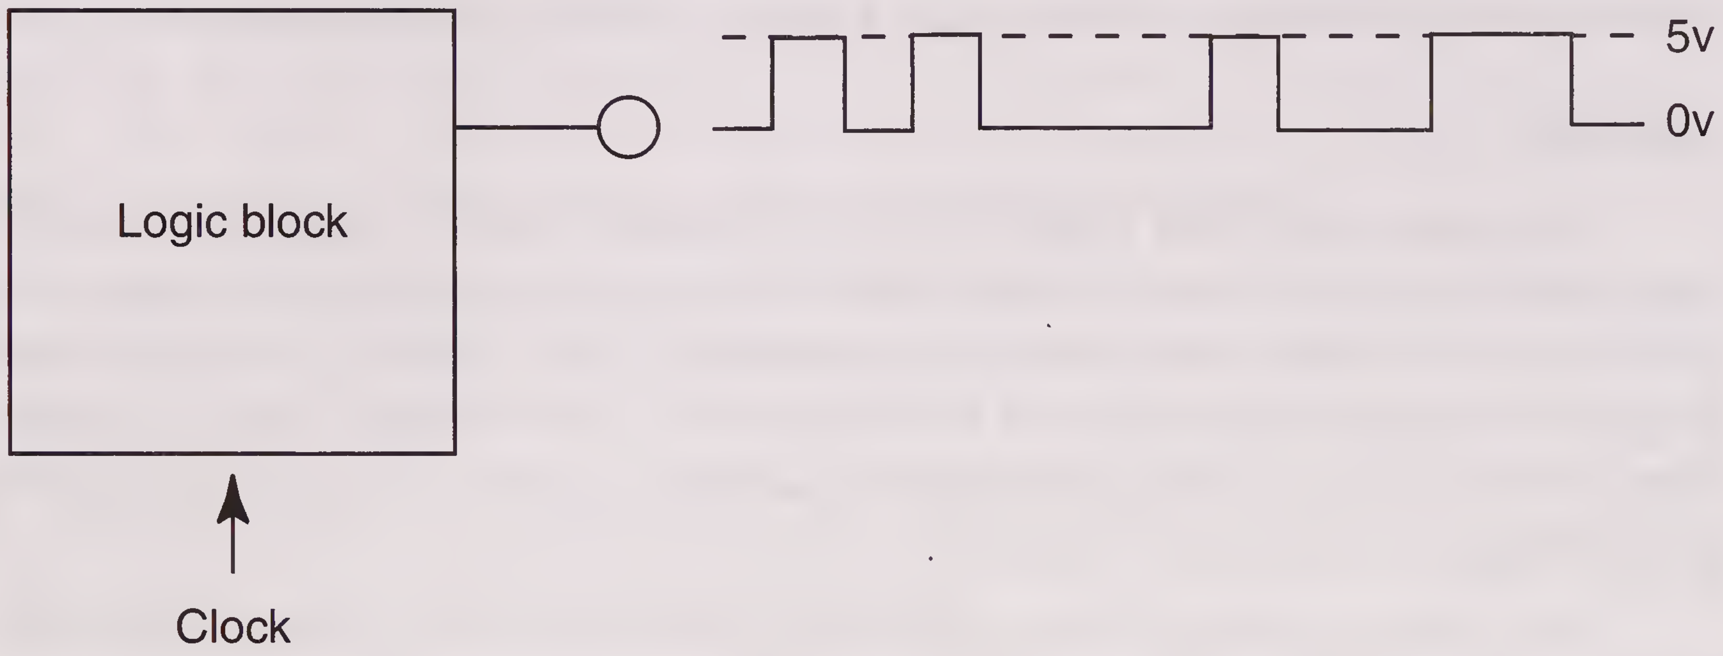


Figure 190

Specifications

The function of each digital integrated circuit is given by its part number. The basic electric characteristics are the same in the entire family. It is important to remember that TTLs always need 5 V to be powered and CMOS needs any voltage between 3 and 15 V.

WARNING—The integrated circuits of the CMOS family are very sensitive to electric charges stored in the body (static electricity) as are the CMOS transistors. Never touch the terminals of these devices directly. The discharge of the electric charge stored in your body can destroy the device.

Where they are found

As in other cases, the equipment where CMOS and TTL devices are found depends on several factors. Today, in modern equipment, the tendency is to place all the functions of a circuit inside one. This chip can contain the equivalent of hundreds or even thousands of TTL or CMOS-isolated ICs.

Although the operation principle is the same, you don't have access to each one and if something happens with one of them you must replace all of the circuits or the IC. On the other hand, the electrician, in his work with electronics, can find older equipment or equipment made by small manufacturers that doesn't use complex circuits, and also where isolated TTL or CMOS circuits are found.

Their circuits perform simple functions, such as those of timers, sequencers (light effects and signaling), alarms, remote controls, automatic lamps, night lamps, and inverters.

A basic circuit can show to the reader how they are used, such as the interesting circuit found in common applications that is shown in Figure 191.

This is a sequencer circuit using the common 4017. Each pulse you apply to the input makes one output of the circuit go to the high logic level, which means the voltage rises from zero to the power supply voltage. It is possible to select which output goes to the high logic level or is activated by the number of pulses applied to the input.

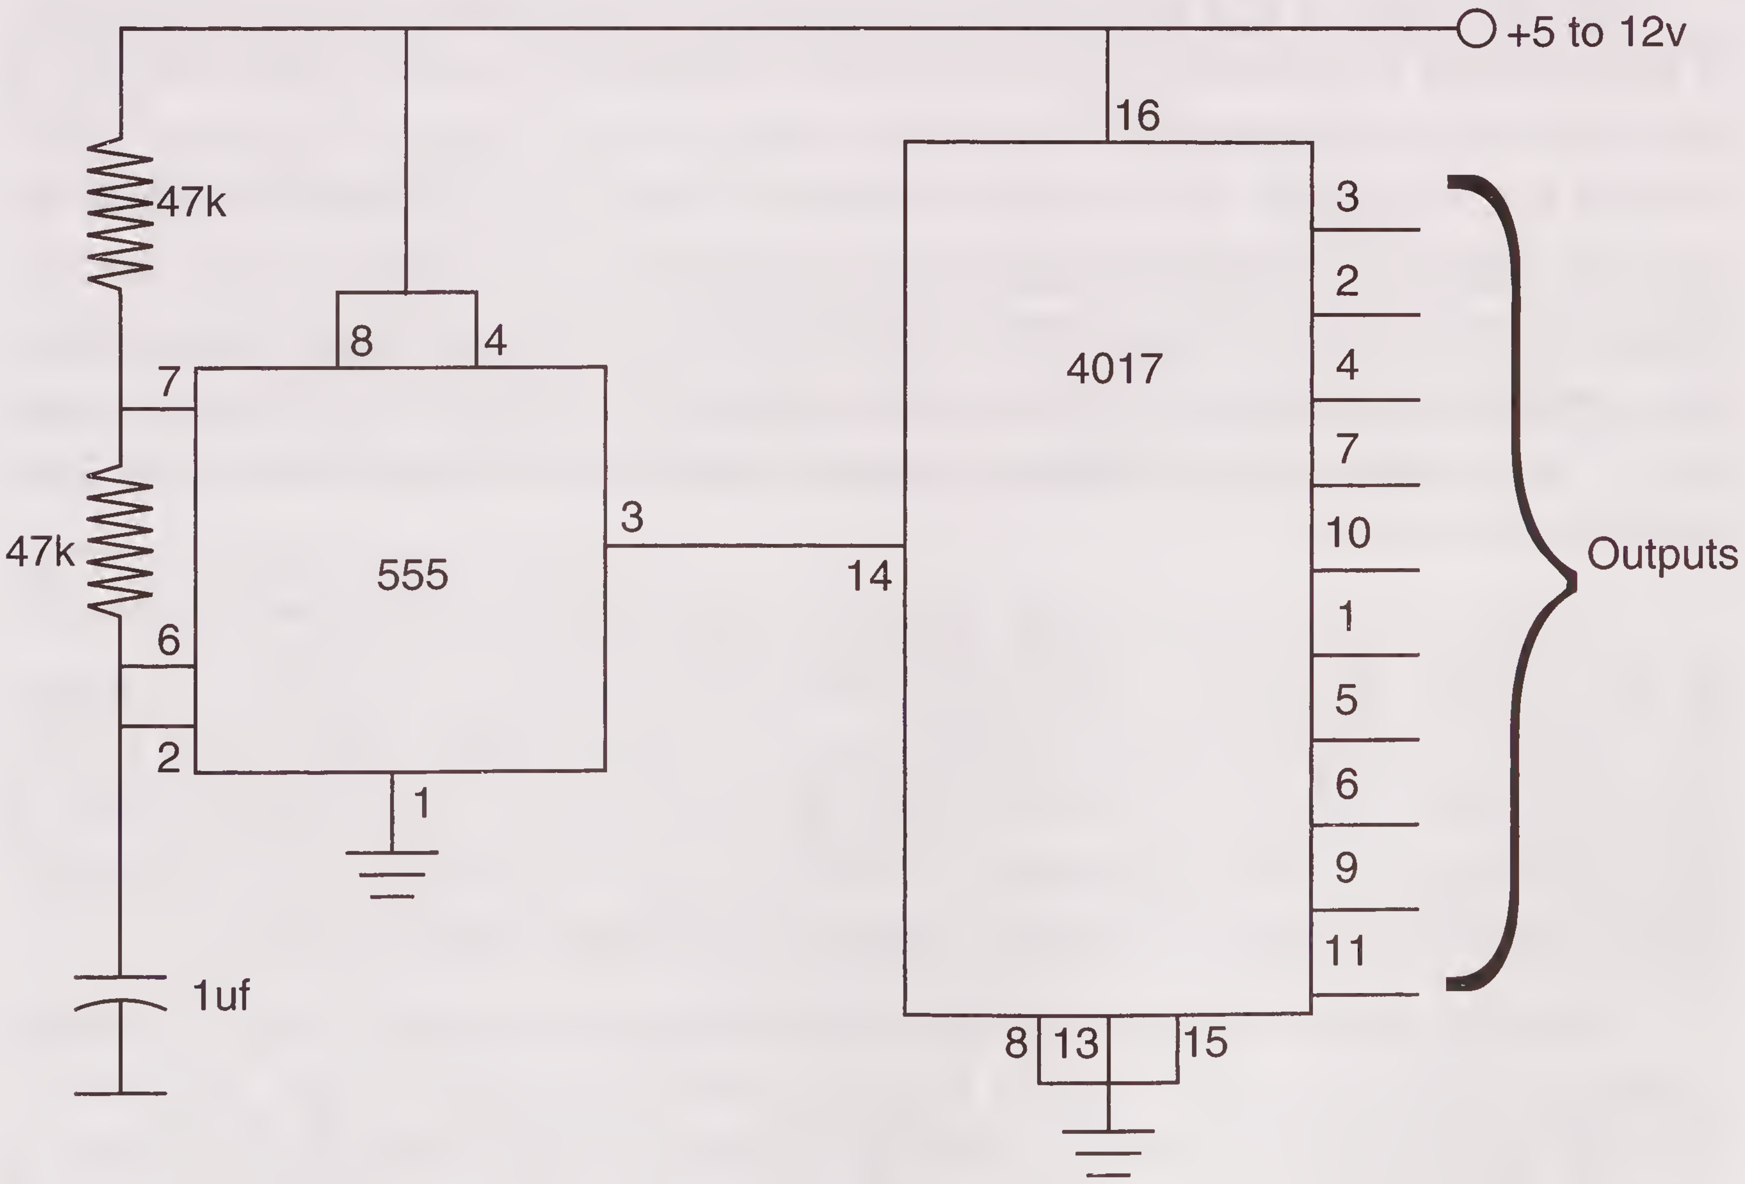

Figure 191

Testing

Testing of digital integrated circuits must be done using special instruments. The simplest way is measuring the voltages with a multimeter, but it is not conclusive in many cases (depending the way the circuit operates). The advanced test uses logic probes or oscilloscopes to monitor the digital signals in each IC.

Custom and Embedded

Today almost any function or circuit can be made in the form of an integrated circuit. To reduce costs and space the manufacturers can create their applications and put almost all the circuits in a single chip. This means that their products don't use many common integrated circuits, but instead use only one circuit dedicated to a specific use. In some equipment using these integrated circuits, functions like the power output can be performed by common transistors or SCRs, but the core of the circuit is a single chip with no equivalents.

As the cost of ICs for these applications falls, along with the quantity of equipment manufactured, the boards these ICs are installed on have become very inexpensive. This means that in the case of failures, entire boards are replaced. The main problem for the technician who makes repairs on these is that the boards are found only in authorized repair shops. Neither the board nor any of its components can be found at regular dealers. Another problem is that in many cases the equipment is a one-way type. This means once a failure occurs it is better to discard the equipment and buy a new unit.

Another kind of technology found in new equipment is one referred to as embedded. Embedded devices are used to control, monitor, or assist the operation of equipment, machinery, or entire areas, according to the IEE definition. These components are an integral part of the system where they operate. In a car, embedded circuits control all operations of the electrical system including electronic ignition and electronic injection.

They are basically formed by microprocessors and microcontrollers in the form of integrated circuits that are mounted inside black boxes. Access to embedded circuits is through cables. They allow the system to exchange control and sensor signals.

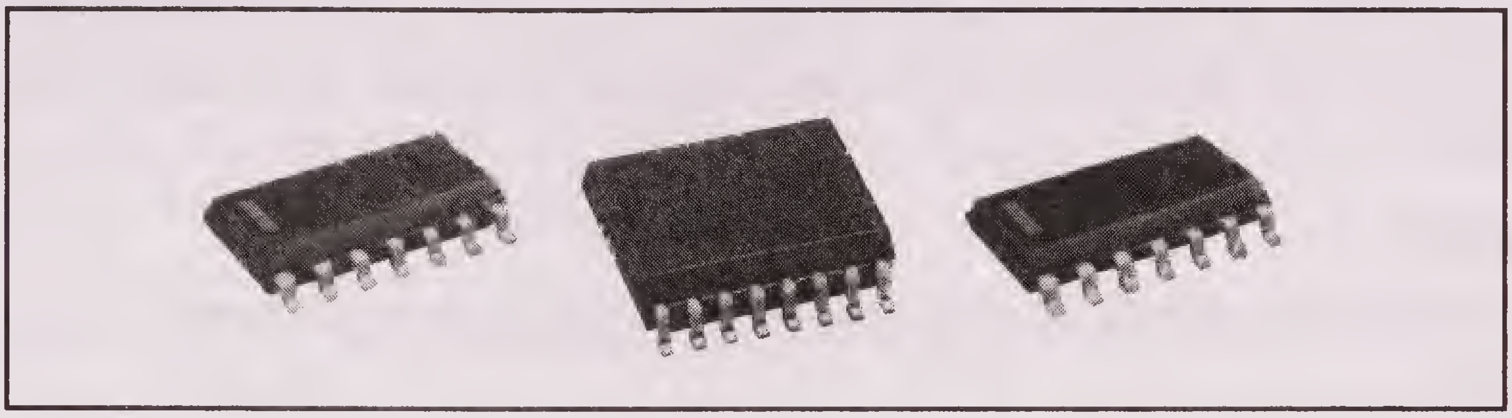

Figure 192

Types

No special symbol has been adopted to represent this kind of circuit. Figure 192 shows various types of these devices.

As the device is not intended to be handled by technicians, but only by machines, it is common to find them on boards in the SMD format, or a format called on-board. In the on-board format the chip, without case, is soldered directly on the printed circuit board and protected by a rosin or epoxy.

Specifications

In some cases the manufacturer indicates the IC by a part number, but in some one-way applications the device could only be identified by the manufacturer. In some cases, as in the black boxes of many embedded systems, the devices do not have any identification displayed.

Where they are found

The embedded functions are found in car equipment, home appliances, and toys just to name a few. For example, you can find these ICs in calculators where the manufacturer "creates" the circuit he needs to perform a function and places it directly on the board. Another example is electronic dolls that have a chip with voice-programmed functions so it can talk. The low cost of these specialized circuits and the form in which they are mounted make them impossible to be repaired or replaced.

Clocks and watches also use special chips containing the complete function they need in a single chip. Some of them can include the display. The clocks, counters, and other functions formed by a chip and the display are called modules. Many appliances use complete modules of counters, meters, clocks, and other basic functions. In some cases, if the function is not critical, the module can be replaced by another that has the same function.

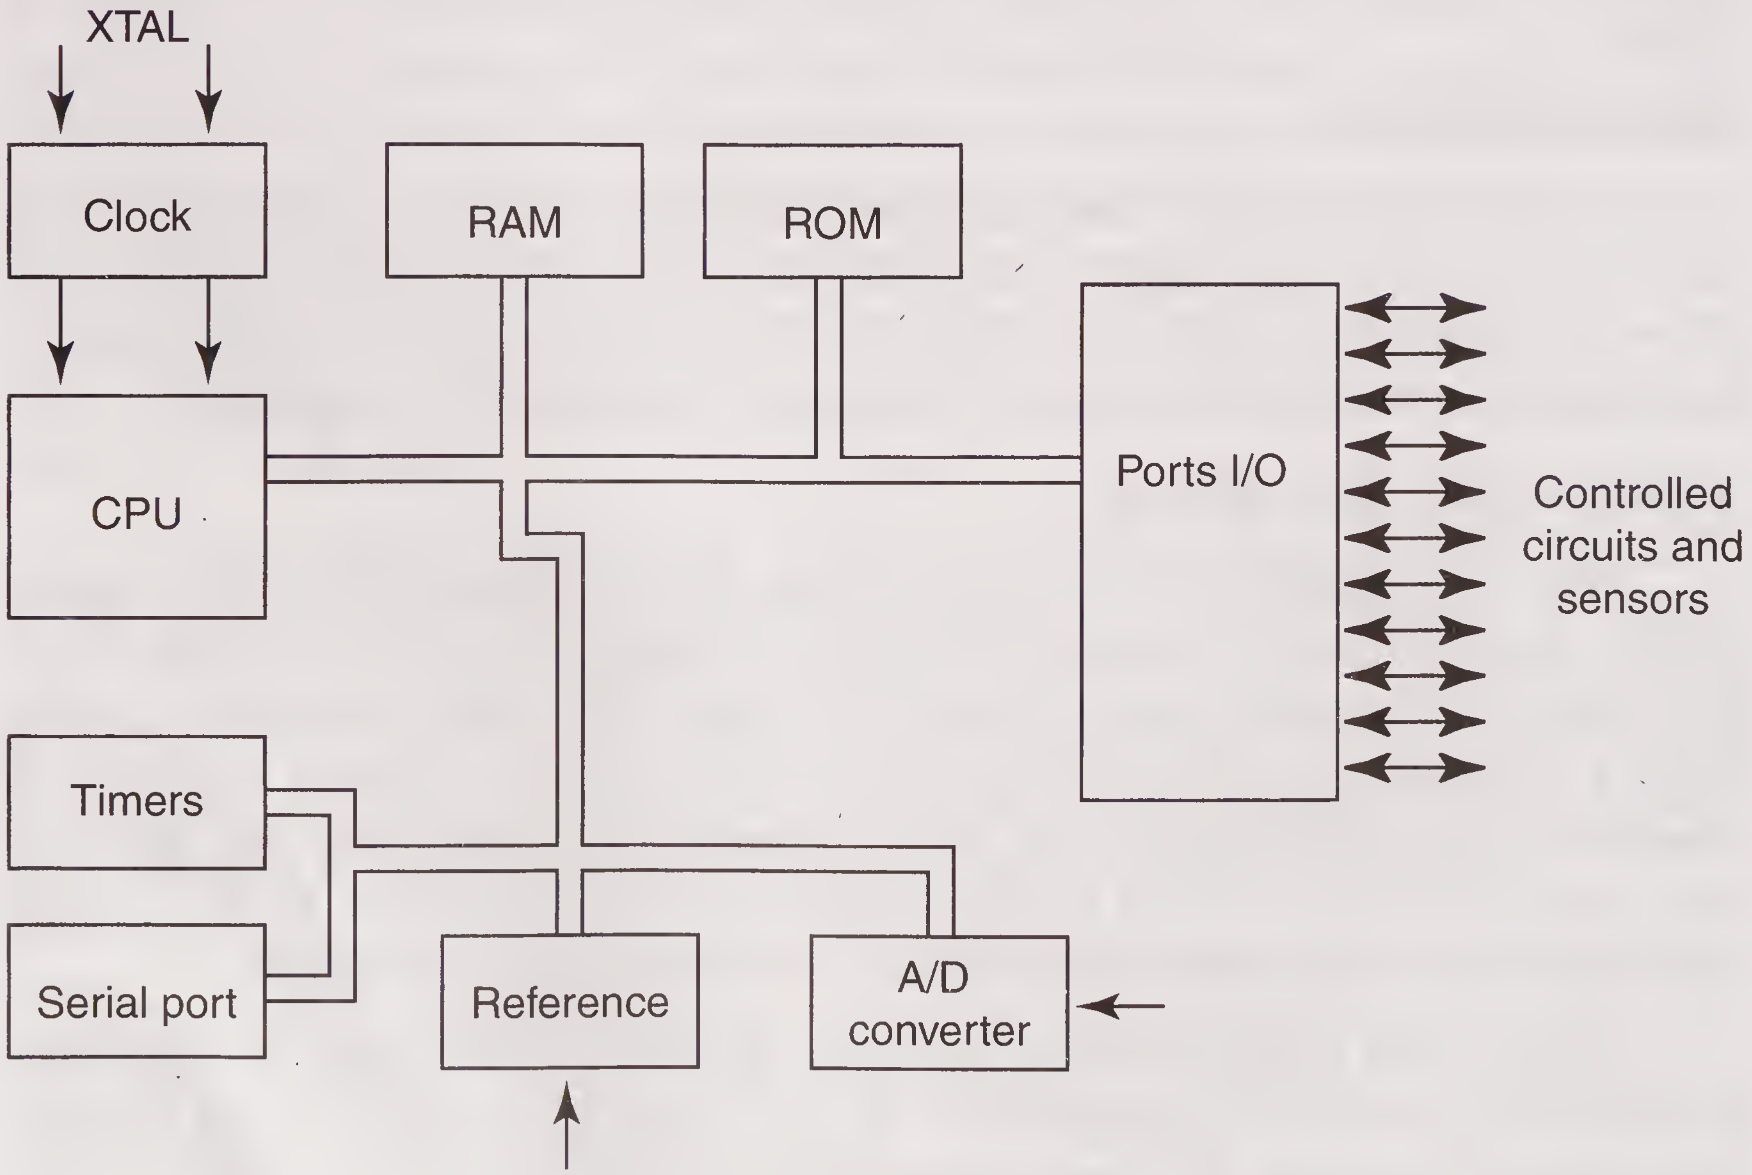
Testing

There is no practical way to test them as each represents a separate function.

Microprocessors and Microcontrollers

Microprocessors and microcontrollers represent another great group of devices in the IC family. In a single chip thousands and even millions of components are used to perform a complex digital/analog function. Microcontrollers are intended to control applications, such as those in industrial machines and automatic devices. The microcontroller is formed by input/output blocks, a processing unit, and a task-programmed memory.

Figure 193 shows the structure of a typical microcontroller block.



XTAL

Figure 193

Microprocessors are also used to perform complex mathematical and logic operations and are used in computers and other equipment. The microprocessor only works with digital data performing operations and returning with the results in the digital form. Figure 194 shows the block diagram of a typical microprocessor.

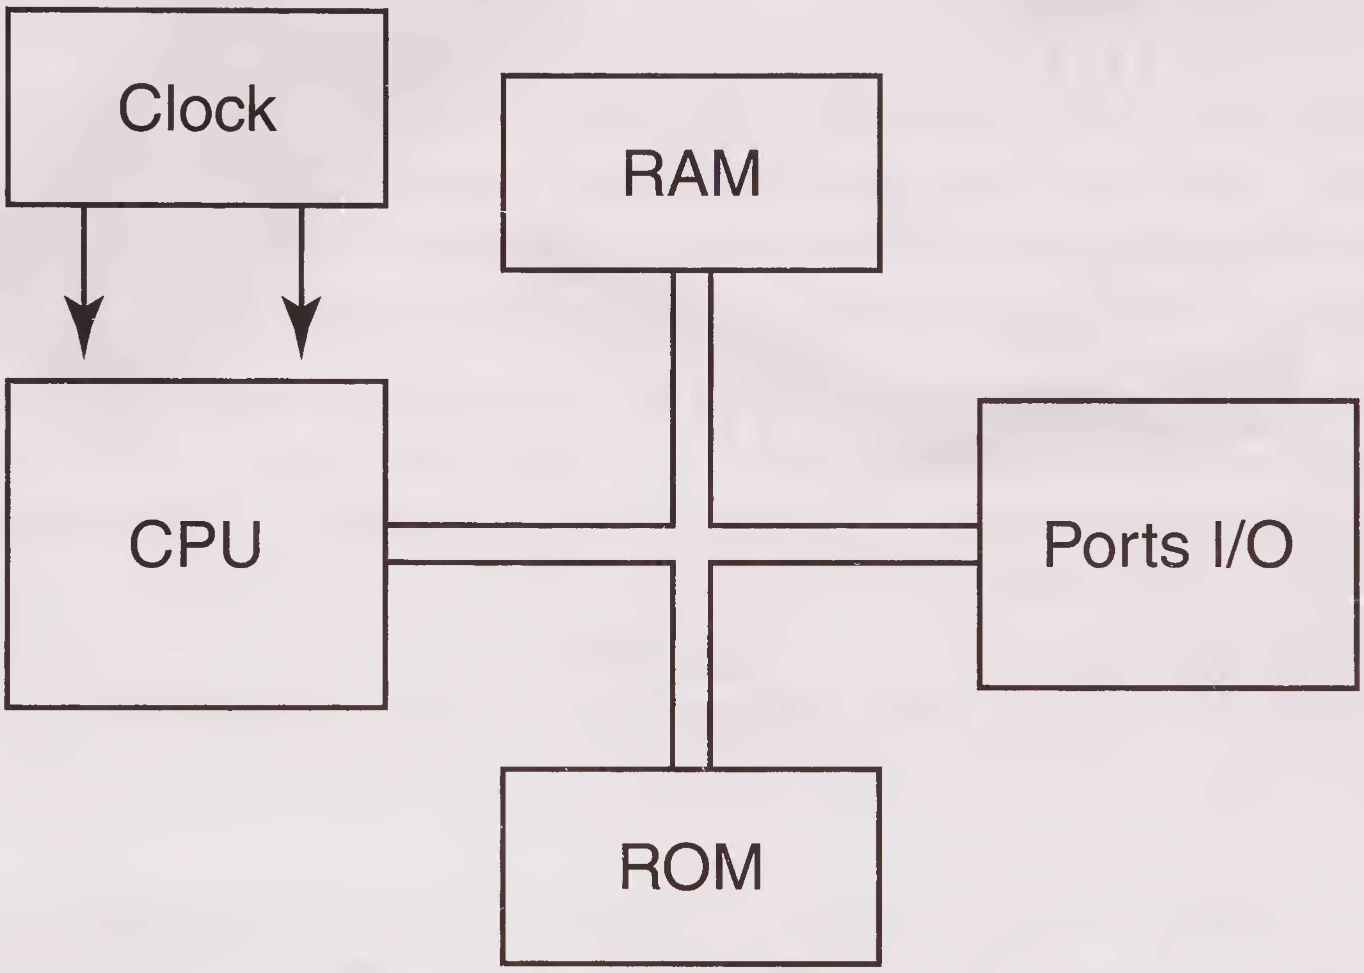

Figure 194

Microprocessors have input and output ports (I/O) where the information is placed and gathered, a CPU (central processing unit) where the mathematical and logic calculations are made, a memory, and other supporting circuits. Microprocessors are found in computers. Some families of microprocessors exist that are very common today.

Starting with the Z80, an 8080 is found in many old appliances as a "brain" where functions are calculated. More often now, we are using the microprocessors of the X86 family. The "X" is a number indicating the specific type. Several years ago, the 286 was common, now it is the 586. Variations with different names that include the Pentium K6, Athlon, and Celeron are prevalent. These microprocessors become famous through recognition in the personal computer (PC) field where they are used as the core.

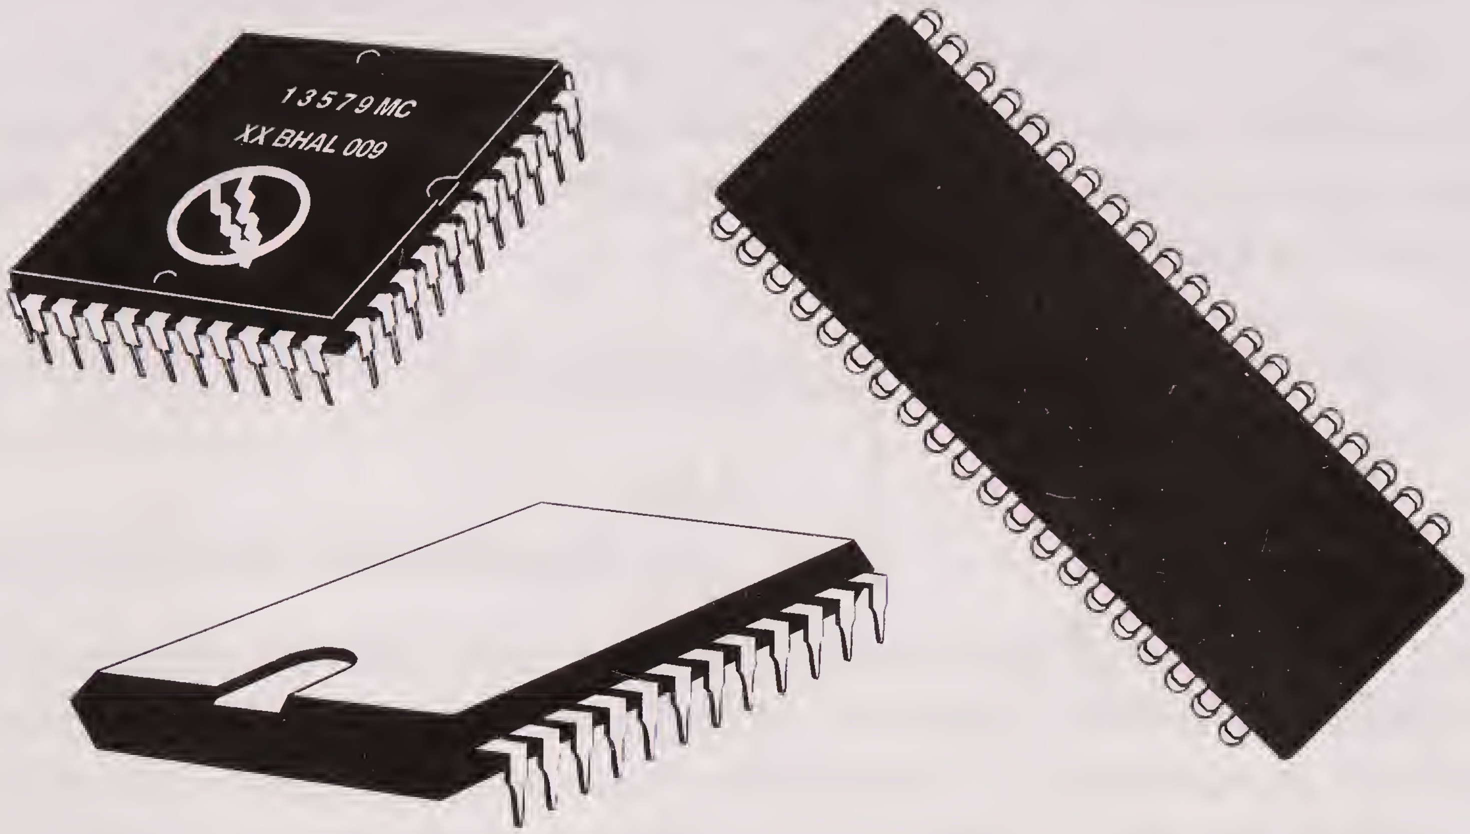

Figure 195
Chips and microprocessors similar to those used in PCs

The electrician who intends to work with computers will find a board inside, referred to as the mother board, where the microprocessor (also called CPU or central processing unit) is placed. The microprocessor is a very complex integrated circuit, containing millions of transistors and using a special body as shown in Figure 195.

Microcontrollers are found in industrial machines, appliances, cars, and other equipment performing control functions. They appear in the form of common integrated circuits in DIL bodies or more complex circuits (SMD and other) based on the number of pins and functions. Some families of microcontrollers are popular and are used in many applications. The 80C51, PIC, COP8, and others can be found in professional equipment.

The use of a microcontroller depends on some resources. The designer must have the tools to program them including a special board with a socket where the microcontroller is placed, a computer, and software to prepare the program. The designer should prepare the program that says what the microcontroller must do. Once prepared, the PC transfers the program to the microcontroller.

Specifications

Microcontrollers and microprocessors have large databooks to provide all their specifications. The technician wanting to use these devices needs special courses that involve a large amount of technical information.

Digital Signal Processor—DSP

Many other devices in the form of ICs can be found in electronic equipment including those related to electric installations and cars. New functions like the DSP are an example of devices that are designed to perform specific functions normally determined by the manufacturer (custom).

These devices are found in many kinds of electronic equipment, such as cellular telephones, computers, fax machines, industrial machine controls, dishwashers, clothes washers, remote controls, electronic injection, and ignition controls in cars, DVD players, TV satellite receivers, and videocassette players. They are not simple devices or components, but complete circuits programmed for a predetermined purpose, mounted on a chip, and installed inside a case like the ones used in any other integrated circuit.

What is a DSP?

The traditional analog circuit operates with analog signals like sounds, images, or voltage changes from a sensor, along with traditional components and circuits such as transistors and filters. The analog circuit uses the electric properties of the components to introduce some alterations in the signal's original form. For example, a bandpass filter lets only signals for a determined frequency band pass through it; an amplifier changes the amplitude of a signal.

Depending on what you want to do with a signal, the implementation of a network using common devices is not only very difficult, but is not very accurate. However, if we consider that any analog signal can be represented by number or a stream or numbers (converted to a digital form), why not perform the desired function with the signal working in the form of numbers? Instead of using a network that lets only a determined frequency band pass, convert the signal into a stream of numbers in a computer, apply an algorithm to the numbers that recognizes the frequencies and amplitudes, and the undesirables values are cut. (An algorithm is a sequence of mathematical and logic procedures.) After that, the remaining values are converted again to the analog form.

Figure 196 shows, by a block diagram, how the DSP works.

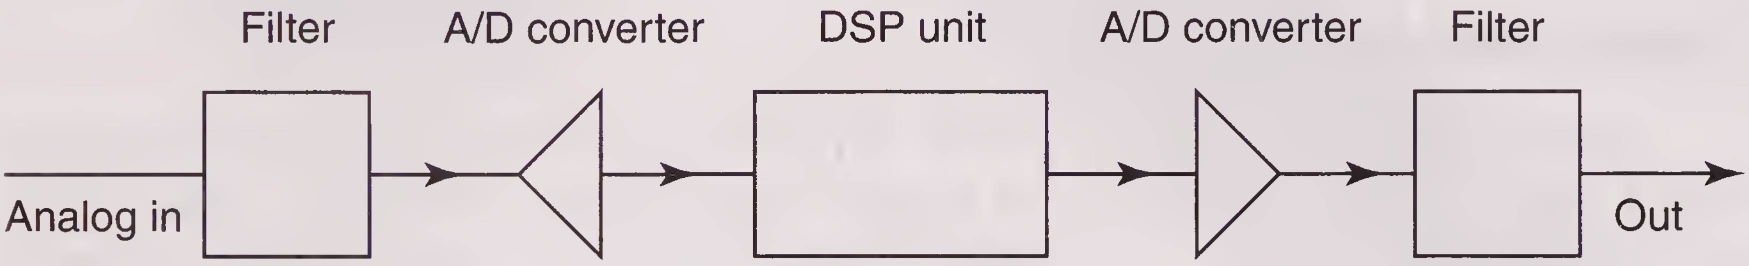

Figure 196

Since a computer is precise and fast, the results presented by this kind of circuit are fantastic—much better than a common analog circuit designed to do the same task. The processor inside a DSP is fast and can perform extremely complex operations, making it possible to make almost everything you want with a signal depending only on the software (algorithm) used. Using a DSP, what a circuit will do no longer depends only on the components used, but on a program!

Many DSPs are used today in common electric and electronic appliances in control functions to replace microcontrollers. For example, a manufacturer can buy an empty DSP and program it to perform all the functions needed to control the motor of a clothes washer, including functioning as the water-level sensor and the temperature sensor. The DSP processes this information and determines the voltage (speed) to be applied to the motor, the voltage applied to the water heater, etc.

To install it on a board, there are specific DSPs for this product without the need of common devices in a large board. The same DSP can be used by another manufacturer to control the motors, solenoid, and relays of an industrial machine. The only thing the other manufacturer has to do is plug the necessary peripherals into the DSP and install the appropriate software.

Of course, if a DSP fails in a machine, the technician has no other solution than to look for the original part from the manufacturer. Also, a single DSP (without the program) doesn't work in a machine if it isn't programmed with the original software. The DSP must be purchased with the original programming of the manufacturer. The problem is simpler if a peripheral component fails, such as a transistor, SCR, or relay. In this case, the component can be easily replaced.

It is important to know that the DSP is identified by a part number (Texas Instruments, Analog Devices, and Motorola are manufacturers of DSPs), but if you buy one at any dealer it comes without the programming. If you intend to build any electronic equipment, depending on its function, the use of a DSP should be considered.

Surface-Mounted Devices—SMDs

Many of the devices we have seen before can be found in an ultraminiaturized version mounted by machines in large manufacturers' assembly lines. Notice the majority of the devices are in cases. The active element of a resistor is only a thin layer of carbon; the active element of a transistor, SCR, or triac is a small silicon chip. The active element of an integrated circuit is also only a small silicon chip.

The body, for the most part, represents more than 95 percent of the size and weight of the component. It is clear that, if the body is reduced, we can gain space and profit, but on the other hand, we lose the ability to handle it. The basic idea of the SMD is to reduce the body to the minimum,

Figure 197

in a way that only machines can handle it. Reducing the size of the components in the equipment makes them cheaper, smaller, and lighter. Resistors, capacitors, diodes, transistors, and ICs can all be found in SMD versions as shown in Figure 197.

This figure shows the typical dimensions of these components and how they are mounted on a printed circuit board. Special machines place the components on a board using glue and solder. The working technology applied in this case is also called SMT (surface-mounting technology), so it is common to refer to devices used in this form as SMD and the technology as SMT.

It is important for the electrician to understand that the functions and the circuits are the same as those used in the common components. The difference is only in the size and shape of the components. The main problem is how to handle them if a repair is needed.

Special kits, consisting of small tweezers, screwdrivers, and other delicate tools are available to help technicians replace SMD devices when repairing equipment. The same dealers usually can furnish resistors, capacitors, and many other components in the SMD format as well.

Section 3

Troubleshooting and Repair

One of the purposes of this book is to give an electrician some basic knowledge about electronic components and circuits—knowledge that is necessary to make simple repairs and install electronic equipment coupled to electric installations, powered from electric installations, or even found in a car. It is not up to the electrician or professional of any field other than electronics to make complex repairs in electronic equipment. This task must be left to professionals. But, depending on the problem, repairing electronic equipment is not difficult if an electrician knows some basic procedures. There are two kinds of problems with electronic equipment the reader of this book can solve:

1. Simple problems with the equipment circuit.
2. Problems due to the installation or operation of the equipment.

This section presents a basic look at symptoms and causes of simple problems the reader, who may not yet be familiar with the operation of electronic circuits, can solve.

Because we can't see, hear, or smell electricity, knowing exactly what is wrong in a circuit only can be discovered with the aid of instruments or a procedure using symptoms as a basis for troubleshooting.

Of course, as this book is introductory, a reader wanting to go a step further will need more information. If you want to go into the profession, you will have to learn much more in a technical course as well as obtaining access to a variety of technical databases. It is also important and helpful to read technical periodicals because they provide useful procedures and ideas on new technologies.

The First Step

If a piece of electronic equipment doesn't work as expected what are the basic procedures to find the cause and how then to repair it? It is a false idea (coming from the tube age) that you should replace a given part when a certain symptom occurs. This is not valid for very complex equipment and circuits where hundreds or thousands of interdependent components exist. In complex circuits the same symptom can occur when any one of many components fails, and in some cases, many of them fail at the same time. You must know how the circuit works to form a hypothesis about what the cause of the trouble is.

For an electrician who is now starting with electronics, it is too early to try real troubleshooting and repair work in complex equipment. We can, however, provide some basic procedures to allow determination if the cause of a problem is inside the equipment (and requiring professional help), in the installation itself, the result of improper use, or some other external problem.

The basic procedures are also useful to determine the cause of simple problems that need no professional help to be solved, such as burned-out fuses, unplugged connectors, and broken wires.

Safety Rules of Troubleshooting

These are the most important items when working with any piece of AC-powered equipment, and even equipment powered by other sources can use high voltages. It is very important to know the hazards associated with the equipment you are troubleshooting. Electricity can kill and the electrician working with dangerous AC voltages must know that.

- Don't turn on the equipment without thinking about it first. Start with some analytical thinking. Be sure that you know how to operate the equipment you are troubleshooting before powering it on.
- Don't touch parts if you don't know what they are for or how they work. You can cause more damage to the equipment; a simple problem can be turned in an expensive problem.
- Look for visibly damaged parts such as burned-out resistors, interrupted cables, and bad connections. Many problems have simple solutions. The visual inspection is the starting point in any troubleshooting work.
- Learn from mistakes; incorrect procedures when troubleshooting can turn a simple problem into an expensive one. Let a tool fall inside equipment being tested causing a short and you will have a real example of what that means.
- Working with modular parts: modern electronic equipment often uses modular parts. If you can identify the cause of a problem in a module, it is easier to replace the complete module than trying to repair it by looking for burned-out components.
- Don't always trust your instruments. If you are using a multimeter to measure voltages or a resistance in a circuit and the reading is confusing, don't assume that is something wrong with the circuit. In many cases, the characteristic of the multimeter and the presence of other components near the one being tested can mask the results. Using the multimeter is an art and only with experience can you begin to trust all the measurement made by this kind of instrument.
- However, the multimeter is probably the most useful of all the instruments the electronics professional can have. It is very important for someone wanting to become an electronics professional to be familiar with all the uses of this instrument. The next section discusses some more of its uses.
- Film canisters, plastic ice cube trays, eggs trays, and pill bottles can be used for sorting and storing screws and other small parts when you disassemble equipment. Use a notebook to mark the position of any

screw in equipment tested if you have difficulty memorizing it. A leftover screw when reassembling a device can cause a big headache.

- Don't force any part of the enclosure in equipment when disassembling it. If you have to force it, it may be because you are not doing things correctly. The direction you are moving the part is not the correct way or there are more screws to be taken out.
- ESD (Electrostatic Discharge)—Some components, including the CMOS transistors and ICs, are very vulnerable to ESD. Don't touch their terminals when working with them.
- If possible, use a schematic. Many pieces of equipment have manuals or schematics that provide important information for the reader when troubleshooting. If you intend to go further in this field, knowing how to read a schematic is essential to the repair of any equipment.

Schematics

Sams Technical Publishing has circuit diagrams, schematics, or service information for many pieces of electronic equipment sold since the 1940s. You can access the company's service using this Internet URL: *http://www.samswebsite.com*.

You can also reach it at the following address and phone number:

Sams Technical Publishing
5436 W. 78th St.
Indianapolis, Indiana 46268
Customer Service: 1-800-428-7267

Many large public libraries may subscribe to Sams Photofact and have the documents available for photocopying.

Quick Tips for Troubleshooting and Repair

- A totally dead piece of equipment or one with many functions affected may have a defective power supply. Check whether the circuit is correctly powered. For example, see if there is voltage in the AC power line.
- Erratic or intermittent problems are almost always due to bad connections, such as cold solder joints or connectors that need to be cleaned.

- Gradually changing problems (problems that decrease or disappear completely when the equipment warms up) are often due to dried electrolytic capacitors.
- The majority of problems in equipment with many mechanical parts, such as VCRs, CD players, or DVDs, are due to mechanical or optical failures.

The Multimeter

The multimeter, VOM (Volt-Ohm-Milliamp meter), or Multitest is the most important instrument for an electrician who wants to work with electronics. Any test in electronic circuits or electronic components begins with the principle that when it is working, some measurable electric quantity exists. Here, three quantities are the most important: voltage, current, and resistance.

Measuring the current or the voltage in a circuit allows us to determine if the circuit is good or bad. In some cases, measurements can also determine the cause of a problem. Many electronic devices can be tested with some simple resistance measurements.

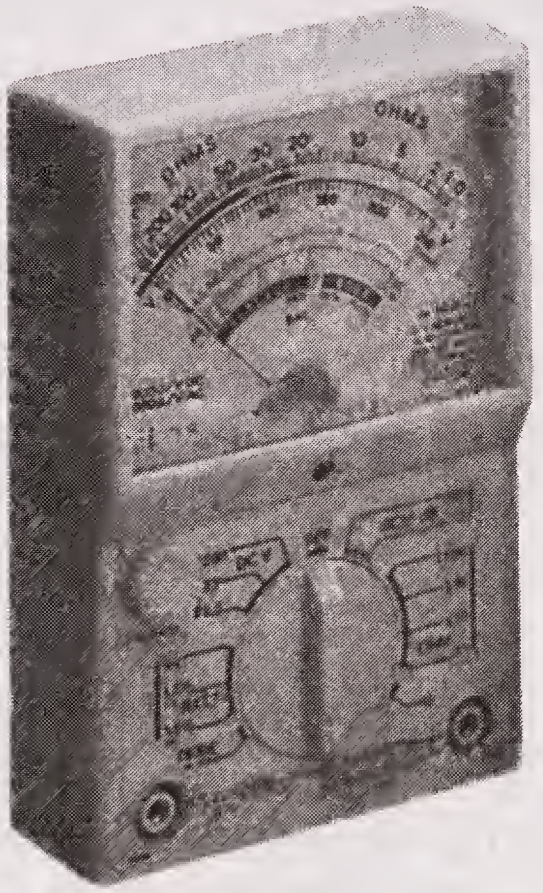

Figure 199
A low-cost analog multimeter

Analog Multimeters

There are two types of multimeters an electrician can purchase to work on not only electric installations, but also on analog and digital electronics. The analog multimeter is formed by a moving coil meter (microamperimeter) and circuitry with functions selected according the quantities to be measured.

For example, if an electrician must measure resistances he needs to select one of the resistance positions on the switch according to the expected value. If the position ohms x100 is selected, the values read in the scale must be multiplied

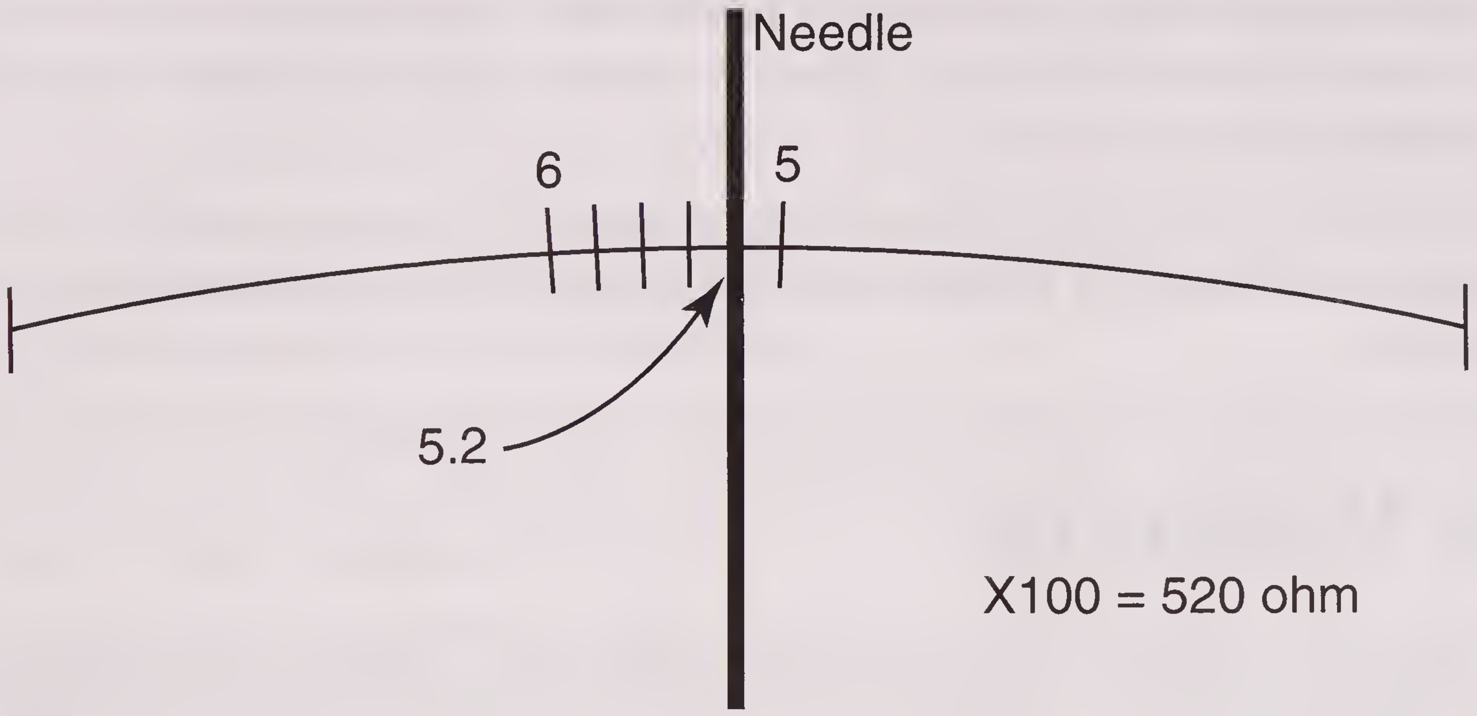

Figure 200

by 100. An indication of 5.2 as shown in Figure 200 indicates a resistance of 520 ohms.

The selection of the quantity to be measured is made by a switch or selected by jacks where the probes are connected. Figure 199 shows this kind of multimeter. The most important specification of an analog multimeter is its sensitivity. The analog multimeter, when measuring voltages, needs power to move its needle. The power comes from the circuit being measured. This power alters or "loads" the multimeter changing the value reading. The better the multimeter, the lower the load needed from the circuit to be measured, meaning a better multimeter can pick up lower voltages.

The sensitivity of an analog multimeter comes from its internal resistance when measuring a voltage (it is associated to the sensitivity of the moving coil meter). This value is indicated in ohms per volt (Ω / V) and should be as high as possible. Less expensive multimeters have a sensitivity of around 1000 ohms per volt. Better multimeters have a sensitivity of 10,000 ohms per volt or more.

When using a low-sensitivity multimeter, an electrician must take care to not be tricked by the voltages indicated when measuring high-resistance or high-impedance circuits. These are circuits where the presence of the instrument can cause great alterations in the voltage measured. This occurs because the presence of the multimeter loads the circuit .

Digital Multimeters

Many low-cost digital multimeters are available today. Although by many aspects they are better than the analog type, some functions or measurements exist where the analog multimeter is the better choice. For the electrician who is not familiar with multimeters, using this type of tool is not recommended as a starting point. When beginning, it is easier to use the analog type.

The digital multimeter is formed by an electronic circuit that presents the results of the measurements in a liquid crystal display (LCD) like the one shown in Figure 201. The functions for measurement using a digital multimeter are the same as analog multimeters.

Because the digital multimeter uses an internal power supply (normally a 9V battery), it doesn't need to extract large amounts of energy from the circuit where the voltages must be measured as the analog multimeter does. This means that the circuit being tested interprets it as a very high-impedance load not causing significant changes in the quantity to be measured. The problem of inaccuracy found in analog multimeters when measuring low voltages in high-resistance circuits doesn't exist in the digital types.

Figure 201
A low-cost digital multimeter

How to Use a Multimeter

Voltage measurements.

Electricians must take care not to overload the instrument when measuring voltages. This can cause damage including burning it. They must also differentiate the points where AC and DC voltages are found.

When measuring a DC voltage, place the function selection switch in the scale that gives you a comfortable reading of the expected voltage. For example, if you are expecting a reading of about 12V in a circuit, place the switch in the position 0-15VDC. The position 0-150VDC is not recommended because with 12V, you would have a small deflection of the needle.

Observing the poles, place the probes in the circuit to be measured. If you invert the probes or the poles are different from what is expected, the needle tends to move in the wrong direction, indicating something less than zero. If this happens, invert the probes to correct the reading. Some instruments have a pole switch that inverts the probe connections without moving them. Figure 202 shows how the multimeter is used to measure a DC voltage in a circuit. This process is for digital and analog meters.

Some digital multimeters indicate the value with a "–" sign if the voltage is negative or if the probes are inverted. If you have no idea about the voltage present in a circuit, begin by using a higher scale.

Current measurements

Current measurements are not very common when working with electronic circuits because the circuit where the current is measured must be interrupted to place the multimeter's probes (Figure 202).

When measuring DC currents, polarity must be observed when positioning the probes. It is very important to choose the correct scale when measuring currents. If a low-current scale is chosen in a high-current circuit, the meter can be damaged or the internal fuses can burn. Use the higher current if you have no idea about the value of a current to be measured in a circuit. The procedure is the same whether using a digital or analog multimeter. In some cases the multimeter has a self-adjusting scale and no switch is necessary for this task.

Resistance measurements

The resistance measurement and the continuity test are the most common in normal work with electronics. To run a resistance test, apply a voltage to the circuit or device to be measured. The magnitude of this current causes the multimeter to display the value of its resistance.

Analog multimeters use an internal cell (normally a 1.5V AA cell) and digital multimeters use a 9V power supply. As the batteries in a multimeter lose power, so does the multimeter. Before each use, analog types must be adjusted to zero. This adjustment is shown in Figure 203.

B) Measuring the current in a curcuit

DC mA
−
+
Direction of current
Interrupt

Figure 202

Place the probes together and adjust the "zero adj" potentiometer until the needle in the scale indicates zero. After this procedure you can use the multimeter to measure resistance.

Choose the appropriate scale for the resistance you expect to measure. A better reading is one made from the central region to the right extreme. For instance, if you place the switch in the ohms x 1k scale, it means you have to multiply the readings by 1000. Figure 204 shows that an indication of 4.3 in this scale means you are measuring 4300 ohms.

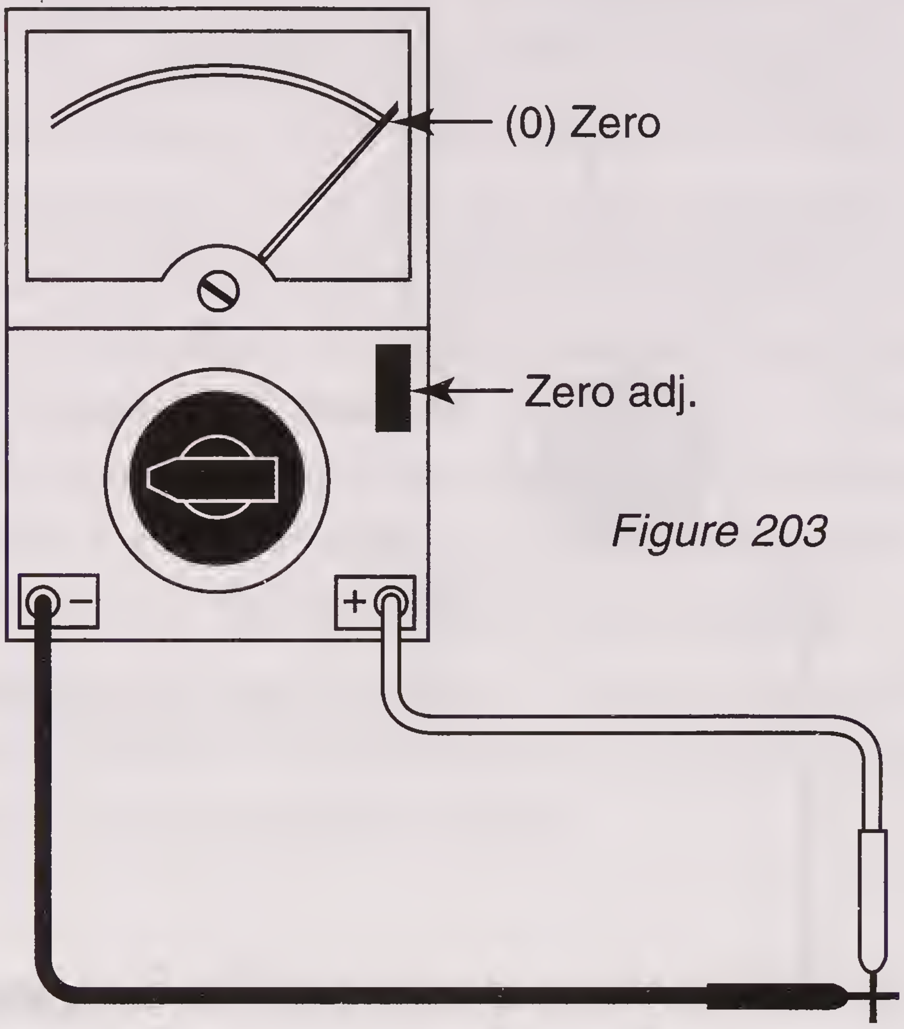

Figure 203

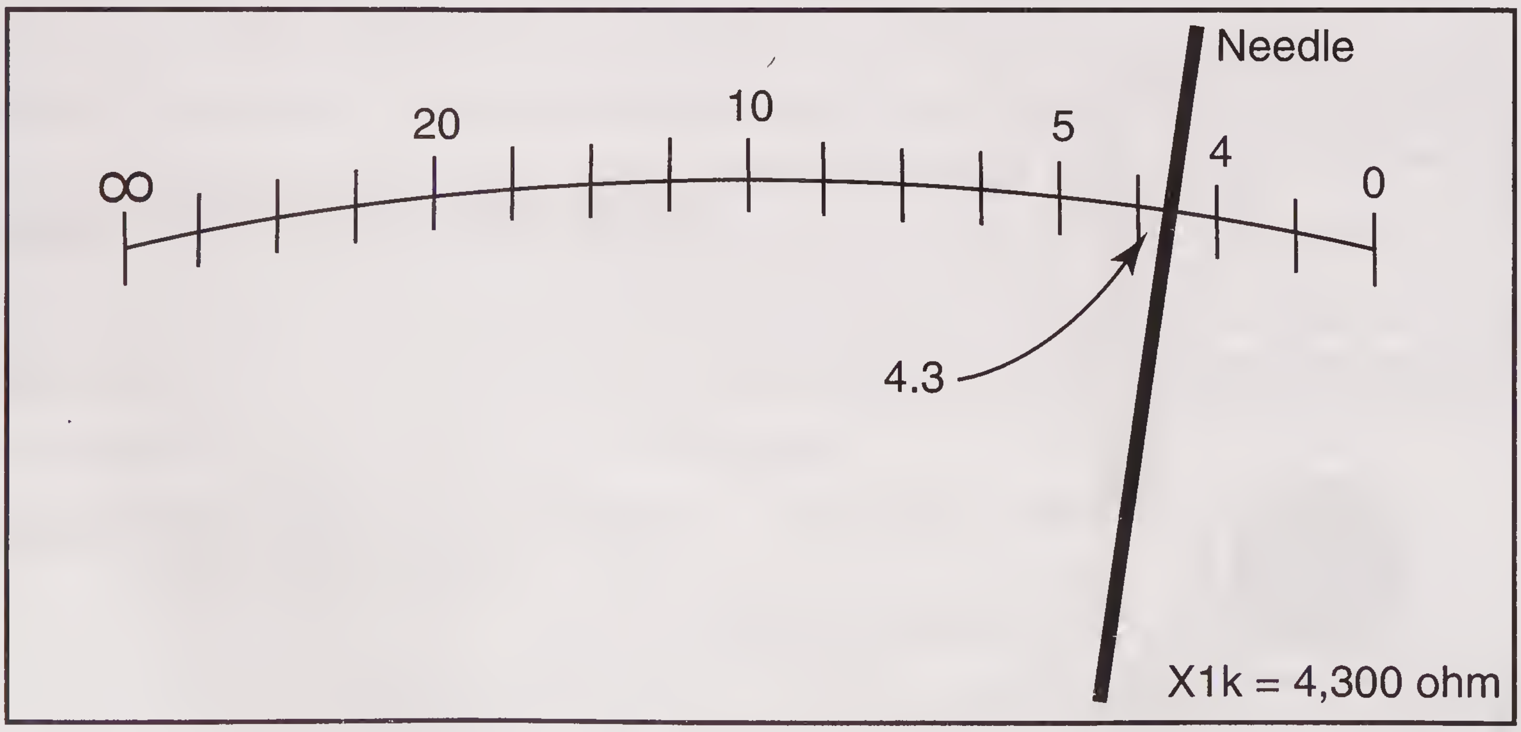

Figure 204

Other Multimeter Functions

Many multimeters can measure other quantities besides resistance, currents, and voltages. Multimeters with battery test scales, decibels, continuity test function, diode test, and transistor test are common.

Reading and Interpreting Multimeter Values

Knowing that placing the probes of a multimeter in the terminals of a component and having it give you a reading either with a needle or LCD is not enough. You need to know what the reading means to conclude something of value. Some components are good when they present high resistance (capacitors, reverse-biased diodes, open switches, etc.) and some components are good with the reverse indication—when they present low resistance (fuses, wires, direct-biased diodes, coils, etc.).

At the end of the description of each component, the text explained how to test many components using a multimeter. When measuring voltages in a circuit, you must take care with interpretation of the values. Although the schematics indicate some voltages, depending on the multimeter, the presence of the multimeter in the circuit can change the values and give a false reading (mainly in less expensive analog types). Don't trust your multimeter! You must be sure that your multimeter can measure the indicated voltage in a circuit.

Finding Parts

Electronics today often are made up of one-way circuits. Once they present any problem, the entire board—including other components and parts—is replaced. Few components in equipment such as this can be replaced when problems occur. In some cases, the cost of replacing the components is actually higher than the cost to replace the board. The price of a technician's hourly work also figures in here. But, repairing old equipment or equipment not designed to be discarded when something inside is burned out, is possible and a technician must know how to do it.

After pinpointing the location of the cause and the components involved in the failure, the next problem to solve is finding a replacement. Today technicians can count on many component dealers, many of whom work through the Internet and mail order. Once contacted, most dealers will send the component(s) directly to your home, often in a few days, and in some cases, a few hours!

For those with access to the Internet, some important dealer addresses in the United States and beyond are provided. Visit their web sites for more information about locations, shipping, and prices. Phone and fax numbers of many are also listed.

Another important resource for components is old equipment that no longer functions. This equipment often has many parts that can be used as replacements. If you like to repair things and are always trying to recover old equipment, it can be interesting to have old boards or even seemingly ancient tube radios and amplifiers as a source of electronic components.

Transistors, resistors, and some types of capacitors are hard to destroy and can be found in good condition even many years after the original equipment is abandoned. The more critical components are electrolytic capacitors that can become dry after long periods of time, losing capacitance or going to a low-resistance state (short or loss) and can't be used. It is recommended to test all components before using them.

Equivalents

A common problem facing an electrician working with damaged electronic equipment is finding replacement parts when the original is not available anymore. When this occurs, an equivalent part is needed. However, these parts are not always exactly the same as manufacturer originals, and the same one cannot necessarily replace the same device in other equipment.

The most problematic cases involve semiconductors. Diodes, bipolar transistors, FETs, power-FETs, SCRs, triacs, and ICs come in millions of different types. Many manufacturers create their own types or designations to replace those made by competitors. In some cases they even add internal alterations, changing the basic characteristics for better performance. For example, an operational amplifier, such as the popular 741, can be found with designations LM741, 1741, uA741, LH101, CA3056, MC1539, and many others. Theoretically, they are the same component, but small internal differences can alter the performance and make one type improper for replacement depending on the application.

Transistors suffer from this problem as well. Many manufacturers used to adopt their own code when placing a transistor in equipment. The common 2N3904 or the BC548 can be remarked as, for example, 3X456-V-334-bis or something like this by a manufacturer. This makes the work of a technician replacing this component difficult. In many cases the intention is to force the user to look for an authorized service center in the event of problems.

When the component is common, it can be easy to find a replacement beginning with its characteristics. Experienced technicians, by simple observation of a circuit, often "know" which transistor is the ideal replacement type. As a general rule, the replacement type must have characteristics equal or superior to the original. If you are just starting out with electronics, it is not a good idea to attempt replacing pieces with these kinds of problematic designations.

Practical Circuits: How They Work

As pointed out in the beginning of the book, electricians today are finding electric parts not only in domestic, commercial, or car installations, but many electronic circuits. Another problem concerning an electrician relates to the electronic devices and appliances that operate from electric power and are sometimes in building installations. Although a deep knowledge about how these things work is not necessary to repair or install circuits, an electrician should have basic information about the operation. This information can be very useful when installing or troubleshooting an electric installation with a problem.

Let's look at the operation of some electronic circuits and devices found in electric installations and AC powered in homes, commercial buildings, and even cars. How do they operate and how are they placed in electric installations?

AC/DC Adapters

Many small electric and electronic appliances operate from DC power supplied from cells and batteries. In some cases, it is more convenient to run these devices from AC power to preserve battery life. AC/DC adapters or DC power supplies convert the high AC voltage present in the AC power line to a low DC voltage (in the range between 1.5 and 12V).

AC/DC adapters are formed by a simple circuit with a transformer to isolate the AC power line, avoiding shock hazards and stepping down the voltage to the desired value. Current follows the transformer leads to a rectifier (diode) and a filter (capacitor) in a typical configuration like the one shown in Figure 205.

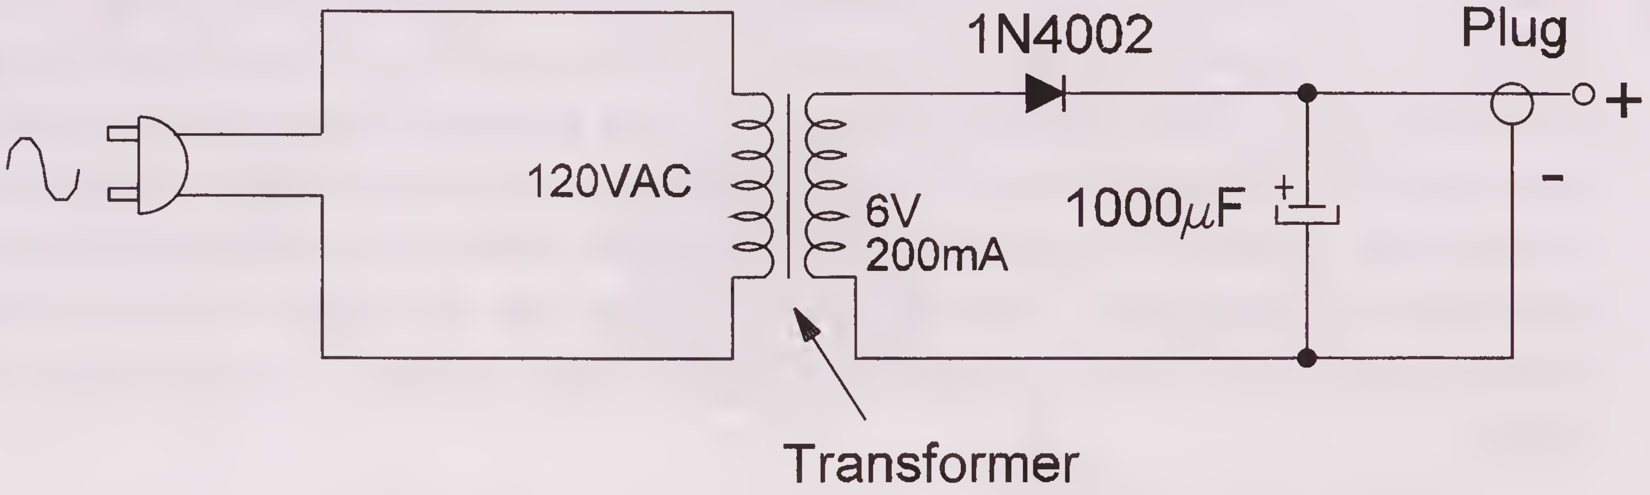

Figure 205

The output to the powered device is normally made by a cable with a plug as shown in the same figure. There are some details an electrician should pay attention to when using an AC/DC converter.

- Output voltage—output voltage can vary from 1.5V (one cell) to 12V (eight cells or a battery) for common AC/DC adapters. In some types, this voltage is fixed; you choose the voltage when buying the unit based on the voltage of the appliance. It is easy to identify this voltage from the number of cells. Each cell represents 1.5V, so if the powered device uses four cells it needs an AC/DC converter for 6V (4 x 1.5V). Some converters have a switch to choose the voltage. This switch can be adjusted based on the voltage of the powered device. It is important to make the correct adjustment because if it is a higher voltage than supported by the device, that device can be damaged.
- Output current—nominal output current is determined by the consumption of the appliance you intend to power. Normally, the consumption is evaluated by the size and type of the cells or batteries used to power it. In many of the cases, the current is indicated in the device, but if this is information is not available, use the next table to choose an AC/DC adapter.

Type of Cell	Current
AA	100 to 200mA
C	300 to 500mA
D	1 to 1.5A
9V cells	50 to 200mA

- Polarity of the plug—AC/DC adapters can be supplied by plugs with a positive or negative pole in the center. Be sure that the correct plug is used because if the polarity is inverted, the appliance can be damaged. Some AC/DC adapters have a switch to choose the polarity of the plug. Figure 206 shows a universal power adapter that can be plugged directly into the AC power line. This kind of adapter can be used to power small appliances, such as CD players, toys, video games, calculators, and radios.

An important point to observe is that common AC/DC adapters, in general, are very simple circuits with no voltage regulation stages. This means that the circuit presents a higher voltage in the output until the moment the appliance is plugged in, then it drops. This fact is important when testing an AC/DC adapter; the measured voltage in the output is normally higher than the adjusted or expected load until the device is powered on. When powering appliances where voltage is critical from the AC power line, it is important to use the specified types of adapters recommended by the manufacturer.

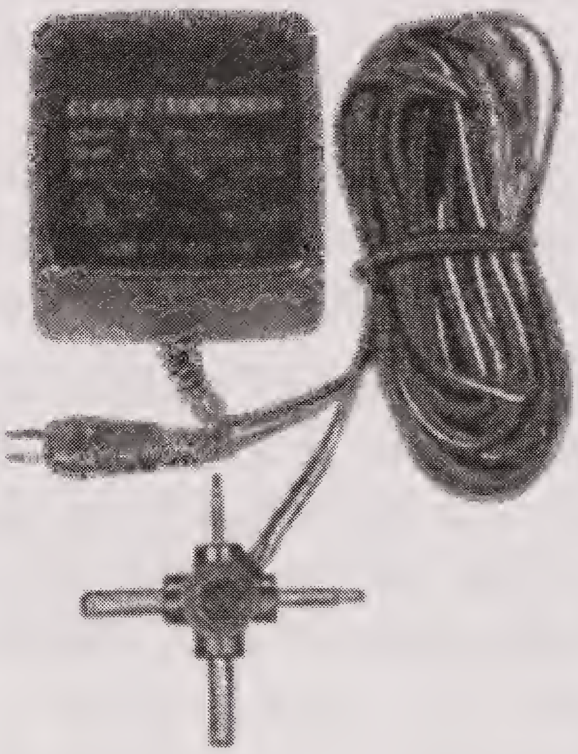

Figure 206
A Universal Power Adapter

Dimmers/Power Controls

Dimmers and power controls are devices used to control AC loads from an AC power line. They can be used to control the brightness of incandescent lamps, the temperature of heaters and small ovens, or the speed of motors including fans and pumps. The most common dimmer circuit is the one described in the Triac section starting on Page 162, where a sample configuration was analyzed.

This sort of circuit is usually small enough to be placed in the wall as a common switch, as shown in Figure 207. This dimmer can directly replace a wall switch. Equivalent dimmers using slide controls are also common and easily found for purchase.

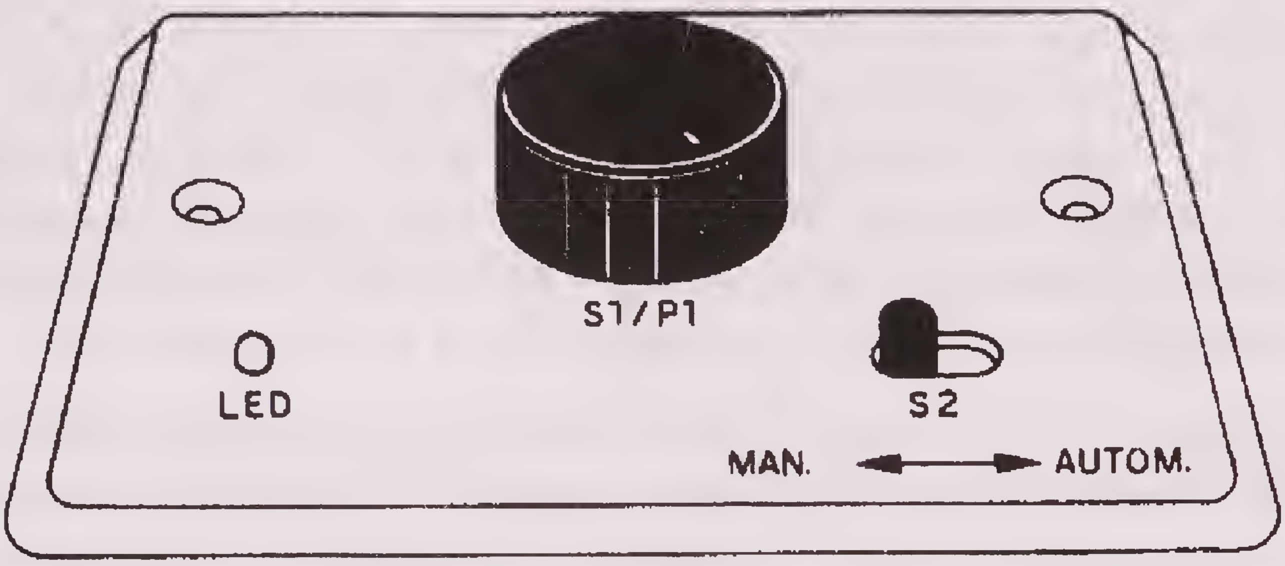

Figure 207

Another type of dimmer that is becoming popular is the touch dimmer. No mechanical parts are used to control the power applied to the load in this dimmer. The touch controlled dimmer uses a small metal plate where, by the touch of your fingers, the power applied to the load changes, slowly rising or falling to the desired level.

There are some special integrated circuits that have been designed for the task of operating a device with touch. One of them is the SLB0587 from Infineon, which contains all the processor circuits to slow up and slow down the power applied to the load from the touch in a sensor.

Dimmers can replace any wall switch in basic applications. When working with a dimmer an electrician must be attentive to some details.

A. Be sure the dimmer can control the load. Fluorescent lamps can't be controlled by common dimmers. Electronic appliances, such as audio amplifiers, TVs, VCRs, and some others can't be controlled by a dimmer.

B. Invert the positions of the wires in a dimmer if it doesn't control the load properly.

C. Use filters (see the sections on SCRs, triacs, and EMI for more information) if the circuit causes interference in other electronic equipment.

Inverters

Batteries are low-voltage DC power supplies and can't be used to power devices plugged into the AC power line. Inverters or DC/AC converters are designed to convert a low DC voltage from a battery or cells into a high AC voltage like the ones found in an AC outlet. An inverter is a complex circuit that not only has to step up the low voltage found in the battery or cell, but also convert it into an AC voltage with the same wave shape and frequency of the AC voltages found in the power line.

Keep in mind when using an inverter that it is not possible to create energy. This means that all the power needed by the load must be generated by the batteries or cells. Batteries and cells are low-power energy sources, which means that the amount of power sourced by an inverter can't be high, or under any circumstances, higher than the capabilities of the cells or battery. As a general rule, inverters powered from cells or batteries are only used to power low-consumption appliances, such as large fluorescent lamps in emergency systems, signaling devices, and xenon beacons. Inverters powered from car batteries or other heavy-duty batteries can source energy to medium-power appliances like small TVs, electric razors, small fluorescent lamps, transmitters, laptop computers, small xenon beacons, and incandescent lamps.

How they work

A typical inverter is formed by a low-frequency oscillator running on the AC power-line frequency and a high-power output stage using transistors (bipolar, power FETs, or IGBts) to drive a transformer, as shown in Figure 208.

The signal applied to the low-voltage winding of the transformer appears as an AC high voltage in the secondary winding. The quality of the transformer determines how much power can be transferred from the low-voltage to the high-voltage circuit, determining the efficiency of the converter. Values as high as 90 percent are common in commercial types, meaning that for each 10 watts of power drained from the battery, 9 watts are load and 1 watt is transformed into heat by the circuits.

Most of the heat is converted by the output transistor because they are mounted in large heat sinks. In commercial types, the metallic box is used as a heat sink.

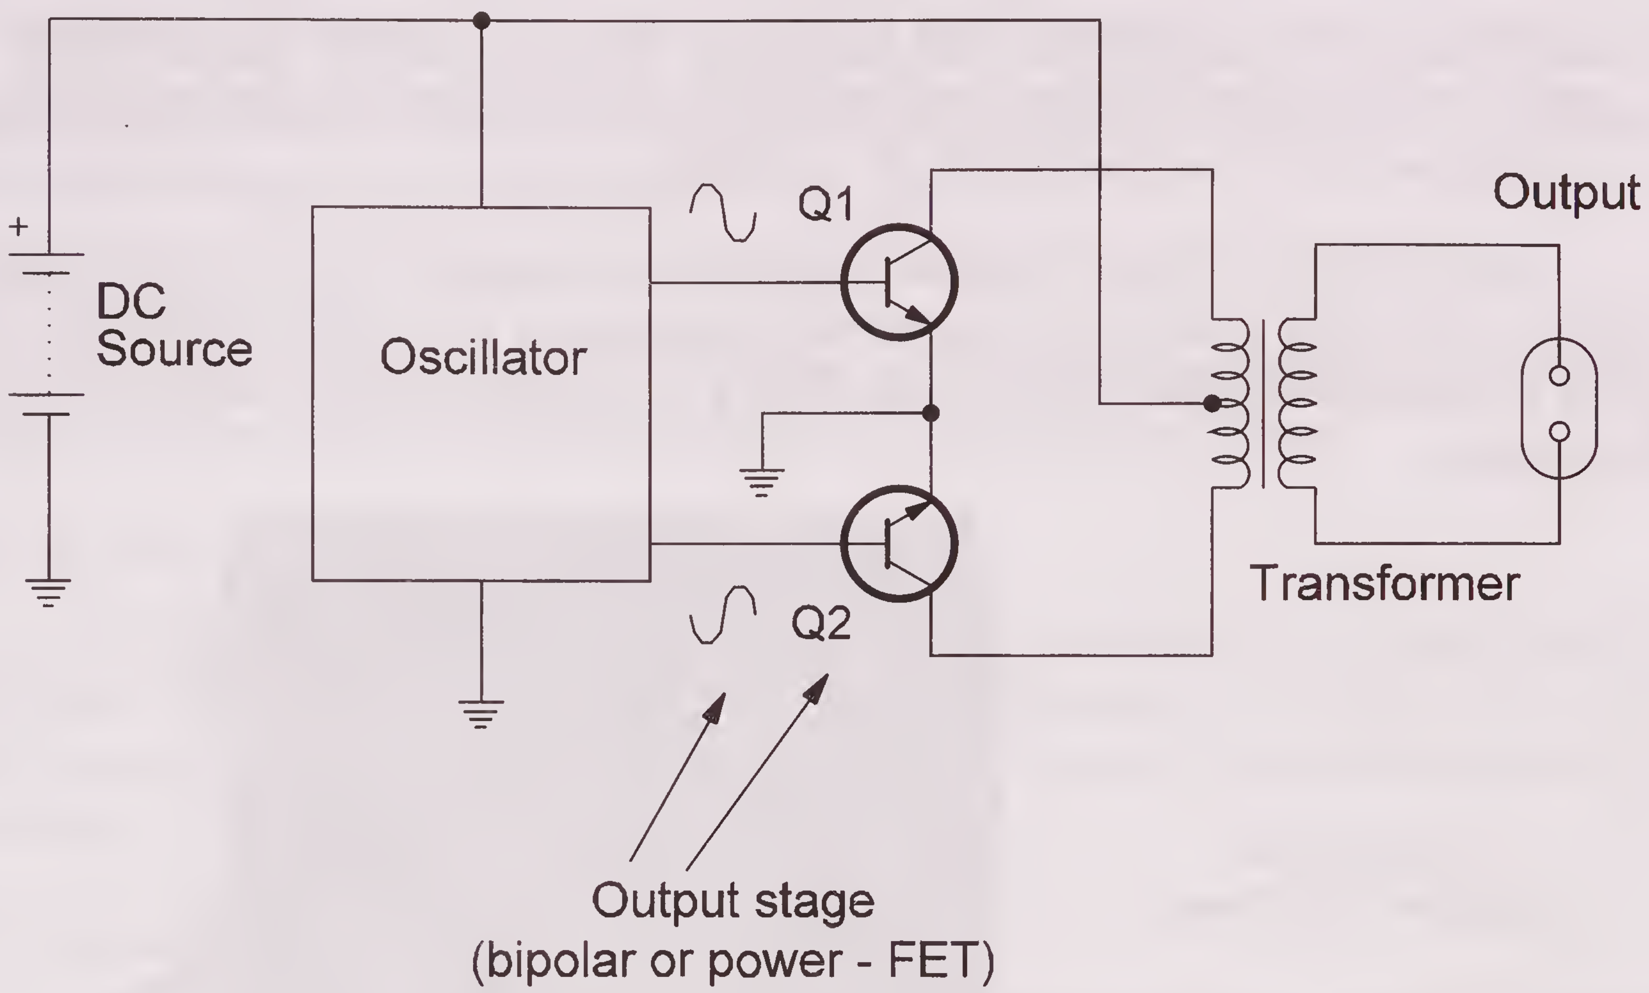

Figure 208

It is important to observe that in many types, the wave shape of the output voltage is not sinusoidal. The conversion made by circuits using pulses and the construction of the transformer can result in different wave shapes. In the applications here, the wave shape is critical because it is important to see if the inverter is working as needed. For an electrician, the inverters are important because they are found in emergency lighting systems or powering devices that are normally powered from the AC power line.

The following are some important applications for inverters.

- They can be used to power electric appliances from batteries and cells in emergency situations or in places where AC power is not available, such as cars, boats, and on camping trips.
- Inverters for fluorescent lamps are used in emergency lighting systems. The batteries used in these systems are charged by AC power-line voltages.
- They are used in no-break systems for computers, which supply energy for a computer if an AC power outage occurs.

- Xenon beacons and car ignition systems use high voltages that can be generated by inverters. For beacons the AC power-line voltage is stepped up by an inverter, and for ignition systems the car battery voltage is stepped up to values as high as 600V.

Figure 209 shows an inverter that can be plugged into an automobile's lighter outlet and used to power small appliances and other electronic devices by converting the 12V power from the battery of a car into 110-120V AC power.

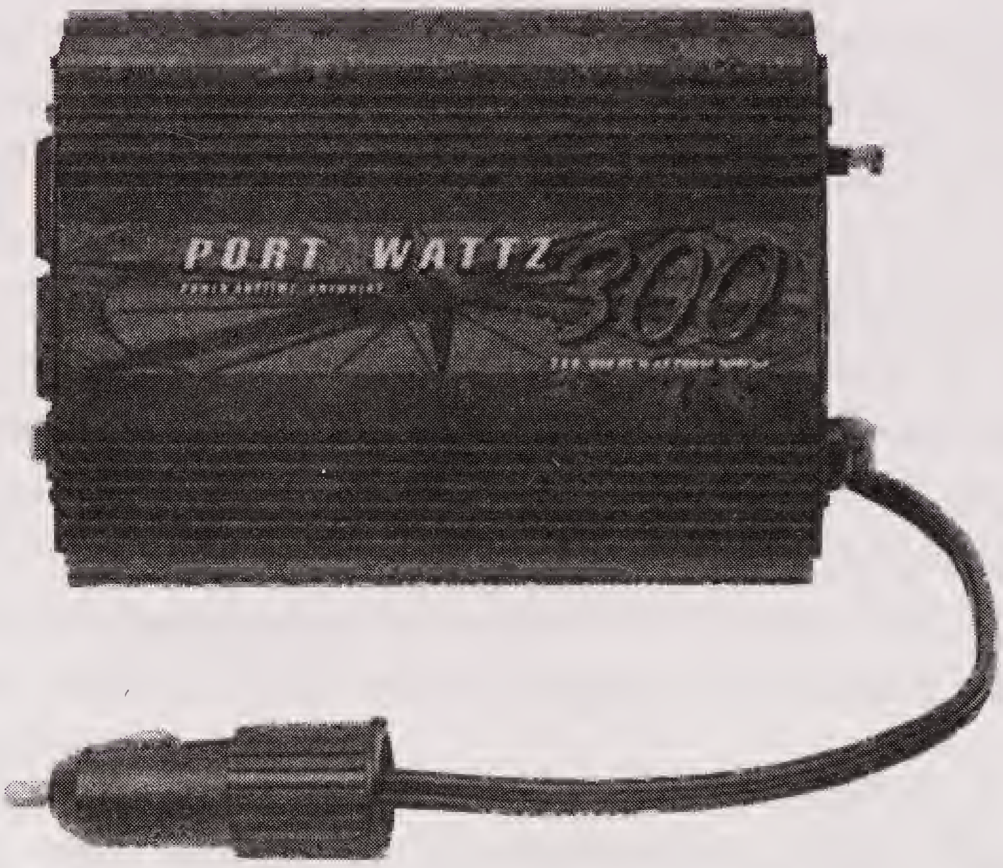

Figure 209
(Courtesy StatPower)

Working with inverters

It is very important for an electrician to know what kind of inverter is recommended for an application. Not only are inverters critical equipment, but also the powered circuits can be damaged if an incorrect choice is made. The following are main specifications an electrician must observe when working with inverters.

A. Output power

It is important to be sure that the inverter can supply enough power to the load. The power specification is given in watts (W). Take care with audio equipment where the output power doesn't reflect the consumed power; it can be given in a unit of watts, peak, or PMPO (instantaneous power peak).

B. Wave shape

The wave shape of many inverters isn't sinusoidal. This fact can be important in some applications. Lamps and heaters don't need a sinusoidal wave shape to be powered.

C. Performance

The higher the amount of energy converted, the better the inverter. Good inverters have a performance of 70 percent or more.

D. Isolation

The high voltages found in the output of inverters can cause severe shocks. Appropriate wires must be used to connect the loads if they are not plugged directly into an outlet, as in the case of fluorescent lamp inverters.

E. Battery placement

If not sealed, batteries used to power the inverter must be placed where the poisonous gases produced can be eliminated.

F. Wiring

Wiring to the battery can be done using wires based on the current drained by the inverter. A 100W inverter with an efficiency of 80 percent can drain a current as high as 12A from the battery. The wires must be able to handle this current.

Troubleshooting

The output transistor is the most fragile component in this type of circuit because it operates under limited conditions. When replacing these transistors, make sure that the type chosen supports the same voltage. The suffix indicates, in many cases, the operational voltage. For example, a TIP32A supports less voltage across it than the TIP32B.

Flashers

Lamp flashers are used in signaling. Garage doors, signal lights for customers in stores, and warning devices are some cases where flashers can be used. The simplest electrical type uses an incandescent lamp with some thermo-mechanics to open and close the circuit. But, with the aid of electronics circuits, the electrician can find many different configurations for lamp flashers.

A. Incandescent

Low-voltage flashers, such as the ones used in cars or powered from DC supplies, can be made with simple configurations like the one shown in Figure 210.

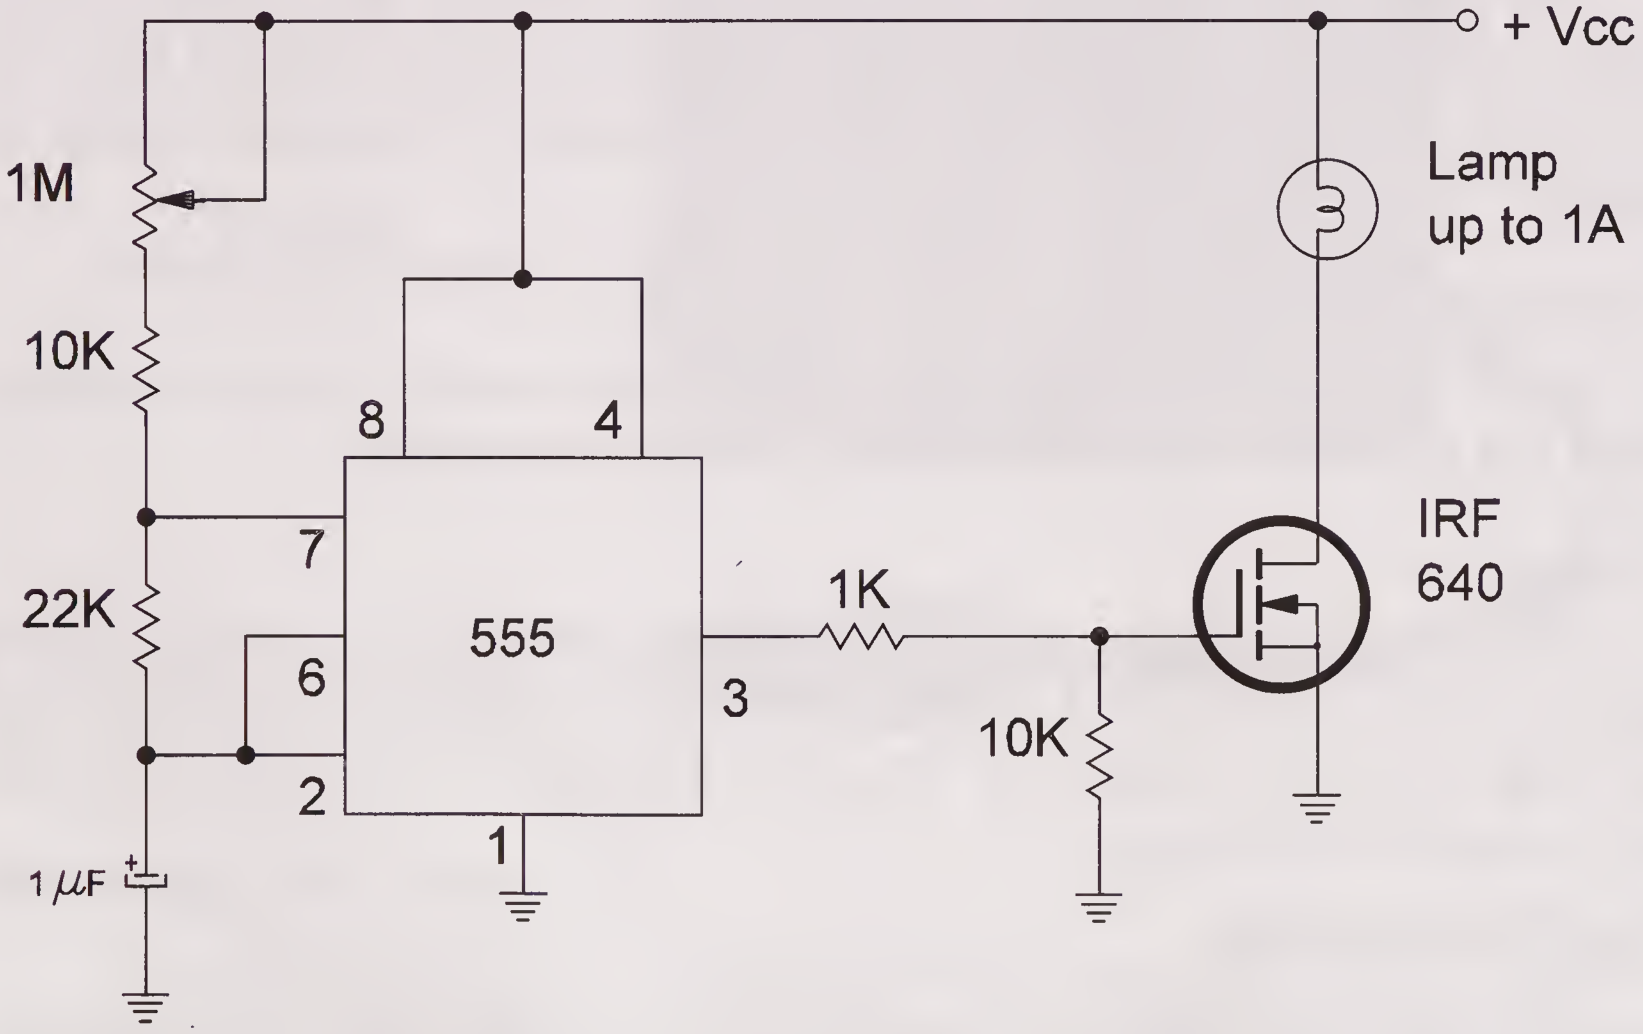

Figure 210

The power transistor (bipolar or FET) controls a lamp that flashes in a rate determined by the circuit adjustment. To flash a high-voltage, AC-powered incandescent lamp, a circuit using an SCR or a triac is more suitable. Figure 211 shows a circuit that can be found in garage doors using two lamps. The lamps flash in an alternating mode and the frequency is determined by an internal adjustment of the circuit.

In both cases the most sensitive of the components are the transistors and the SCRs (or triacs) that can open or short. When replacing these components, an electrician must observe the operating voltages.

low frequency
oscillator

Figure 212

A low-frequency oscillator operates as an inverter driving a high-voltage transformer. This transformer steps up the voltage to the necessary values in order to power the xenon lamp. For common xenon lamps the values are between 400 and 800V. The high voltage is rectified and used to charge a high-value capacitor. This capacitor (in some circuits many capacitors are wired in parallel forming a bank) is used to store electric energy.

At the same time, a very low-frequency oscillator produces pulses that are used to drive another high-voltage transformer. This second transformer has a secondary winding rated to voltages between 800 and 2000V—values necessary to trigger the xenon lamp.

The circuits can use SCRs, transistors, or even ICs to produce a low-voltage pulse to the transformer. When the high-voltage trigger pulse is applied to the lamp, it becomes conductive. The capacitor can then be discharged across it, transforming all the stored energy into a high-power, short light pulse. As long as the capacitor is discharged, the lamp becomes nonconductive again and a new operation cycle begins.

The output power, or luminous power, of a xenon beacon is measured in Joules (J), which is the energy stored by the capacitors. Typical values are in the range of millijoules (mJ).

The operation principle of these xenon flashers is the same as camera flashes. The difference is that, in the camera flash the circuit is triggered when the operator presses a button. In circuits operated from AC power, the inverter stage is not necessary. Figure 213 shows a circuit of this type.

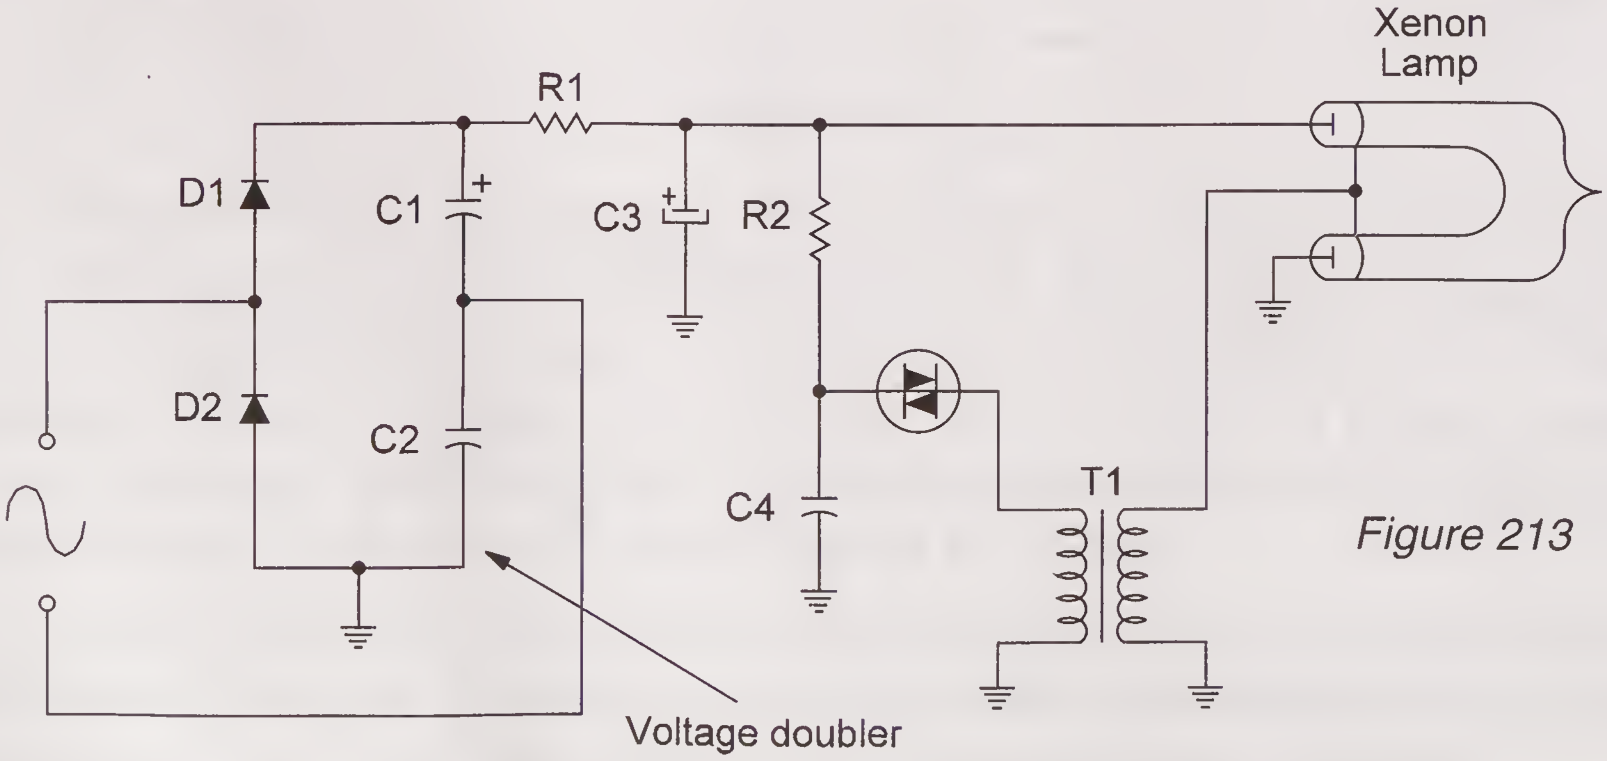

Figure 213

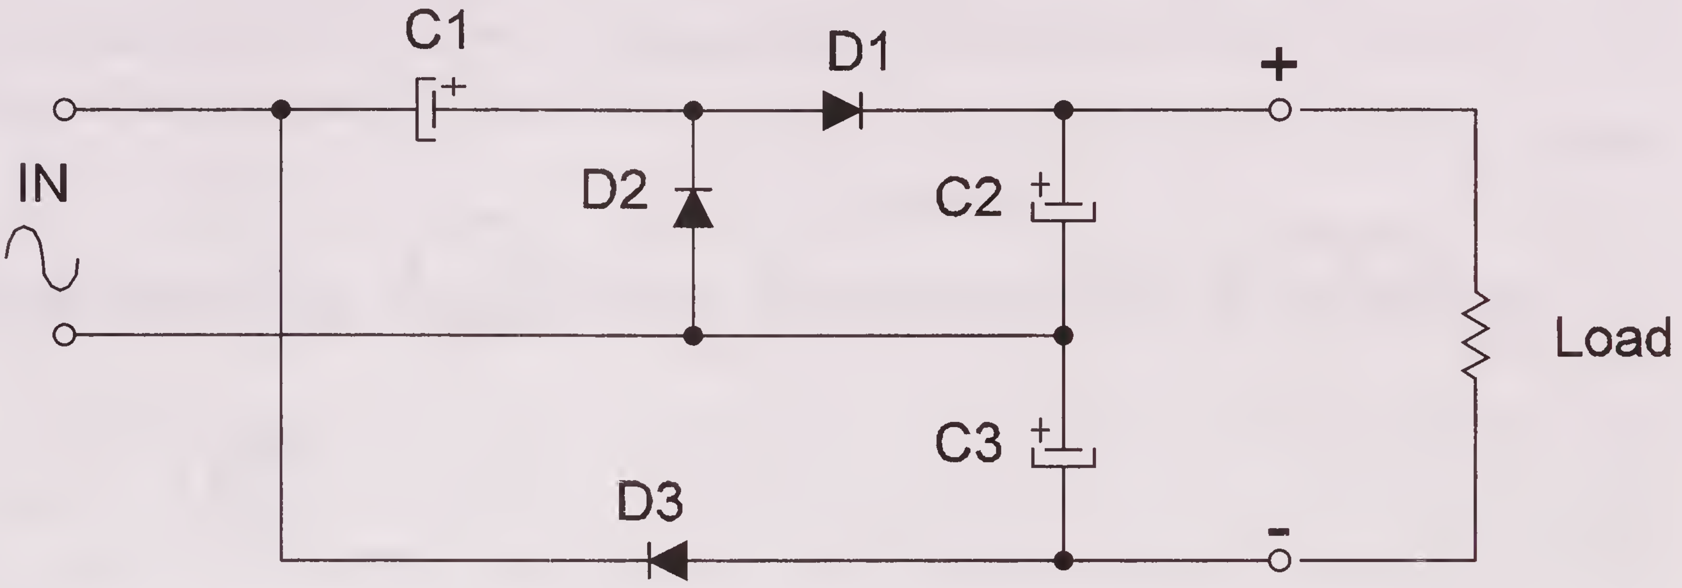

Figure 214

A voltage multiplier or a transformer is used to step up the AC voltage that can raise the necessary values for the lamp operation. A voltage multiplier is a network formed by diodes and capacitors that can step up the AC voltage converting it to a higher DC voltage as shown in Figure 214.

The important parts in this circuit are the diodes and capacitors that store energy. When working with these circuits an electrician must observe some specifications.

- When replacing the lamp, be sure that the replacement type has the same triggering voltage and the same power (mJ).
- Xenon flashers run with AC power are not isolated and can cause severe shocks if live parts are touched.
- In all devices, after the inverter stages, very high voltages can be found. These voltages are present even after the circuit is no longer plugged into the AC power source, as the voltage is stored in the capacitors. Do not touch the capacitors even when the device is unplugged.

C. Sequencers

Another type of luminous signaling device is the sequencer. This kind of device is found in the form of arrows indicating emergency doors or emergency exits and is even used in some types of Christmas tree lights. Figure 215 shows a typical sequencer circuit for incandescent lamps (or LEDs) that can be used in some signaling appliances.

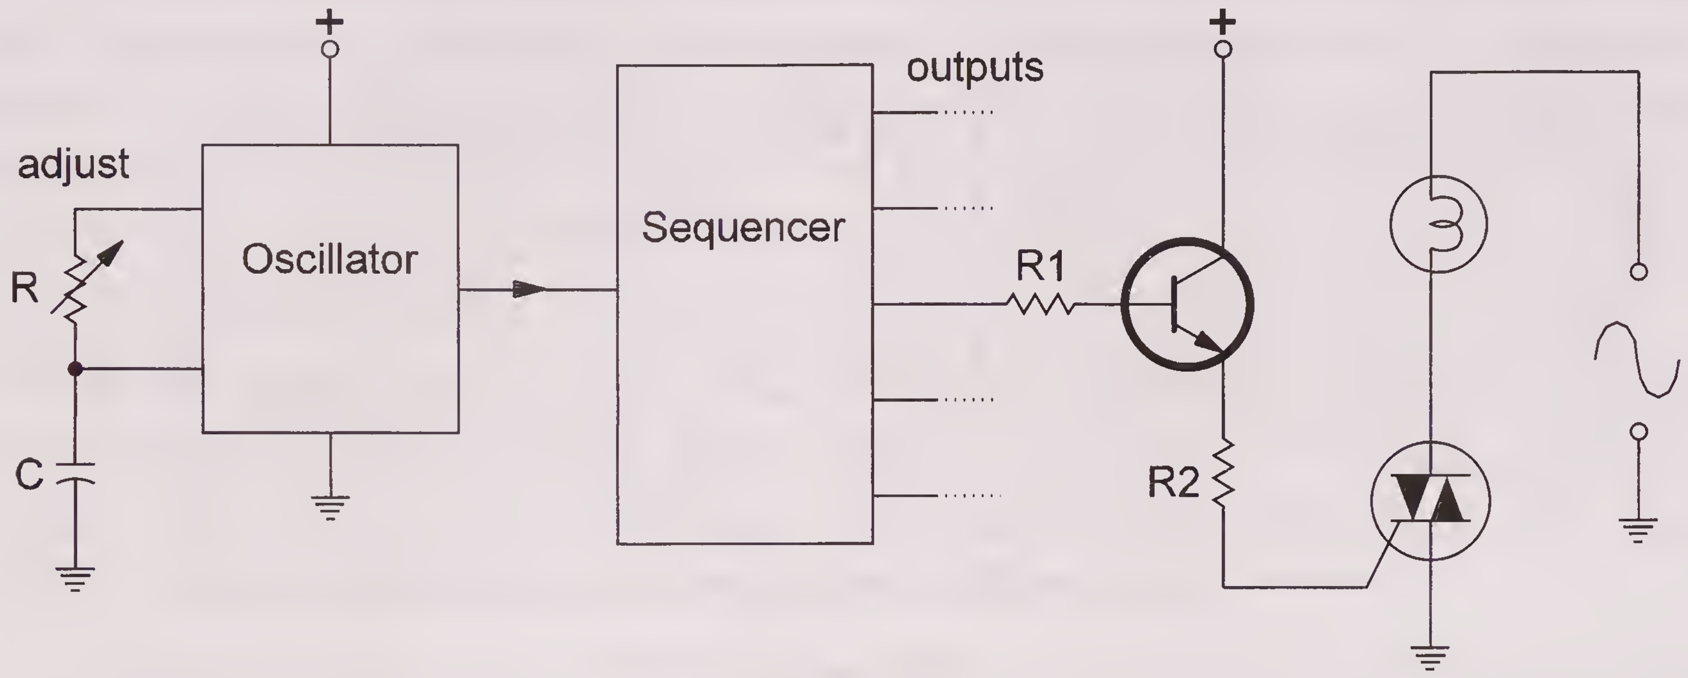

Figure 215

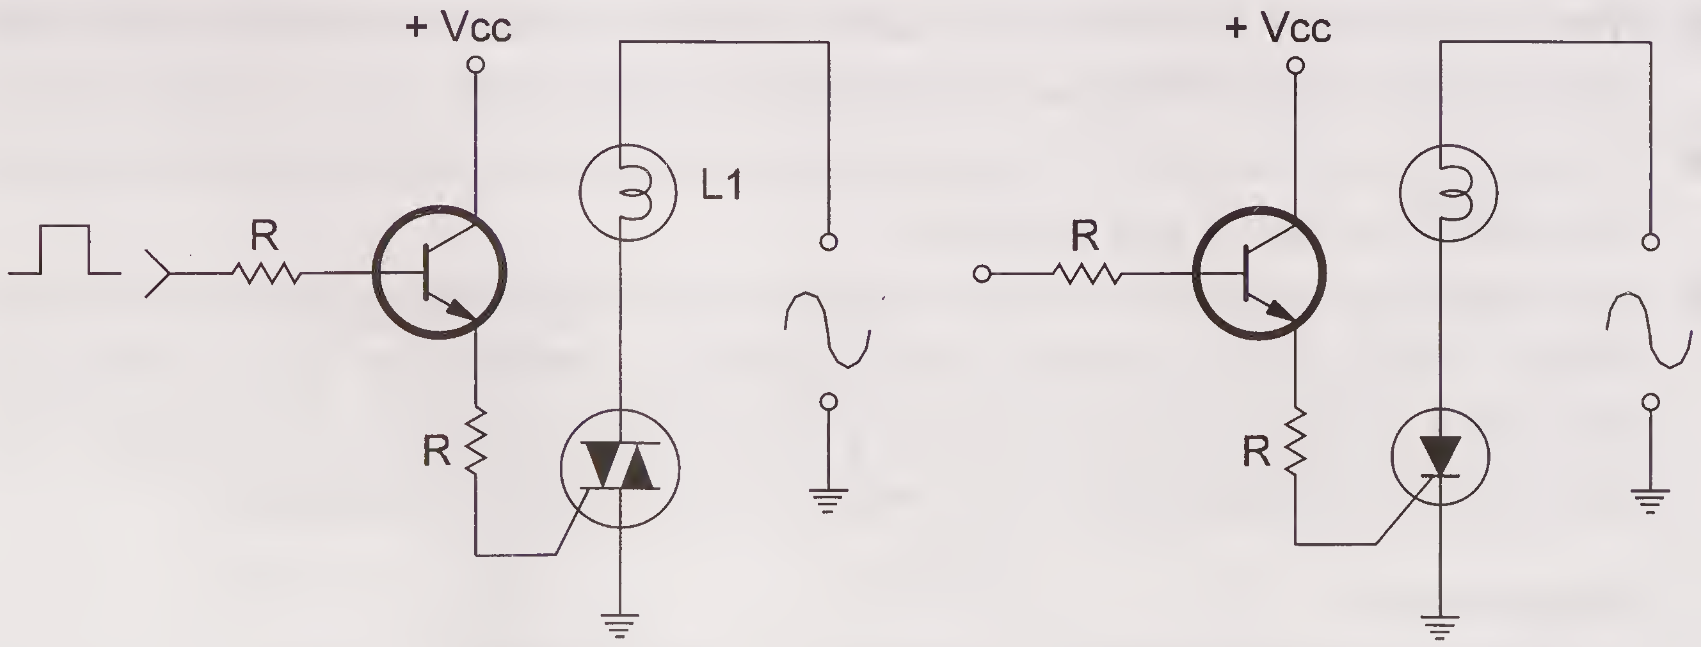
The clock circuit is an oscillator that determines the speed of the effect. The signals from this block drive the counter or another circuit that decodes the desired sequence or effect, such as a microprocessor or microcontroller. The decoded outputs of the sequencer circuit drive a transistor if low-voltage DC loads are controlled, such as LEDs or small incandescent lamps. If high-voltage AC loads are driven, SCRs or triacs are used in typical configurations like the ones shown in Figure 216.



a) Driving a TRIAC

b) Driving a SCR

Figure 216

When using this type of circuit the electrician must keep in mind that the control block is a low-voltage circuit. The power circuit depends on the type of lamps used in the effect.

Automatic Lighting/Emergency Lighting

Some years ago, the common way to control a lamp—turning it on and off—was using a switch. With electronics today, many automatic ways to control lamps have appeared in electric installations. One of these controls is the automatic lighting system. This system is very useful in gardens, house entrances, and other areas where timed lighting is desirable. An automatic light turns on a lamp at dusk and turns it off at dawn. This kind of control is found in many formats from lamps plugged directly into the socket of a common incandescent lamp (Figure 217) to more complex systems that can control all the lamps in a garden or on a street.

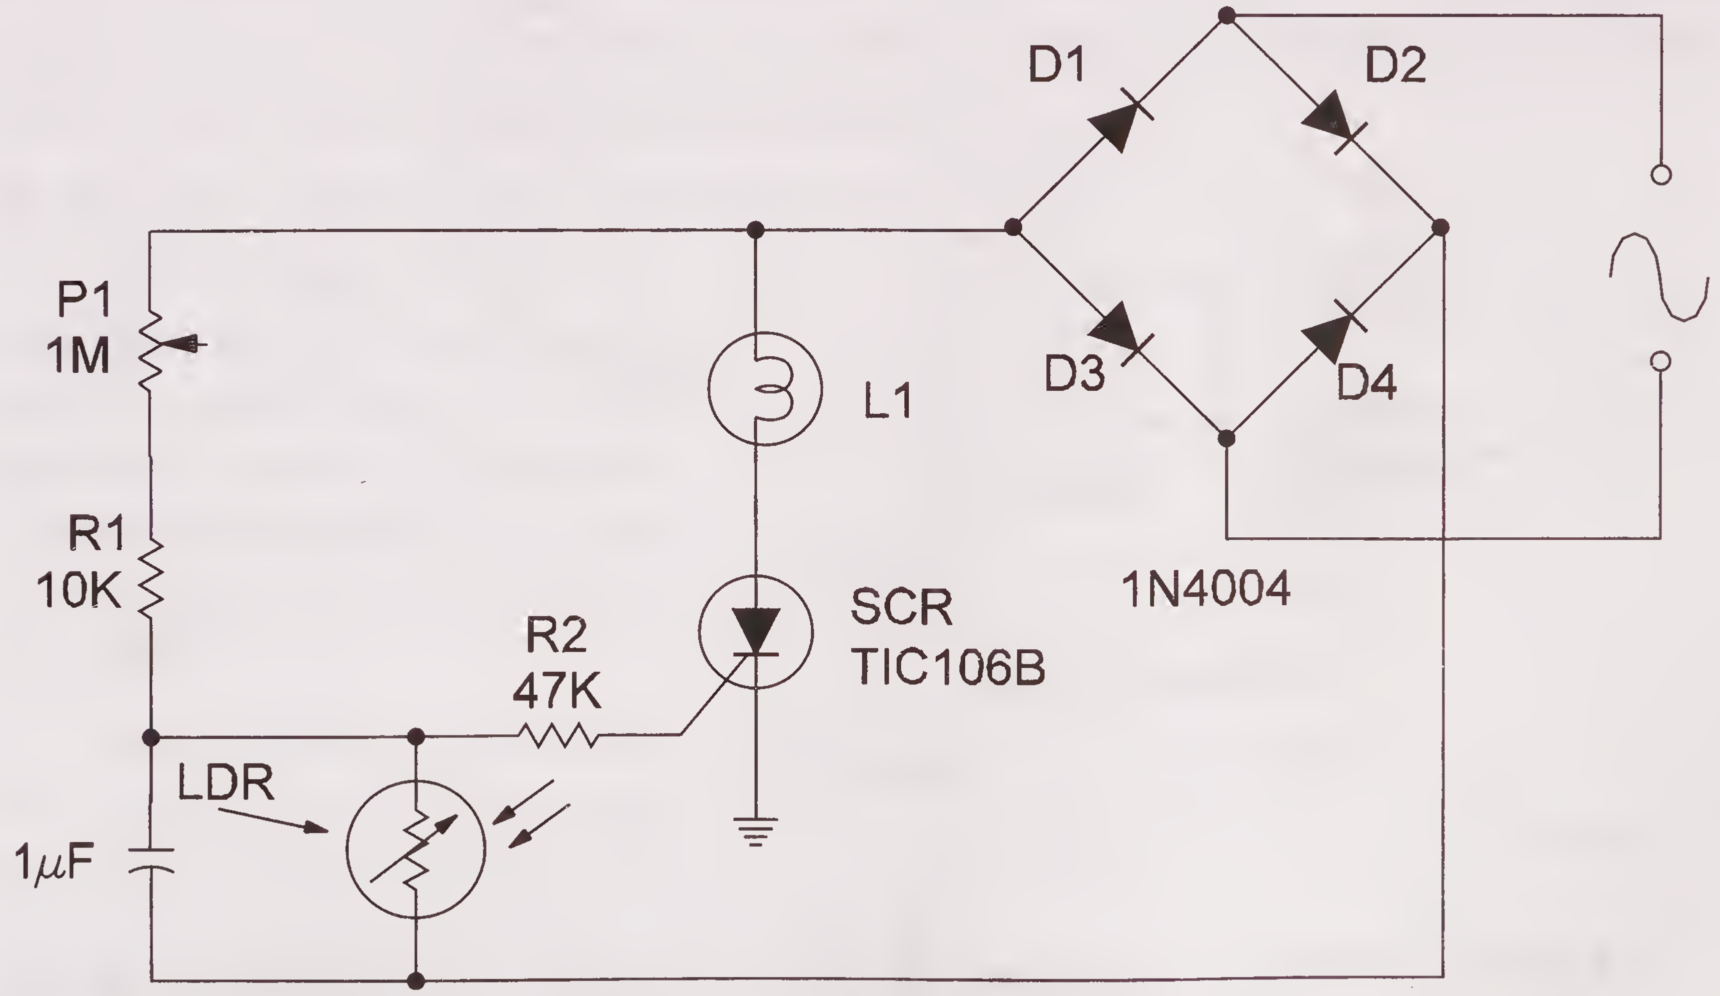


Figure 217

The sensor is an LDR or cadmium sulfide photocell that is mounted in such a way so that it receives only the ambient light and not the light from the lamp it controls, thus avoiding feedback. When the amount of light received by the sensor falls, the circuit triggers an SCR or triac that turns on the lamp. As with any circuit using SCRs or triacs, this kind of control can generate some radio interference (refer to the section on SCRs, triacs, and EMI).

Depending on the application, the electrician must install filters in the AC power line into which the device is plugged. When working with these devices, it is important to be sure that the sensor only receives ambient light. If light from the lamp is picked up by the sensor, a feedback process can make the circuit unstable.

Emergency lights turn on one or more lamps when the AC power fails. These lights are required equipment in public places, such as restaurants, movie theaters, schools, and many others. The basic emergency lighting circuit has an operation principle as shown in Figure 218.

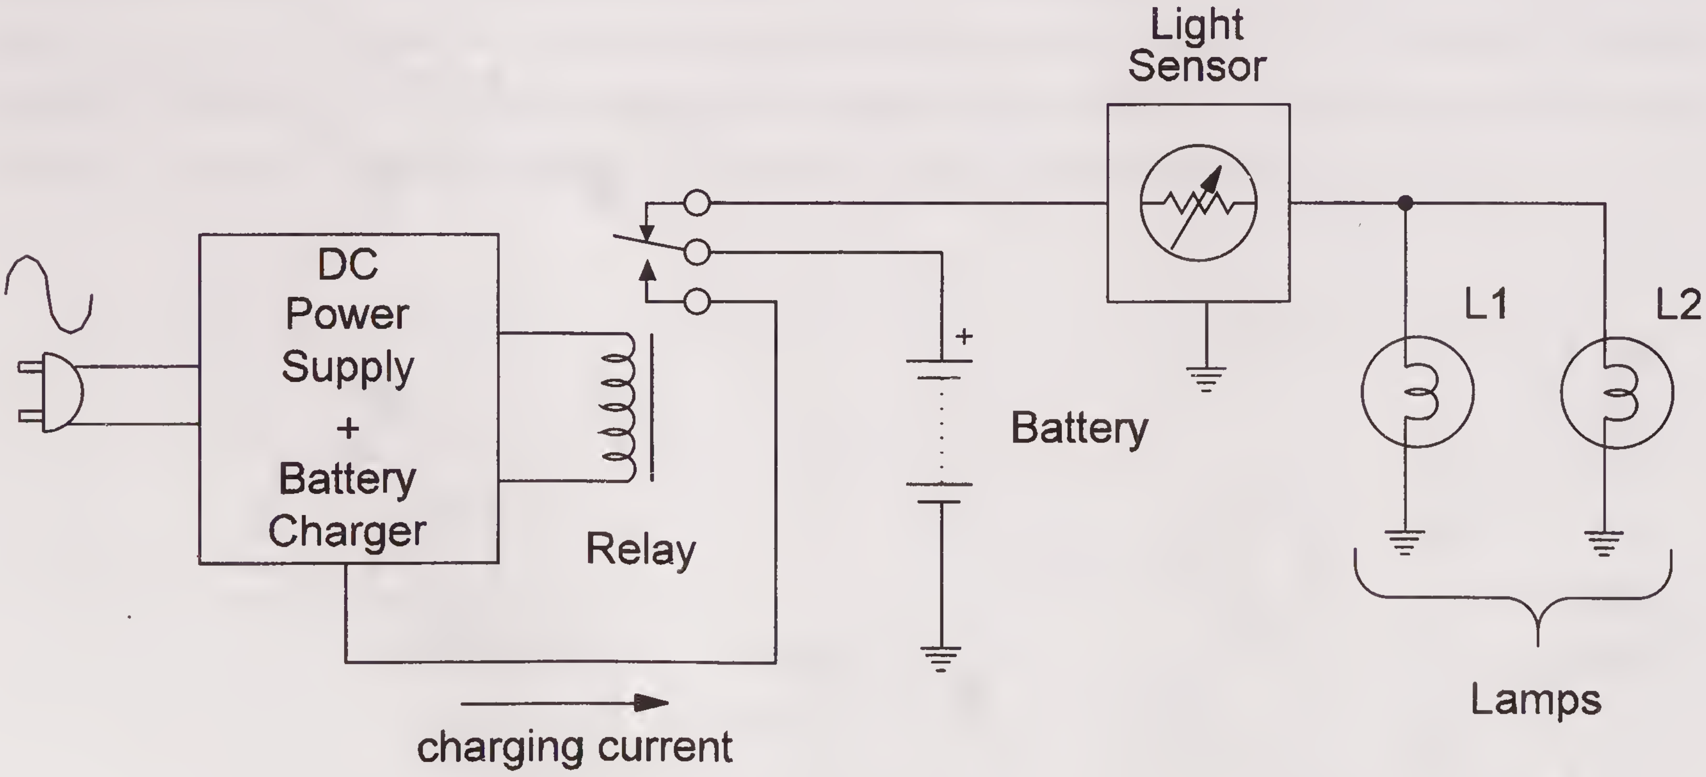

Figure 218

A battery charger is plugged into the AC power line, keeping a battery in a constant charging process. A relay or another switching circuit unplugs this block from the battery when the AC power fails and, at the same time, plugs the battery into the emergency lamps. A photocell is placed between the blocks to give the circuit some "intelligence." This block only turns on the lamps if the location is dark. It is not necessary to turn on the lamps during an emergency if the area is illuminated by natural light. In some systems there is an inverter between the battery and the lamps. This inverter is necessary to drive fluorescent lamps.

Alarms

Home security is increasingly becoming more important. High-tech equipment is available and can easily be installed in any home. The degree of sophistication of systems can vary from simple switches that trigger an alarm if a door or window is tampered with to complex microprocessed systems that dial a security provider's or the police's phone number if some disturbance is detected. Electricians are sometimes called to prepare a home to receive some kind of alarm system, which may include placement of sensors and wiring. They must also install the power supply for the system, which includes outlets, wires for sirens, and other alarm transducers. So, it is important they know how the basic system works to help in the installation or troubleshooting. The following are some of the basic alarm and security systems.

- Magnetic sensors and switches

The simplest alarm system uses a switch to trigger a siren or another sound or light source. Figure 219 shows a diagram of a system that uses a magnetic switch placed in a window.

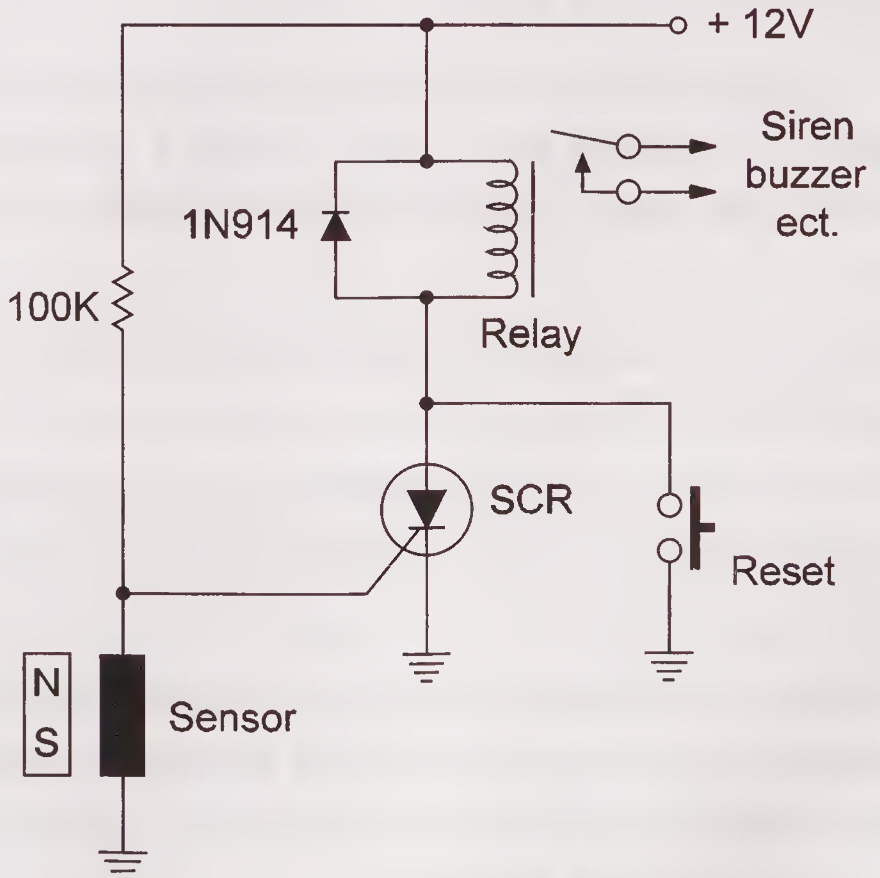

Figure 219

With the window closed, the magnet is in contact with the reed switch, keeping the contacts closed and the circuit off. If the magnet is moved away from the reed switch, the contacts open and the

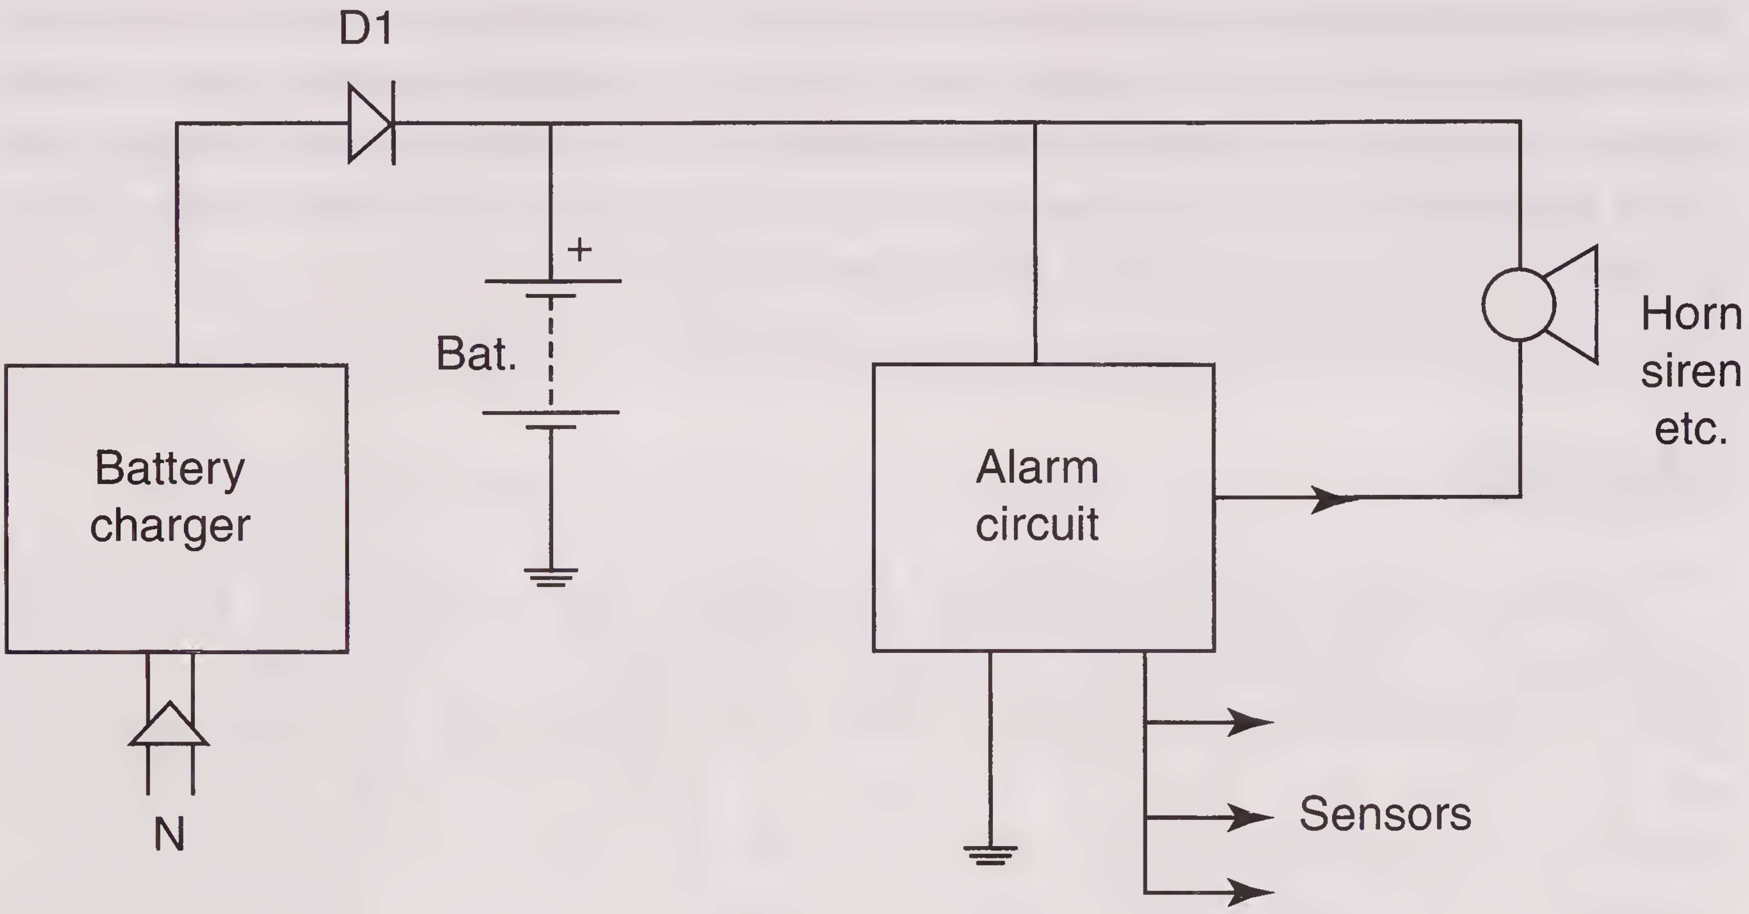

Figure 221

alarm is triggered. Many switches of this kind can be wired in series to protect all the windows and doors of a house or building. The relay is open until one of the sensors is activated. Once triggered, even if the window or door is closed again, the circuit remains on. To stop the alarm it is necessary to turn off the power supply, pressing S1 for a moment. Any number of sensors can be wired in series.

Notice that in this circuit, the current flowing across the sensor is very weak, allowing the use of cells or batteries for power. Radio Shack , Dimango, and other dealers offer the sensors for this type of alarm, and also the detectors, the sirens, and in some cases, complete kits to protect a home. A complete alarm system includes additional resources as shown in Figure 221.

In this system, a battery charger keeps the battery charged to power the alarm even if an intruder cuts the AC energy supply. The circuit also includes other sensors, such as microswitches (small switches activated when pressed or if an object is moved). When installing or repairing this kind of alarm an electrician doesn't need to be extremely experienced as many of the systems are simple, but must take care with the isolation of the wires to the sensors.

Another system includes in the sensor a radio transmitter that sends a signal to a receiver. If the sensor is activated, the signal changes and the alarm is triggered. This system is suitable for cases where there is no space to pass common wiring.

- Photoelectric

The use of photo sensors in alarms is common in many applications. Figure 222 shows a passage alarm or passage detector using a phototransistor as the sensor and an IR (infrared) LED as the radiation source.

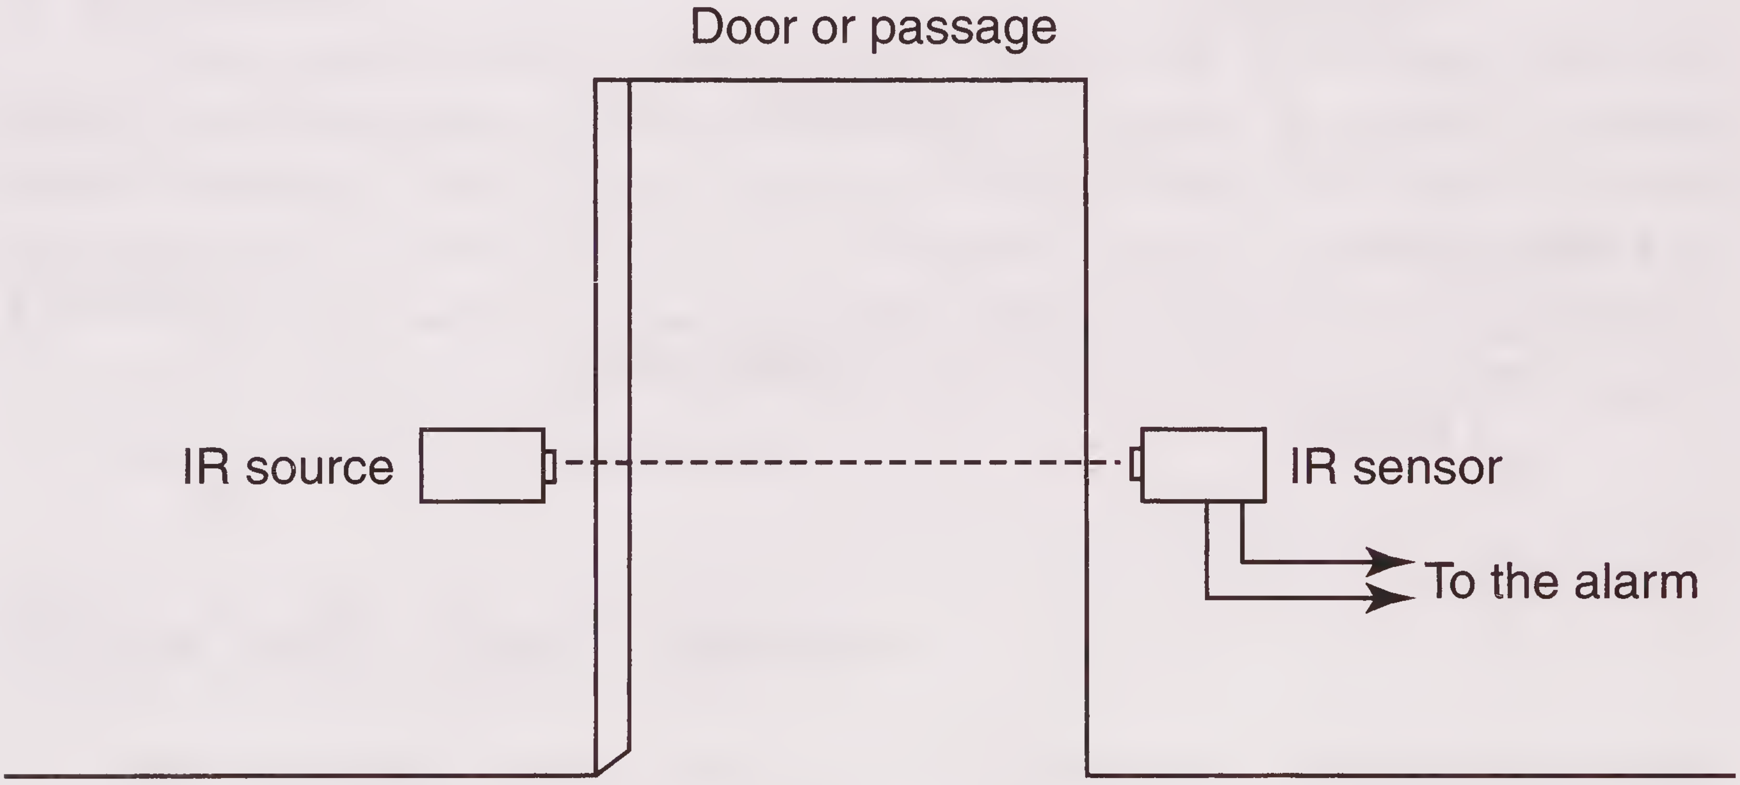

Figure 222

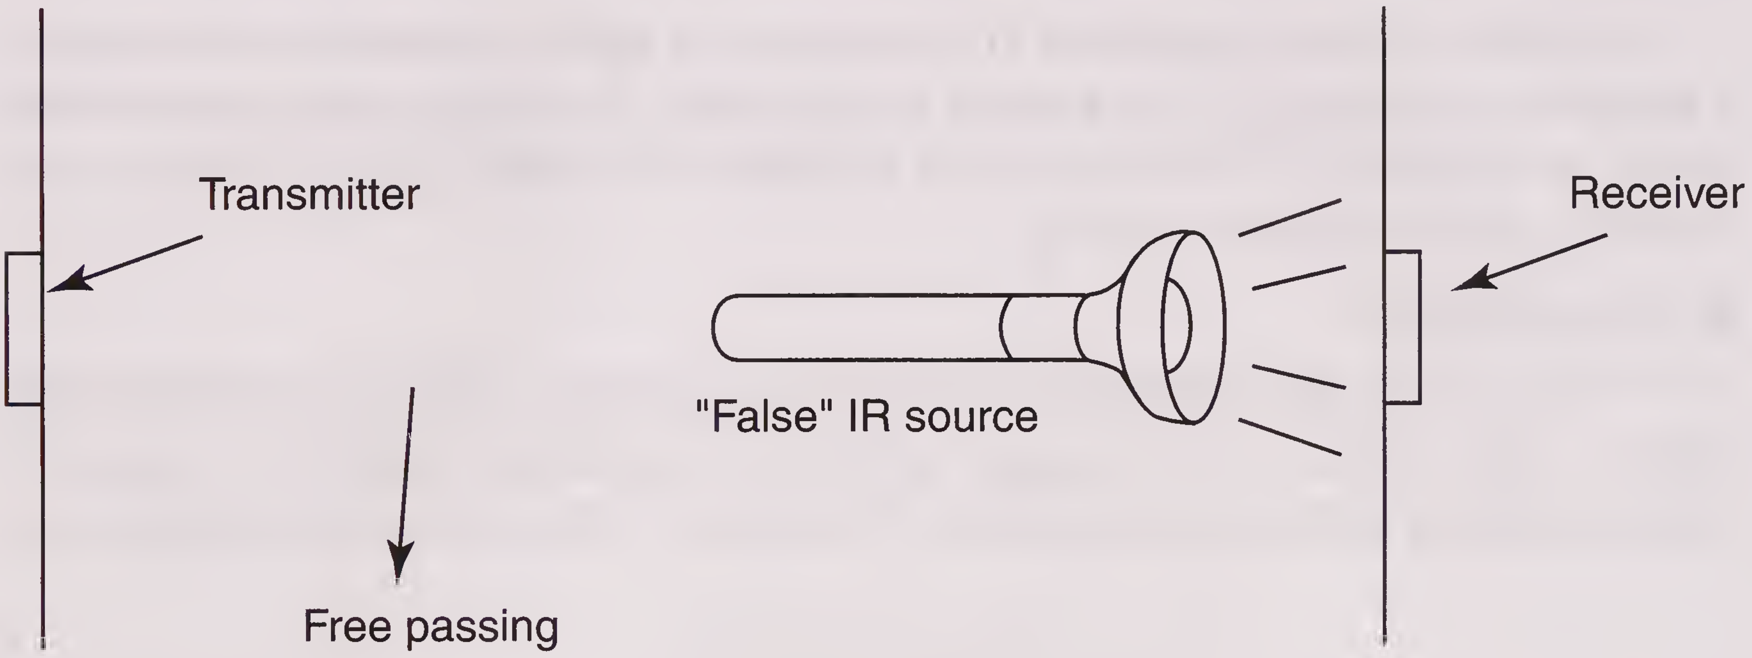
This circuit detects when a person or object cuts the radiation beam, even for a fraction of a second, in the sensor. The use of IR is recommended as the intruder can't see it, and therefore can't see where the system is placed.

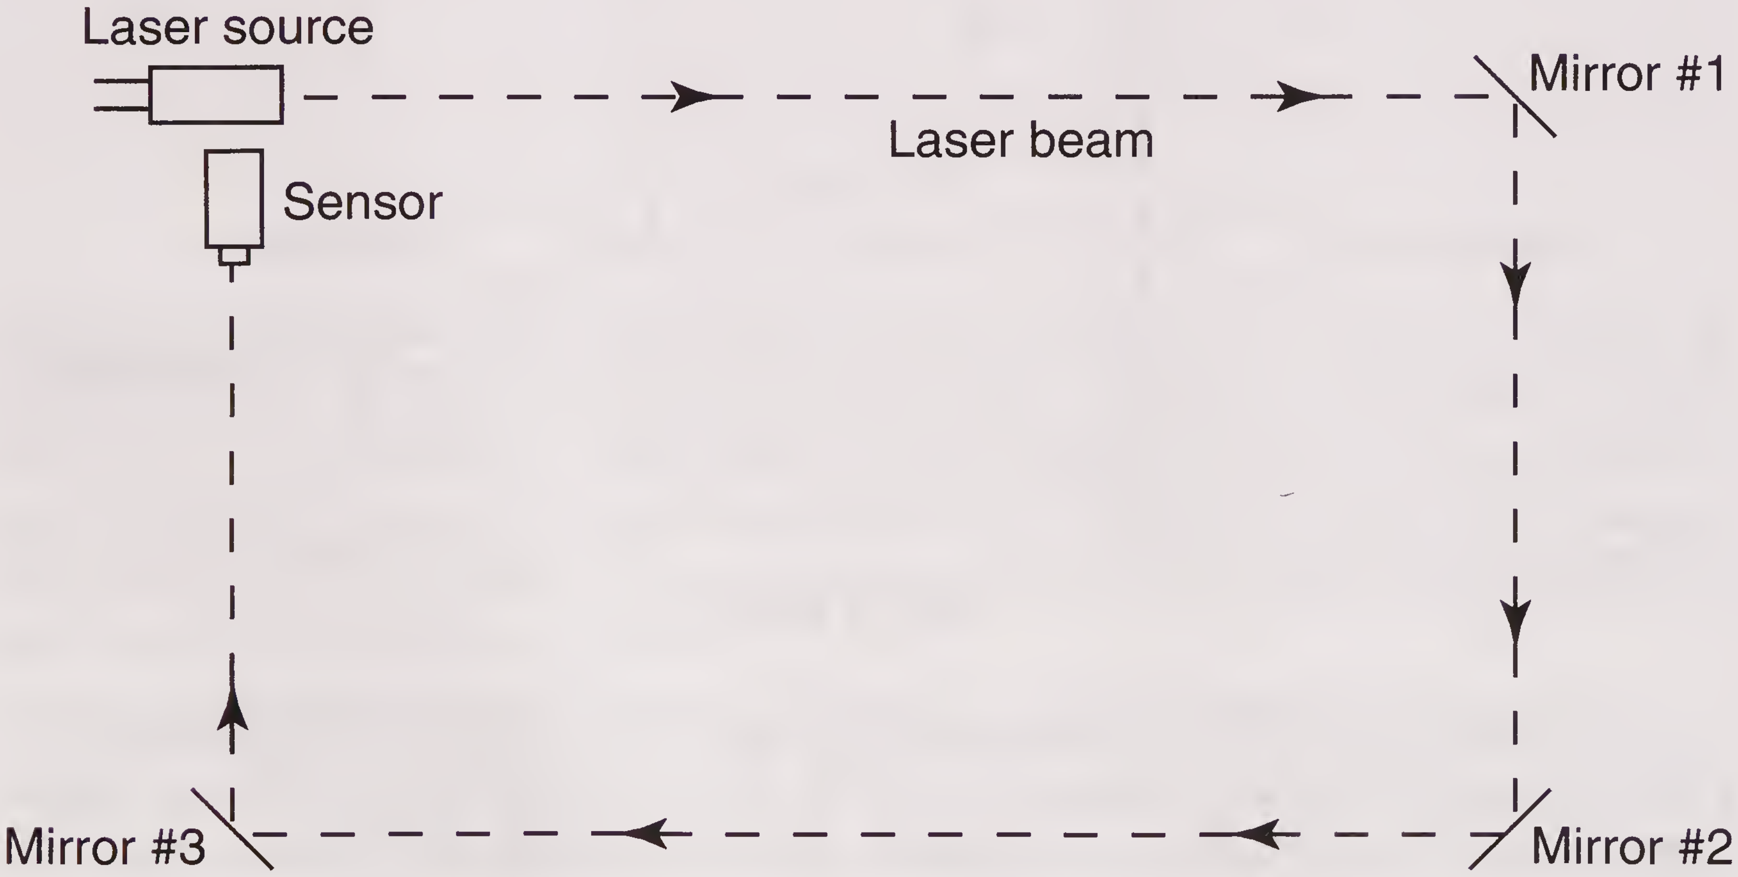
Many circuits operate with modulated IR, meaning the circuit doesn't produce a continuous light beam, but produces short pulses in a certain frequency to be detected by the sensor. This procedure is used to avoid an intruder using a "false" IR source to stall the alarm as suggested in Figure 223.

When installing or working with this kind of device, an electrician must be careful with light sources that can cause interference in the system, such as fluorescent lamps. If large areas must be protected, the alarm can use a laser as its IR source (Figure 224).



Transmitter
Receiver
"False" IR source
Free passing

Figure 223



Laser source
Mirror #1
Laser beam
Sensor
Mirror #3
Mirror #2

Figure 224

Mirrors can bend the IR laser beam, fencing a closed area against any intruder. If the laser beam is disrupted on any side of the area, the alarm will be triggered.

- Motion Detectors

Motion detector alarms use a piroelectric sensor. It is formed by piezoelectric material that presents a surface electric charge that changes according to the amount of IR radiation falling onto it. Because a certain degree of IR radiation always exists, the circuits are designed to detect small changes in this radiation from the presence of a warm-blooded creature, such as a human. To detect the very small changes in the radiation, the circuit used is extremely sensitive and can be complex, involving special ICs.

- Vibration Alarms

Small vibration sensors are placed in home or shop windows to detect any type of impact or vibration. The circuit for this type of sensor is the same as in the magnetic switch.

- Ultrasound

In the ultrasound or super-sound system, the air is filled with inaudible sound vibrations (above 20,000 Hz). A sensor is placed to monitor these vibrations. The system makes an “image” from the pattern of direct and reflected sound waves and any alteration due to movement of an object—an intruder—when detected by the circuit. The sensors and the emitter must be placed in the positions indicated by the manufacturer as it is sensitive to external interference.

Doorbells And Chimes

The traditional electric doorbell is formed by a coil (electromagnet) and a metal plate that vibrates to produce sounds when powered by AC voltage. Modern doorbells and chimes use electronic circuits to produce musical sounds, such as notes in sequence, melodies, and even bird songs. In some cases, sequential systems act on solenoids that beat on metal tubes with varying lengths.

The basic circuit of an electronic doorbell in blocks is shown in Figure 225.

When triggered by the doorbell button, the circuit runs a program that produces a sequence of notes programmed in the chip. The signal corresponds to the notes and is amplified by a common low-power audio amplifier. Audio amplifiers with output powers in the range between 1 and 5 watts are common in commercial circuits.

The way this kind of circuit is installed is not much different from any common doorbell. The trigger button (pushbutton) is placed near the door.

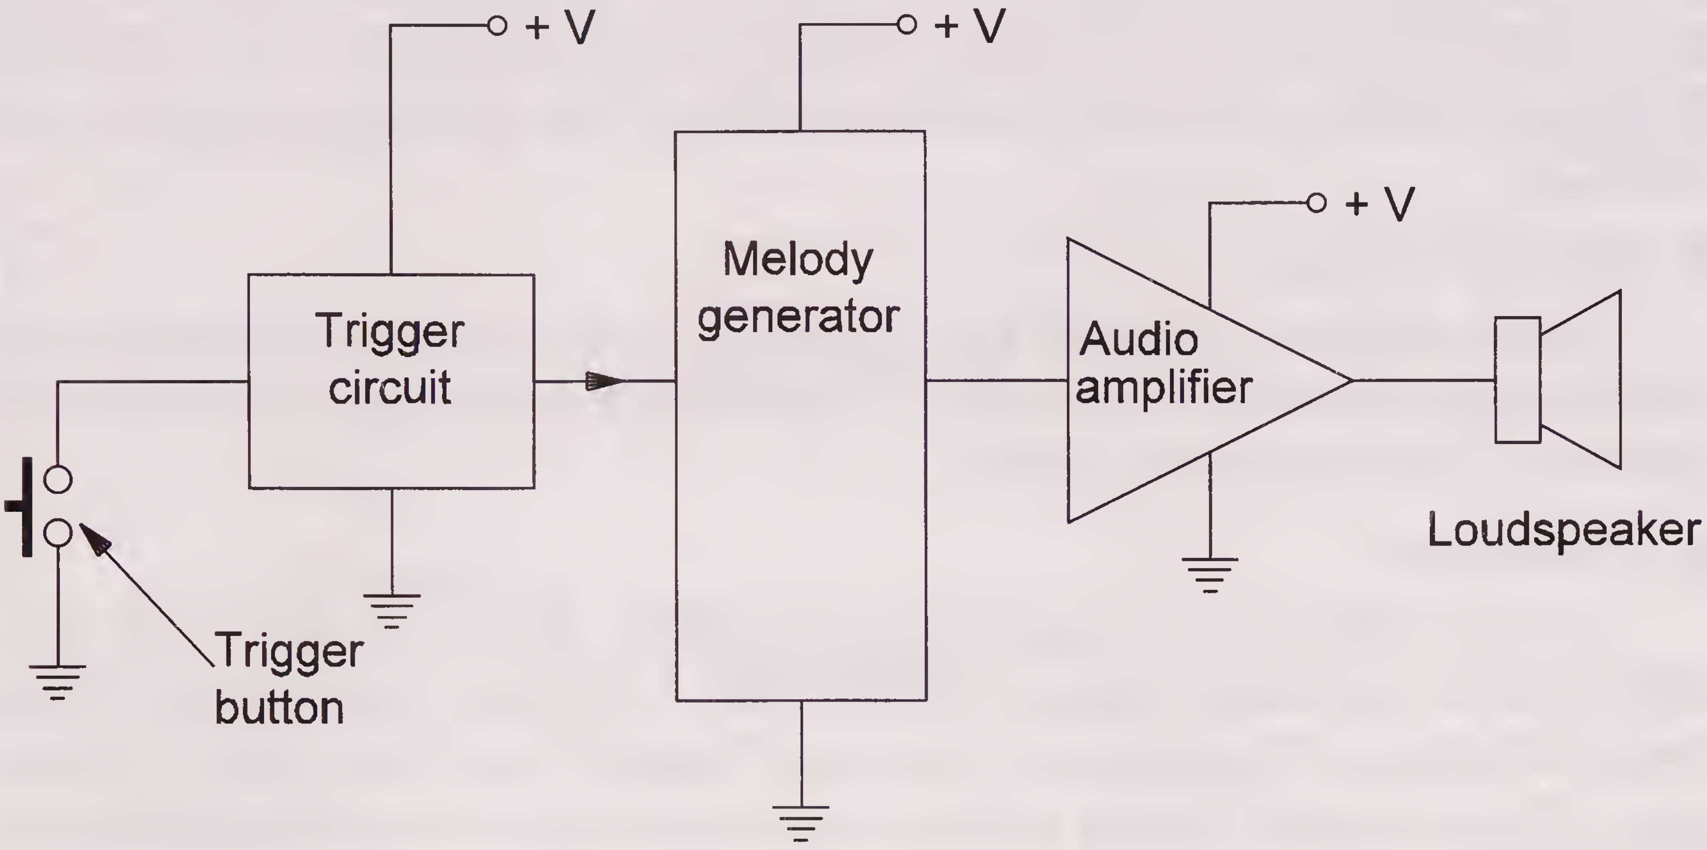


Figure 225

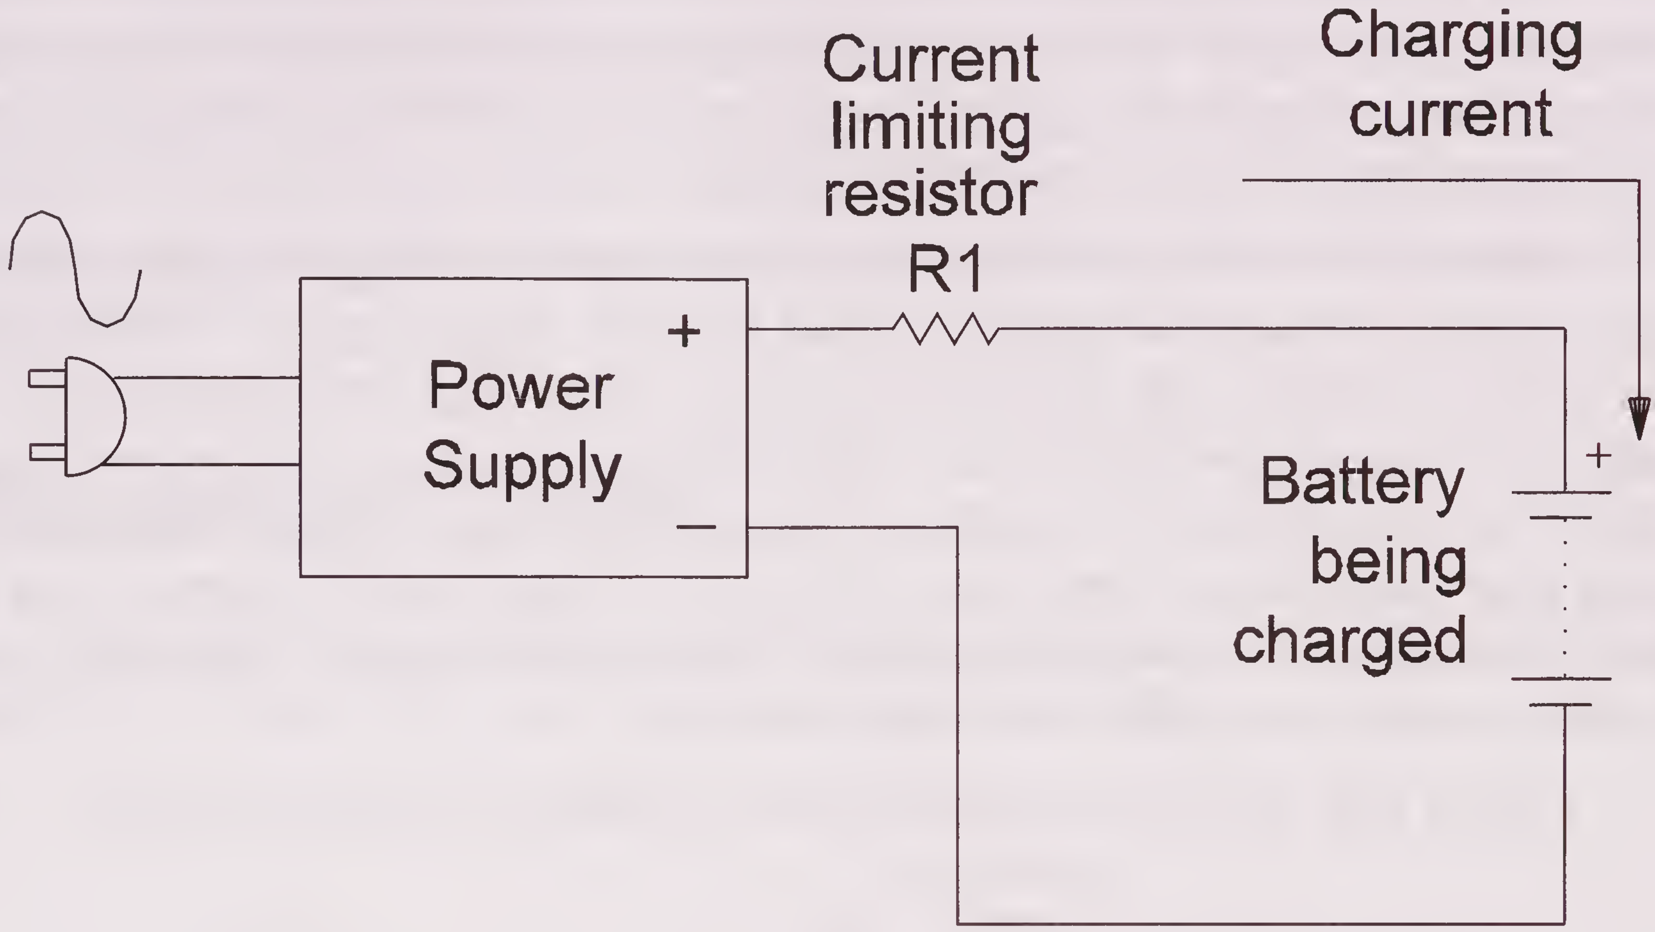
Many types allow more than one trigger point. The circuit is powered from the AC power line with a transformer to supply DC power. The power supply providing the low voltage to the DC circuit needs to remain on all the time. Some types of doorbells and chimes are coordinated with intercoms and video cameras.

Battery Chargers

Two types of battery chargers are used depending on the batteries to be charged. One is the small type used to charge Ni-Cad batteries and cellular telephone batteries or those embedded in wireless telephones and intercoms. This circuit is nothing more than a low-voltage DC power supply with a circuit that supplies constant current to the cells to be charged. The basic idea is that, by forcing a current to flow in the inverse direction of the normal current supplied to the load, a battery is recharged (Figure 226).

In this circuit, the resistors determine the amount of current used to charge a battery based on its type. This means that battery chargers have specifications indicating what type of battery they can accommodate. If the



Current limiting resistor
R1
Charging current
Power Supply
+
–
+
Battery being charged

Figure 226

incorrect current is used, the battery life can be reduced. The most common types are the ones used to charge AA, C, D and 9V, and ni-cad batteries (Figure 227).

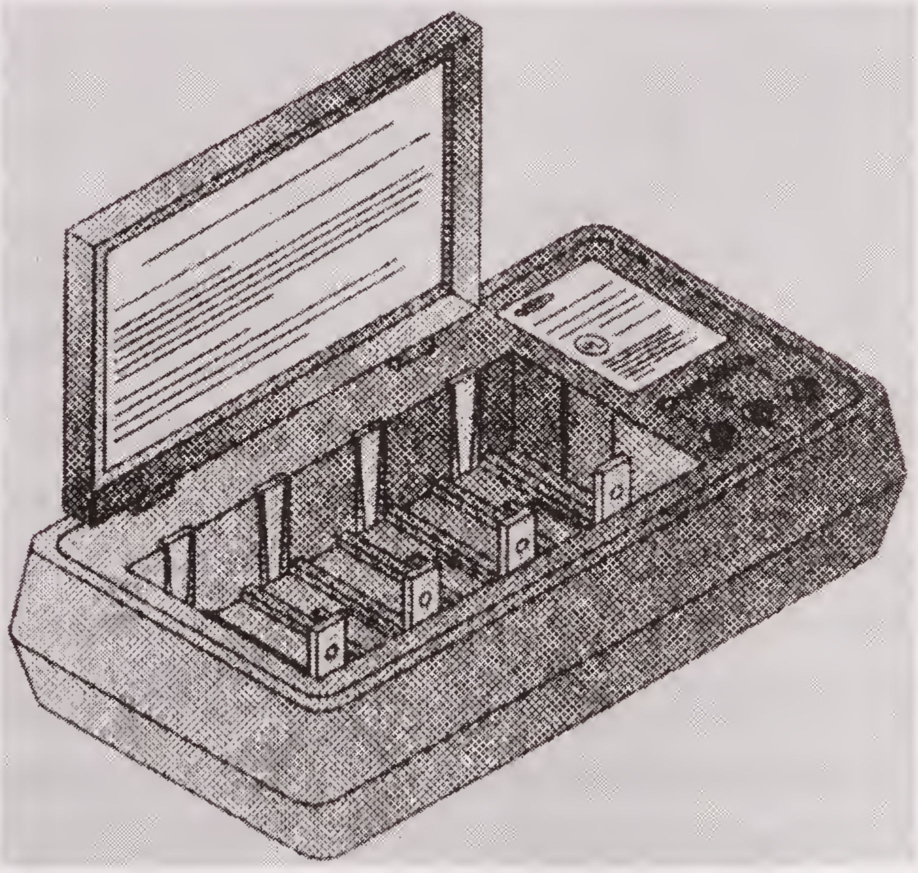


Figure 227

The second type is used to charge car and motorcycle batteries. These batteries need much more current usually over a larger time interval. Car battery chargers are also power supplies with resources to keep the current constant or to limit it to secure values.

Instead of the 100 to 500mA of current used to charge smaller batteries, car and motorcycle batteries need currents much higher. When using the battery charger, car batteries must be unplugged (at least one terminal) from the car's electric circuit. The voltage can rise to values not supported by the electronic circuits of the vehicle. The polarity of the cables must also be observed when using this kind of equipment. It is important to keep the battery in a ventilated place; the nonsealed types can leach poisonous gases during the recharging process.

Figure 228 shows a simple circuit of a battery charger for cars.

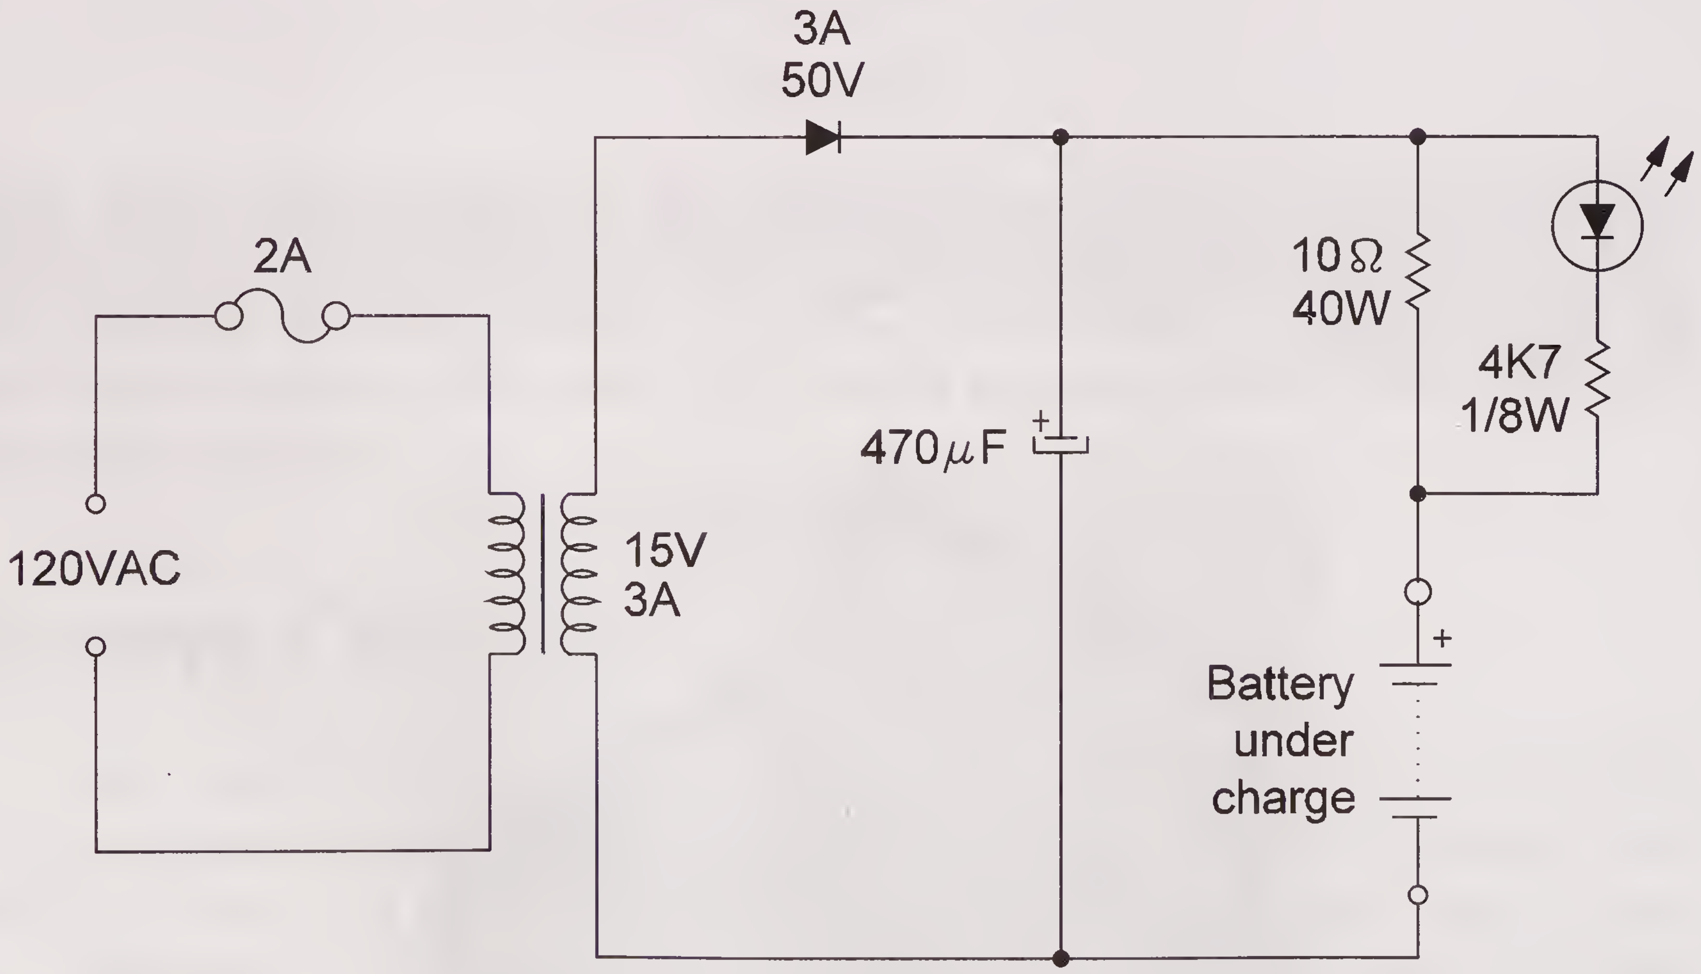

Figure 228

This circuit is a common power supply where the transformer steps down the AC power-line voltage to a value above the battery voltage. After rectification, the DC voltage is applied to the battery in the inverse direction of its normal operation. The resistor (R) limits the current to a secure value for the charge, and the LED monitors the charging process.

The amount of time to charge a common battery can vary from two to three hours to start an engine, and more than 12 hours for a complete charging process. If the battery doesn't retain the charge, it must be replaced. Sophisticated circuits can include resources to detect when the battery is completely charged and automatically interrupt the charging process.

Fluorescent Lamps

In traditional installations, fluorescent lamps use a starter and a ballast in a configuration, such as shown in Figure 229.

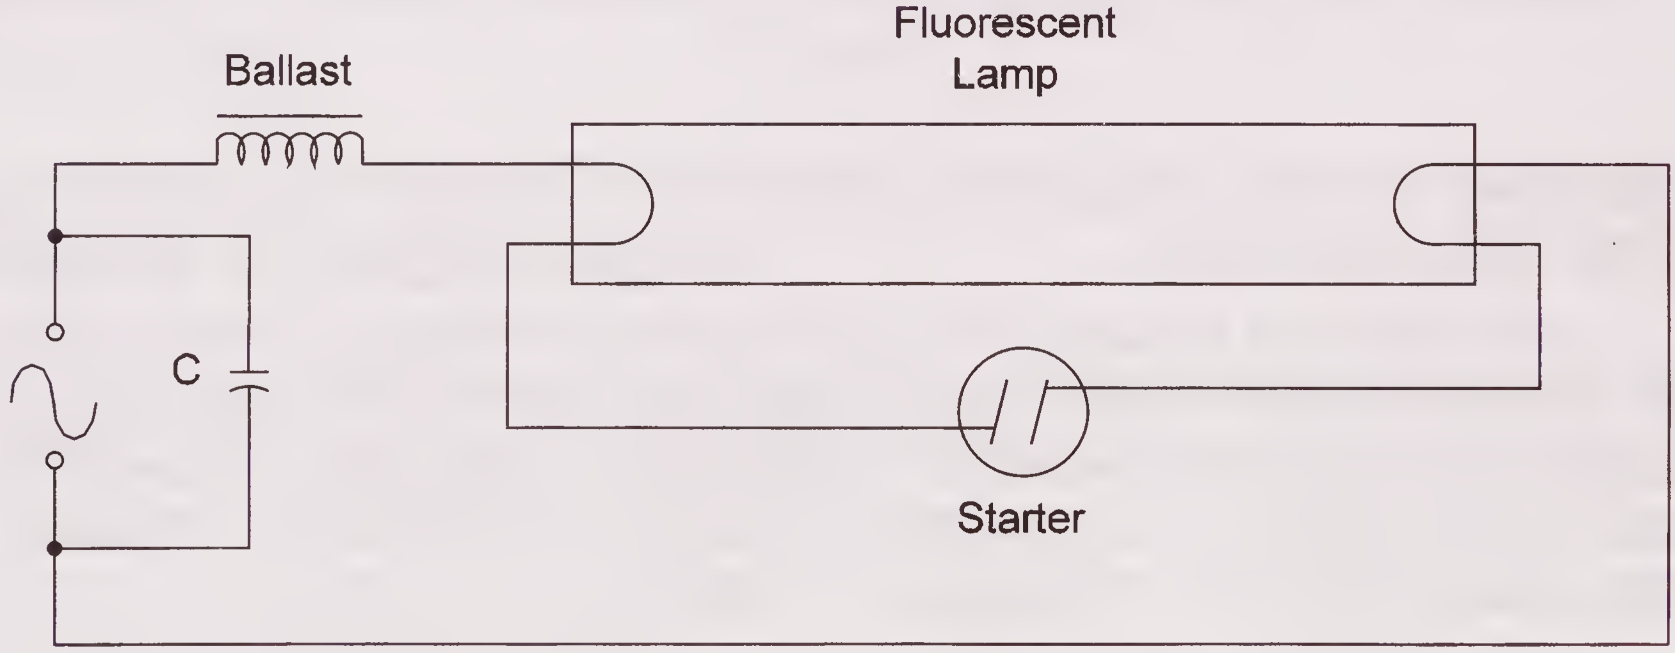

Figure 229

The starter acts as an automatic switch closing and opening the inductive circuit to produce high-voltage spikes. These spikes are necessary to ionize the gas inside the fluorescent lamp. As long as the gas is ionized, the lamp becomes conductive, and light is emitted. When the lamp is conductive, after the initial process, the starter is now inactive.

With electronics, the traditional ballast is replaced by high-voltage and high-frequency circuits that use modern components like power FETs and ICs (Figure 231). This circuit is really a high-frequency inverter operating directly from the AC power line. The AC is rectified and used to drive a

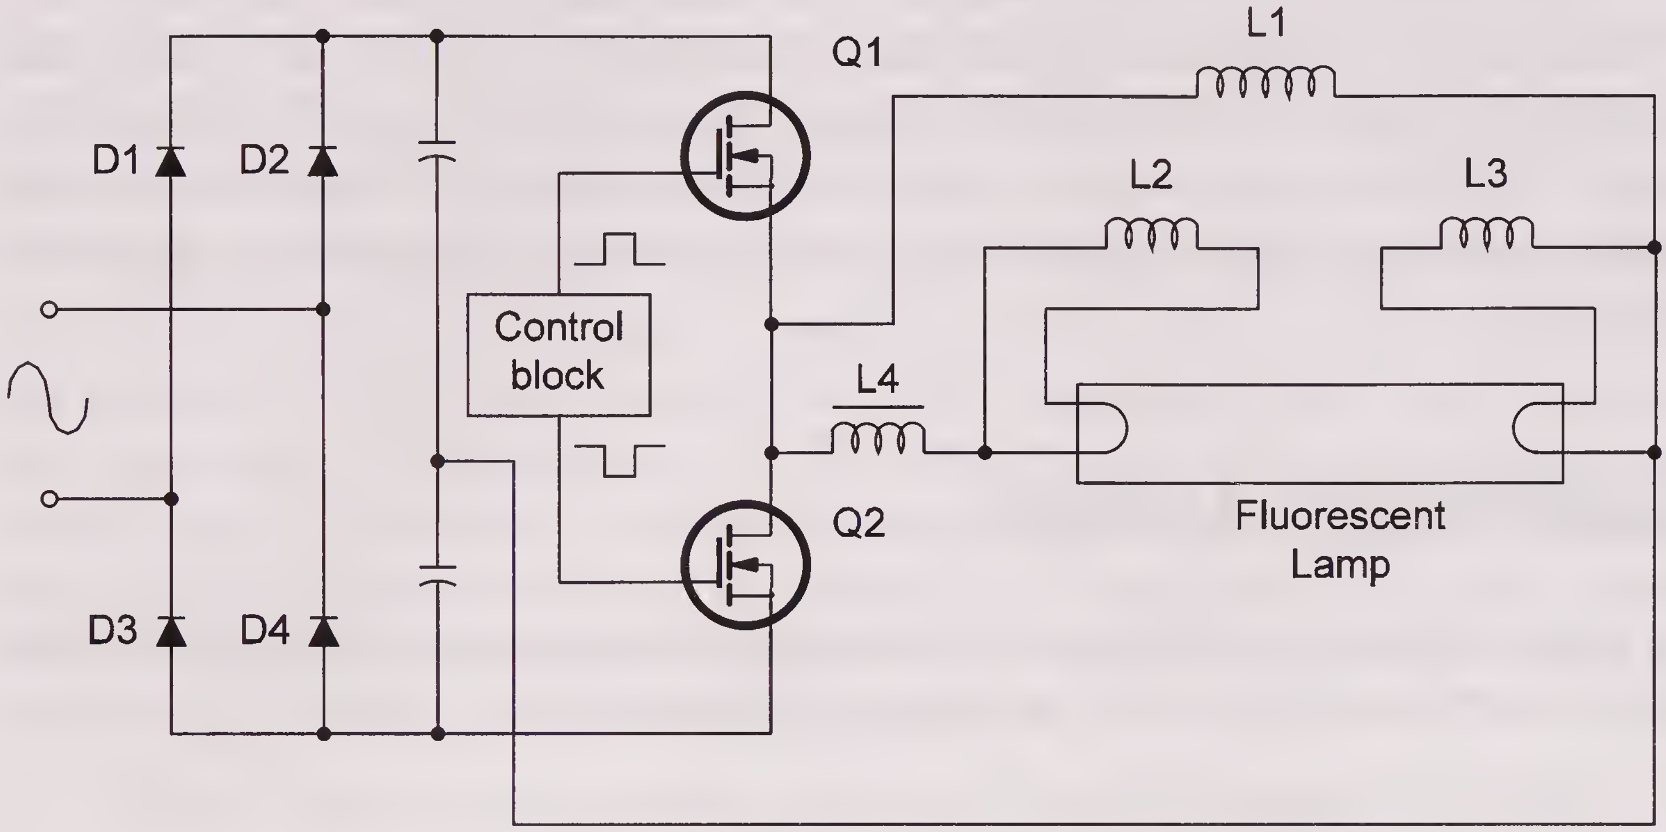

Figure 231

high-power oscillator stage with a transformer. The load of the transformer is the fluorescent lamp.

The difference between this circuit and the traditional configuration is the efficiency (more electric energy can be converted into light), and the oscillations in the AC power-line voltage don't influence or interfere in the circuit operation. But, the basic difference, for the electrician to observe, is the presence of an electronic circuit inside it.

When working with electronic ballast, watch out for EMI. The high-frequency operation of some circuits requires special care to avoid interference with nearby radio equipment. The basic procedures include the use of filters and grounding.

AC/AC Converters

The difference in AC voltages in many countries can be a problem when you have an appliance not able to operate on more than one specified voltage. If you purchased an appliance in another country, or if you are moving to another country, you must consider that your appliances may not be able to plug into an outlet.

The use of a step-up or step-down converter that can convert the 120VAC power-line voltage to 220 or 240VAC or a 220/240VAC to 120VAC is recommended. If you plug a 220/240VAC appliance into a 120VAC outlet, it won't work; however, if you plug a 120VAC appliance into a 220/240VAC outlet, the appliance may burn, have parts damaged , or have a fuse blown.

When recommending a step-up or step-down transformer, electricians must observe the power needs of the appliance. The power is measured in watts (W), meaning you have to use a transformer with more power than required by the load, with a certain tolerance margin to avoid overload. Many step-down transformers used to convert 220/240VAC into120VAC can also be used to convert 120VAC into 220/240VAC when reverse wired to the appliance. This is not a general rule because it is valid only for simple transformers without voltage regulation circuits included inside.

Power Conditioners

In theory, the AC power-line voltage must be kept constant with the 120VAC or another value specified by the energy company or according to the country. Unfortunately, local conditions, as consumption peak hours occur or long wires are used to power an appliance, the voltage can step down to unacceptable values.

Many modern appliances have circuits that include voltage regulators that let them operate in a large range of voltages without problems. But, if this type of resource is not found in the appliance, an external voltage regulator transformer or power conditioner is necessary. An external voltage regulator is an electric/electronic device connected between the appliance and the AC power-line outlet with the purpose of maintaining constant voltage. The most common types are automatic, using electronic circuits that sense the output voltage and correct it by acting on a transformer. When using this kind of device, it is important to check that the specified power is enough to provide the load with the necessary energy.

Intercoms

Many types of intercoms can be found in the electric installations of homes or buildings. The main type is the one associated with the doorbell and used to talk with a person at the front door. It is formed by a low-power audio amplifier where the loudspeaker is used to both reproduce the sounds and to act as a microphone. Figure 232 shows a simple circuit of an intercom using an IC from National Semiconductor.

listen

Figure 232

The switch changes the function of the loudspeakers, plugging them into the input when they are used as microphones (to talk) and as loudspeakers (to hear). Other types can use separated elements for these functions, and electret microphones are used.

The same amplifier can also be used to reproduce the sound of the doorbell. In the basic installation, the central unit is placed inside the building and powered from the AC power line, cells, or batteries. The remote unit is placed at the front door or entrance of the building and two types of wires can be used. In some cases, separated wires for the bell and audio

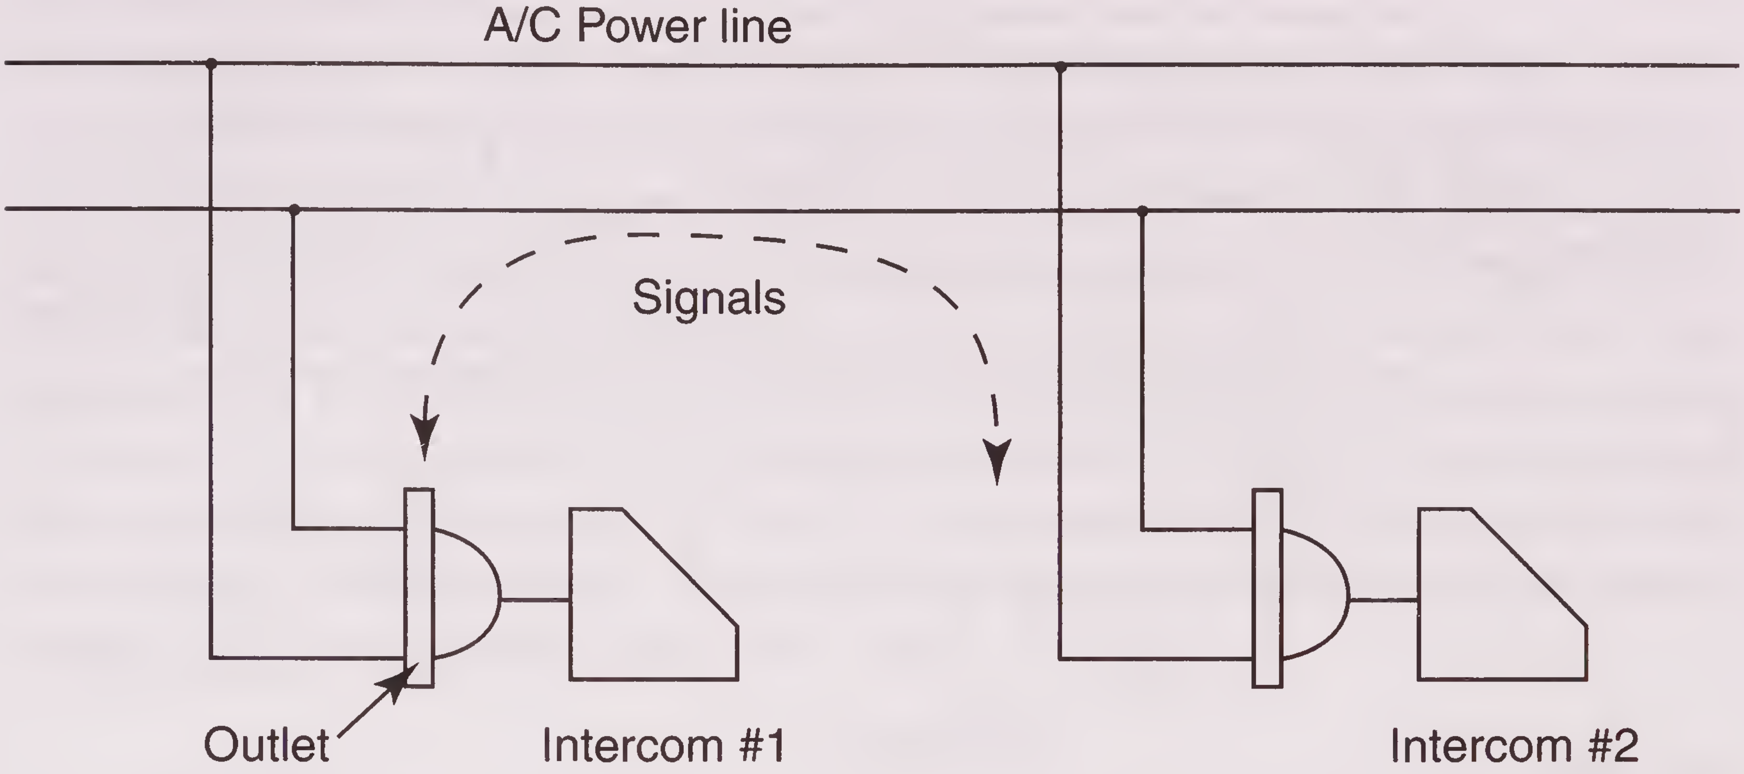

Figure 233

signals are used. The audio signals, in some cases, are conducted by screened cables.

Another type of intercom is one that uses the AC power line to transport the signal between the stations. This means that you only need to plug the units into outlets (Figure 233).

High-frequency signals are superposed to the voltage transporting the audio signals. Common types use PLLs to decode the signals in the range between 50 and 200kHz (refer to the section on PLLs). The principal problem found when working with this kind of intercom is that in some cases the units are plugged into outlets of different branches in an electric installation, as shown in Figure 234.

Even in adjacent rooms, the signals must travel a large distance. Sometimes they are unable to pass from one branch to another. The presence of inductive elements between the branches of the installations can stop the signals. Installing a 0.1 uF/400V paper or polyester capacitor between the branches where the signals can't pass will solve the problem.

Many versions of commercial intercoms can be purchased in many specialized stores and easily installed by an electrician, even one just beginning.

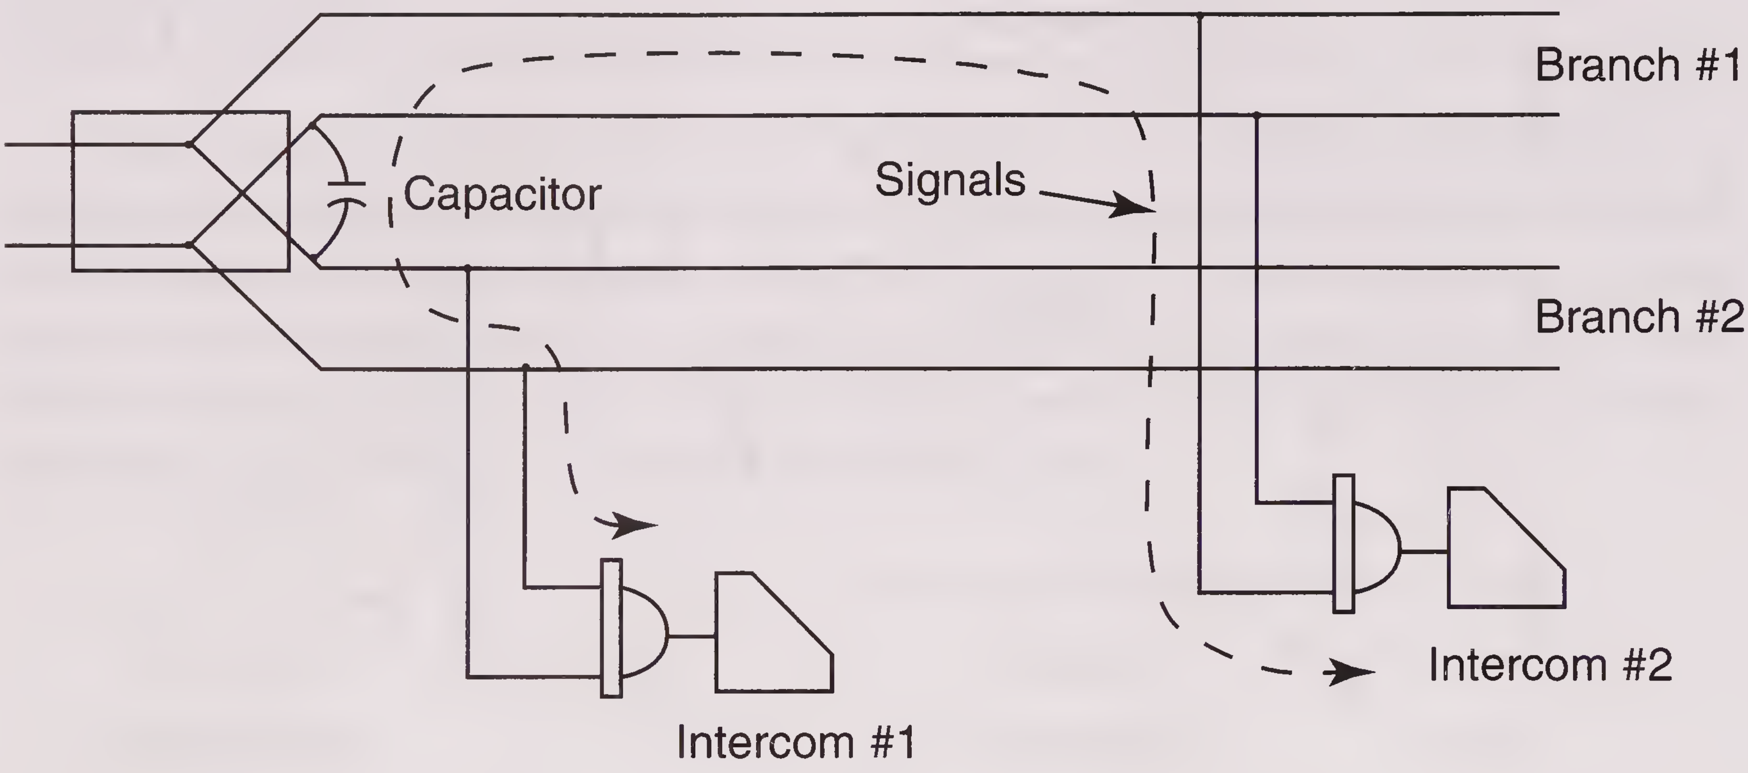

Figure 234

Wireless Systems

The use of the AC power-line voltage is the simplest solution for remote control of appliances and also the most traditional. By placing a switch at any point in the wiring, you can turn on and off any appliance plugged into that line. Today, with the use of complex devices—many of them as small as a matchbox—it is possible to control appliances without wires or the AC power line.

Many solutions have been found to make the control of electric and electronic appliances using electronic circuits easier. The electrician who installs appliances in any building that are AC powered should know how they work. This is especially important to avoid problems with correct installation, interference, or improper use. For example, a remote control for a garage door that uses radio waves in a location with a high level of interference doesn't work well. It can be replaced by an IR remote control with great success.

An electrician can find the following types of remote control for domestic appliances.

- Radio Frequency

This kind of remote control uses a high-frequency transmitter operating in the VHF or UHF band (between 30 and 600MHz) to send signals to a receiver placed at distances of up to 50 meters away, depending on the application. The signals are modulated, (i.e., transport information) communicating to the controlled device what it has to do. The simplest systems use a transistor as an oscillator to produce the high-frequency signals and an IC to produce the coded information to be sent. In some cases, the transistor is replaced by hybrid modules or a complete transmitter mounted in small modules. Figure 235 shows a typical transmitter used to open and close garage automatic doors.

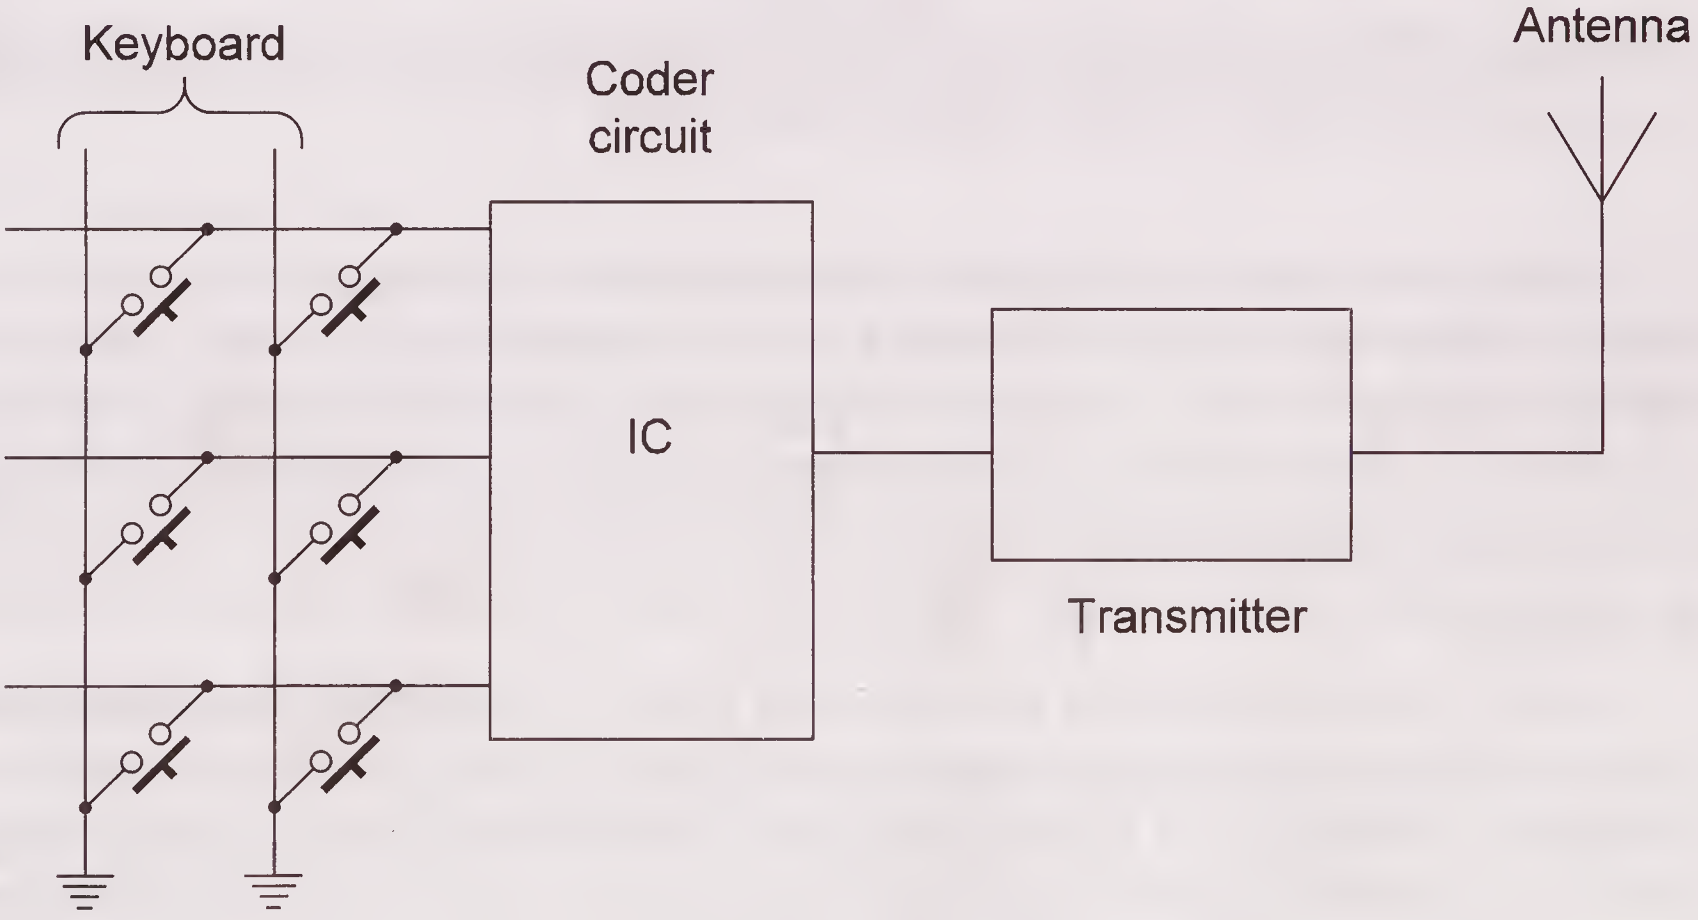

Figure 235

The IC can send a coded signal in a manner so that the receiver only recognizes the signals sent by that IC. The receiver decodes the signals, acting on relays, motors, and other devices to be activated. Normally, in the receiver we find the other member of the pair of ICs used to aid in decoding the signals. Small modules, or hybrid modules, forming pairs of transmitters and receivers are found in many remote control systems, such as the ones shown in the Figure 236.

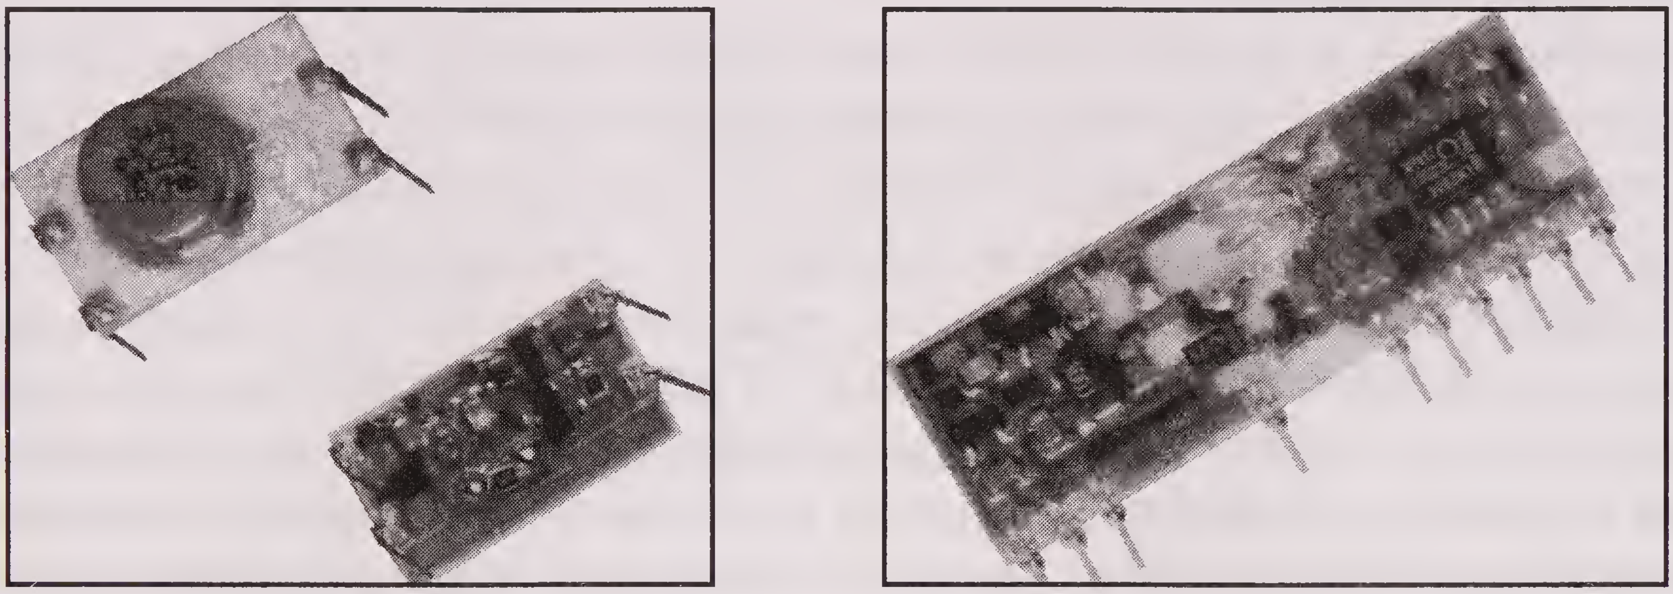

Figure 236
A transmitter hybrid module (left) and a receiver module (right) used in short-range communications and control. (Photos courtesy Tellecontrolli)

The set shown in Figure 236 operate in standard frequencies (315,418MHz and 43,392MHz) and are mounted using the thick film hybrid technology in the manufacturing process. One disadvantage in the use of this kind of remote control system is that it can fail with exposure to a high level of EMI or noise.

■ Infrared

In the remote control is a transmitter that sends IR modulated beams. The modulation can be produced by the same coded ICs found in radio-frequency systems. The information sent by the transmitter communicates what the controlled device has to do. To produce the IR beam, IR LEDs are used. To drive the LED, hybrid modules can be found.

In the receiver, a phototransistor or photodiode exists acting as a sensor for the IR beam. The signal produced by this receiver is applied to a decoder circuit (in some cases the same as found in radio systems) that decodes the information to the driver circuits. This sort of system is found in many electronic appliances, such as VCRs, TVs, and audio systems. It is also found in electric appliances, such as automatic garage doors, remote-controlled fans, and automatic doors.

Although the IR is not disrupted by interference by noise sources like RF or radio systems, its principal disadvantage is that the receiver must "see" the transmitter, meaning the units must have a direct line of communication open. Any solid obstacle can block the IR beam.

The range depends on local conditions, but normally doesn't exceed 50 meters.

- Ultrasound

Ultrasound vibrations can activate some appliances. This system is no longer in use, but it can be found in old appliances including TVs. The transmitter contained a small ultrasound transducer that sent vibrations in frequencies near 42kHz. These vibrations were picked up by a transducer tuned to the same frequency. The signal was also modulated by a circuit that sent information to the receiver, relaying what the appliance was to do. Due to its disadvantages, when compared with other modern systems, such as the IR and radio frequency systems, it is no longer used.

- AC power line

The AC power line can be used to send signals from a transmitter to a remote receiver connected to an appliance. The signals travel through building wiring, which transports information about what the appliance has to do. The operation principal is the same as found in wireless intercoms that use AC power to transport their signals. Although some appliances use this system, its performance is limited to short-range applications.

- Low-current wiring

Sometimes heavy-duty appliances, such as air conditioners, heaters, and high-power motors must be turned on and off remotely. If the control is part of the power cord, large-gauge wires will be needed because of the large current needs. Even the switches must be heavy-duty types, increasing the size of the control unit and adding a danger of shocks and shorts. A solution to this problem is the use of units having relays activated or controlled by low-current circuits like the one shown in Figure 237.

The current used to trigger the relay on and off is very low (milliamperes), allowing the use of low-gauge wires. And, as the control circuit is isolated from the AC power line and the voltage is very low, shock hazards are avoided.

On the Internet, an electrician can find many types of remote controls that can be adapted to common electric and electronic appliances. When

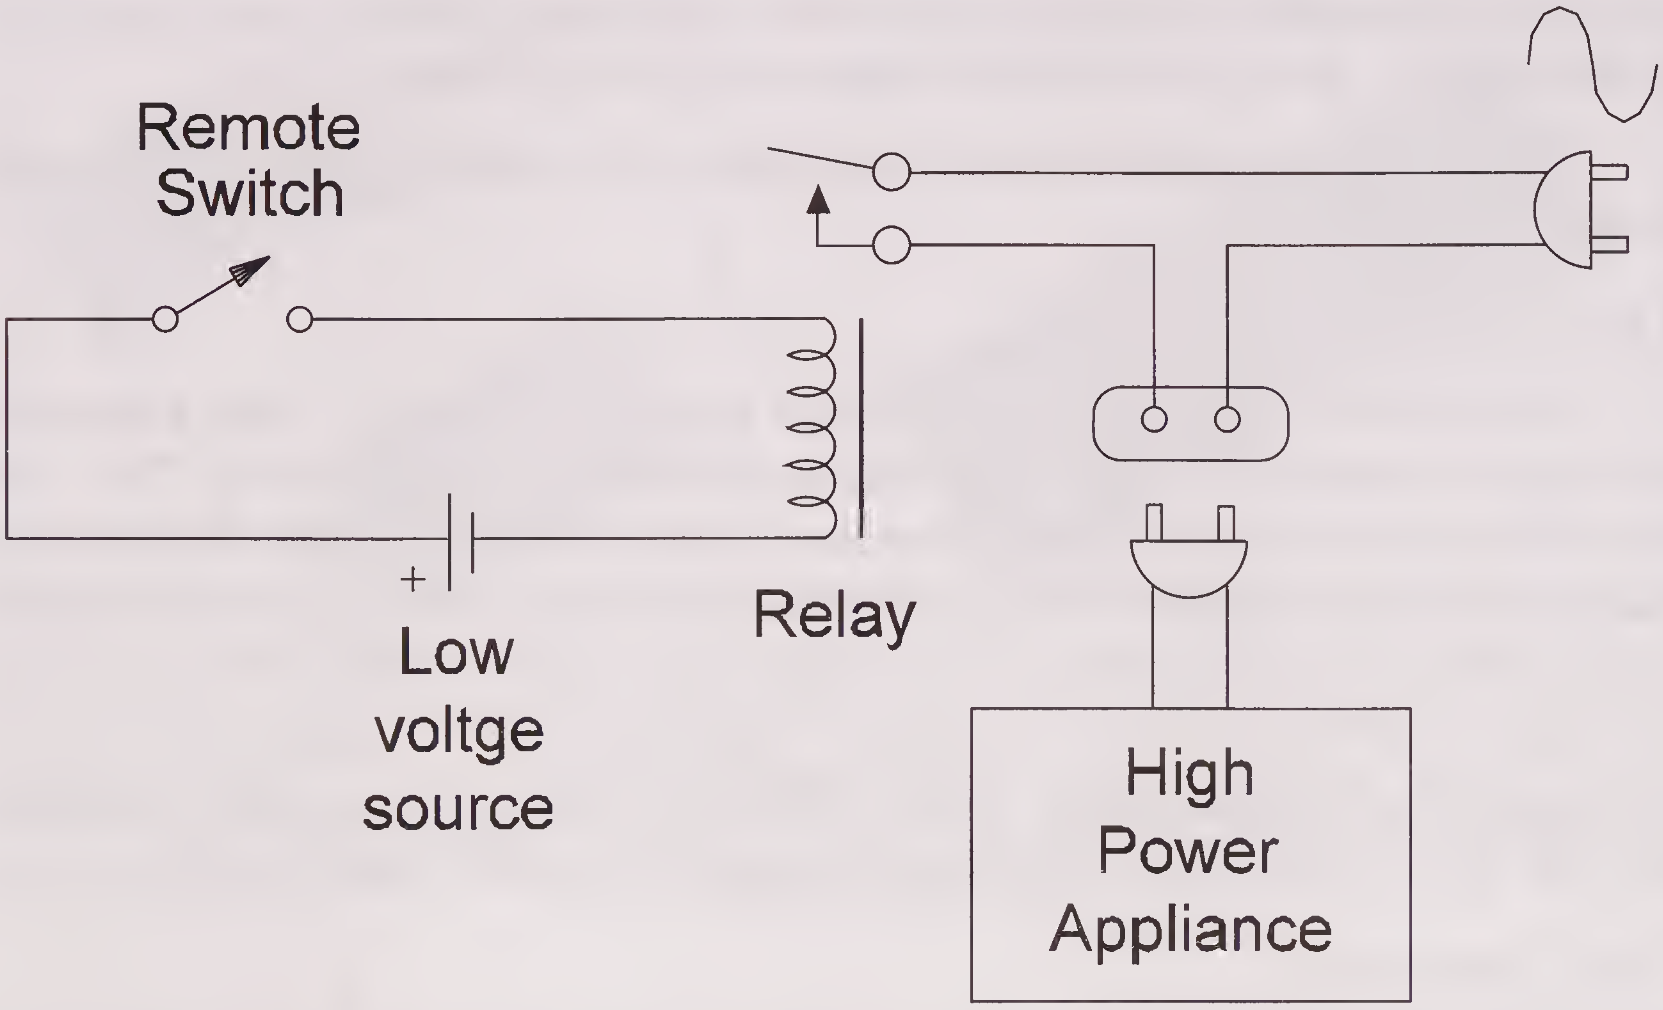

Figure 237

choosing one for an application, keep in mind if the area is noisy, with many interference sources. Avoid radio systems and use IR, or if there are obstacles choose a radio system over IR.

High-Frequency Appliances

Many electric and electronic appliances have high-frequency stages in their circuits. When installing or working with those appliances, it is important to know that radio frequency signals are critical and can be a source of problems for the less experienced electrician.

The first case to be considered is the installation of external antennas for TVs in the traditional VHF or UHF bands. Although the AC power-line voltage can be sent to every part using common wires, this is not a rule for high-frequency signals. High-frequency signals are attenuated by large lengths of wire and can be sensitive to bends or the close proximity of metallic objects.

A single curve in a wire can be sensed as a coil or inductance for a high-frequency signal. Two wires, one passing near the other, can represent a capacitor for high-frequency signals, causing alterations in its strength as shown in Figure 238.

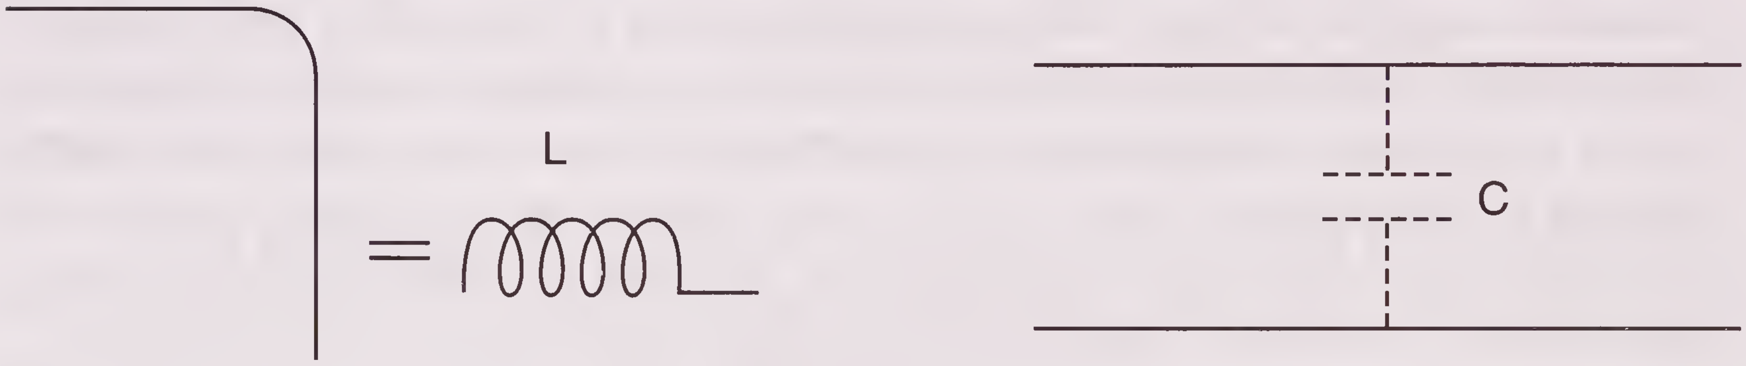

Figure 238

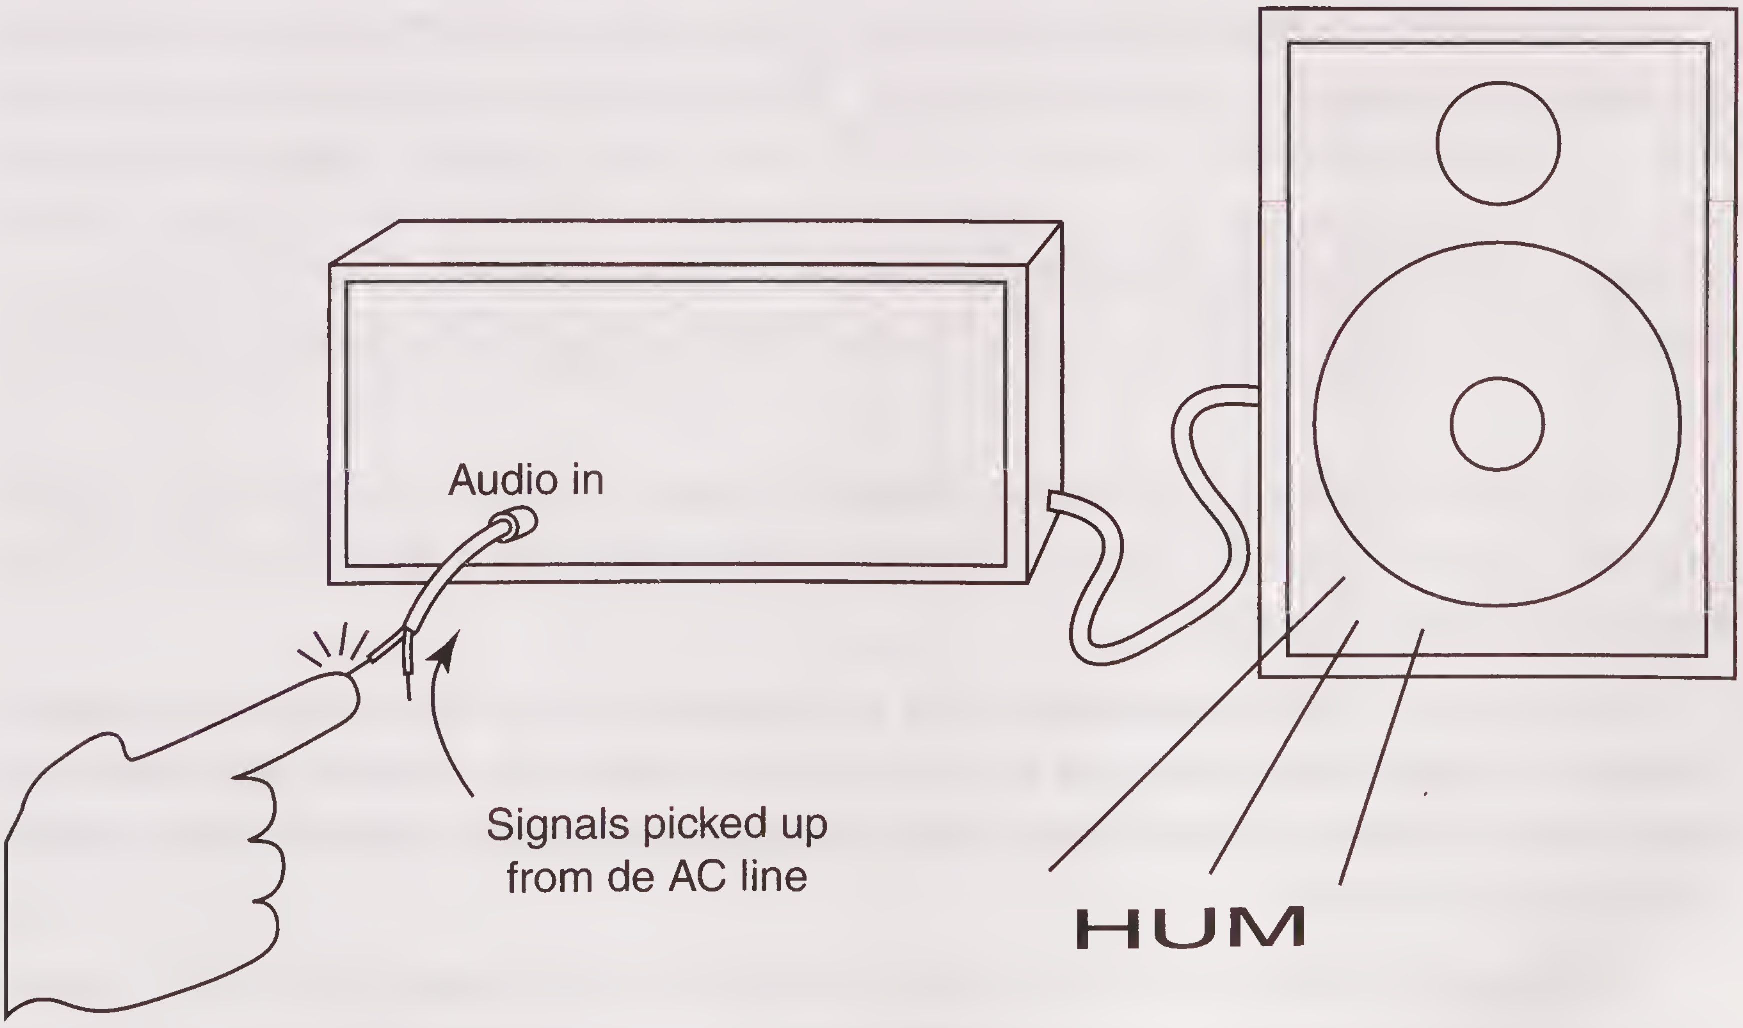
Another important point to consider is the fact that the wiring of a building acts as an antenna, radiating radio signals in the VLF (very low frequency band). These signals can be picked up by any nonshielded wires and, if amplified by audio circuits, can be reproduced as a hum in loudspeakers or phones. This problem can be noticed in audio amplifiers when you touch the input jack as shown in Figure 239.



Audio in
Signals picked up from de AC line
HUM

Figure 239

In audio systems and intercoms, the hum can become a serious problem for an electrician trying to install this kind of equipment. Shielded cables only work if the screen is wired to a good ground. So, it is important to plan an installation for these kinds of equipment.

In video systems, an incorrect connection for the cables can result in noise affecting the image. Wavy images can be produced by noise picked up by cables with shield problems. Another problem are high-frequency signals produced by appliances connected to the power supply line being radiated by the wiring. Triacs, SCRs, and motors as explained previously (see EMI, triac, and SCR sections) are sources of these high-frequency signals that can cause interference in other high-frequency equipment.

Surge Protectors

Brief pulses of voltages that can exceed the normal 120 or 220/240V (depending on the voltage used in the AC power line) are called surges. These pulses can rise, in some cases, to volts as high as 1000 and can destroy equipment. Sometimes these pulses are produced by nearby lightning strikes.

To protect equipment against surges and voltage spikes, outlets equipped with surge protection exist. The protection essentially consists of a voltage-dependent resistor (VDR) placed in parallel with the line or two VDRs connected to a ground connection. When the voltage spike comes, the VDR becomes conductive for a brief instant. This is enough to absorb the energy carried by the spike that can potentially destroy equipment.

Surge protectors can be found inside small outlets that can be plugged directly to the AC power line or inside outlet strips. Not all outlet strips are surge protected, though.

Not all electric and electronic equipment is sensitive to surge and voltage spikes. Incandescent lamps, appliances with motors, and heaters are not sensitive as they have inertia enough to not respond to the rapid changes of voltage.

Otherwise, electronic equipment, mainly those that use CMOS components, is very sensitive to voltage spikes coming through the AC power line. This includes computers, electronic telephone answering machines, VCRs, TVs, and audio equipment. Telephone equipment and computers connected to the Internet by telephone lines are also sensitive to voltage spikes coming through the telephone wiring.

Although they have internal surge protection circuits, in some cases they are not fast enough to handle the spikes, or the spikes are strong enough to not be absorbed by them. So, it is common to find modems and other such equipment destroyed after a severe storm.

It is a good idea to connect all this type of equipment to the AC power line using protected outlets or to unplug them from the telephone line or AC power line during storms with severe lighting.

Conclusion

This book is only a brief introduction to electronics for the electrician. There are so many more things to learn and know about electronics as it relates to electric installation. The buildings are becoming even more sophisticated with electronic equipment being embedded in the electric installations. The electrician of the future will have to know not only about the traditional AC power-line voltages, but should have a broad base of knowledge in many complicated areas including digital electronics, microcontrollers, and DSPs.

The idea of wiring a building to connect with the Internet, to send information to a remote computer, or to have climate conditioning systems plugged into sophisticated computers that can sense humidity and temperature, are not old. The electrician of the future, the construction engineer, and even the architect without some knowledge of electronics will be in an unfortunate situation. Even if you are not directly related to a profession that works with electricity, electronics are present in almost all things we make. To know something about it is important to our comfort, our performance in any job, and even more, to our security. Don't stop here! Learn more about electronics. It is important for you, your job, and your future.

Newton C. Braga
PROMPT

Sourcebook for Electronics Calculations, Formulas, and Tables

Newton C. Braga

For the student, teacher, or experienced technician, this is your one-stop guide for formulas and calculations on nearly any electronics subject, including explanations of use, derivations, and practical applcation examples. Topics include cable resistance, electrolysis, basic capacitor forumlas, harmonics, and many more.

Fun Projects for the Experimenter

Newton C. Braga

Author Newton C. Braga, whose works have appeared in electronics magazines for over 20 years, has collected fifty of his most fun, easy-to-build, and practical projects for your enjoyment. Basic electronic principles and fundamentals are stressed. These projects are primarily stand-alone, low-cost, and with few components, intended for one evening of work. The components needed are listed along with schematics, and hints and questions about the circuits are included to stimulate your imagination regarding possible modifications and alternate use.

Examples of the projects include an LED flasher, mini-metronome, electronic fishing lure, micro FM transmitter, touch switch, wireless beeper, and signal tracer. For hobbyists and students wanting to understand the basic principles of electronics, this book will provide answers to many of your questions.

HWS Servicing Series: Zenith Televisions

by Bob Rose

Expanding on the HWS Servicing Series, author Bob Rose takes an in-depth look at Zenith TVs, with coverage of manufacturer history, test equipment, literature, software, and parts. A variety of chassis are given a thorough analysis.

Troubleshooting & Repair
352 pages • paperback • 8-1/2" x 11"

Servicing RCA/GE Televisions

Bob Rose

Let's assume you're a competent technician, with a good work ethic, knowledgeable, having the proper tools to do your job efficiently. You're hungry to learn, to find a way to get an edge on the competition—better yet, to increase your productivity, and hence, your compensation.

In *Servicing RCA/GE Televisions*, author Bob Rose has compiled years of personal experience to share his knowledge about the unique CTC chassis. From the early CTC130 through the CTC195/197 series, Bob reveals the most common faults and quickest ways to find them, as well as some not-so-common problems, quirks and oddities he's experienced along the way. From the RCA component numbering system to the infamous "tuner wrap" problem, Bob gives you all you need to make faster diagnoses and efficient repairs, with fewer call-backs—and that's money in the bank!

Exploring Solid-State Amplifiers

Joseph Carr

Exploring Solid-State Amplifiers is a complete and authoritative guide to the world of amplifiers. If you're a professional technician or a hobbyist interested in learning more about amplifiers, this is the book for you.

Beginning with amplifier electronics: overcoming the effects of noise, this book covers many useful and interesting topics. It includes helpful, detailed schematics and diagrams to guide you through the circuitry and construction of solid-state amplifiers, such as: Transistor Amplifiers; Junction Field-Effect Transistors and MOSFET Transistors; Operational Amplifiers; Audio Small Signal and Power Amplifiers; Solid-State Parametric Amplifiers; and Monolithic Microwave Integrated Circuits (MMICs). Two bonus chapters are devoted to troubleshooting circuits and selecting solid-state replacement parts.

Modern Electronics Soldering Techniques

Andrew Singmin

The traditional notion of soldering no longer applies in the quickly changing world of technology. Having the skills to solder electronics devices helps to advance your career.

Modern Electronics Soldering Techniques is designed as a total learning package, providing an extensive electronics foundation that enhances your electronics capabilities. This book covers how to solder wires and components as well as how to read schematics. Also learn how to apply your newly learned knowledge by following step-by-step instructions to take simple circuits and convert them into prototype breadboard designs. Other tospic covered include troubleshooting, basic math principles used in electronics, simple test meters and instruments, surface-mount technology, safety, and much more!

Guide to HDTV Systems

Conrad Persson

As HDTV is developed, refined, and becomes more available to the masses, technicians will be required to service them. Until now, precious little information has been available on the subject. This book provides a detailed background on what HDTV is, the technical standards involved, how HDTV signals are generated and transmitted, and a generalized description of the circuitry an HDTV set consists of. Some of the topics include the ATSC digital TV standard, receiver characteristics, NTSC/HDTV compatibility, scanning methods, test equipment, servicing considerations, and more.

Howard W. Sams Guide to Satellite TV Technology

John A. Ross

This book covers all aspects of satellite television technology in a style that breaks "tech-talk" down into easily understood reading. It is intended to assist consumers with the installation, maintenance, and repair of their satellite systems. It also contains sufficient technical content to appeal to technicians as a reference.

Coverage includes C, Ku, and DBS signals. Chapters include How Satellite Television Technology Works, Parts of a Satellite Television Reception System, Installing the Hardware Portion of Your System, Installing the Electronics of Your System, Installing Your DSS, DBS, or Primestar System, Setting Up a Multi-Receiver Installation, Maintaining the System, Repairing Your System, and more.

Complete Guide to Digital Cameras

Michael Murie

The *Complete Guide to Digital Cameras* will appeal to anyone who has recently purchased or is considering an investment in a digital camera. The first section introduces the reader to digital cameras, how they work, uses and features, and how to buy one. The second section gives tips on use, available options, and how to transfer images from camera to computer. The third section focuses on manipulating the images on computer in varying file formats, and looks at some color printers presently available. Along with model comparisons and index of currently available cameras, a CD-ROM contains sample images, trial software, and utilities.

The *Complete Guide to Digital Cameras* is the answer to all your questions. Author Michael Murie, avid photographer and multimedia developer, has compiled a comprehensive volume, covering all aspects of the digital camera world. As a bonus, we include a CD-ROM with sample images and software, as well as a comprehensive table of the latest digital cameras, comparing features and technical specifications.

Home Automation Basics
Practical Applications Using Visual Basic 6
by Tom Leonik, P.E.

This book explores the world of Visual Basic 6 programming with respect to real-world interfacing, animation and control on a beginner to intermediate level.

Home Automation Basics demonstrates how to interface to a home automation system via the serial port on your PC. Using a programmable logic controller (PLC) as a home monitor, this book walks you through the process of developing the home monitor program using Visual Basic programming. After programming is complete the PLC will monitor the following digital inputs: front and rear doorbell pushbuttons, front and rear door open sensors, HVAC systems, water pumps, mail box, as well as temperature controls. The lessons learned in this book will be invaluable for future serial and animations projects!

Home Automation Basics II: LiteTouch System
James Van Laarhoven

Daunted by the thought of installing a world-class home automation system? You shouldn't be! LiteTouch Systems has won numerous awards for its home automation systems, which combine flexibility with unlimited options. James Van Laarhoven takes LiteTouch to the next level with this text from Prompt® Publications. Van Laarhoven helps to make the installation, troubleshooting, and maintenance of LiteTouch 2000® a less daunting task for the installer, presenting information, examples, and situations in an easy-to-read format. LiteTouch 2000® is a true computer-control system that reduces unsightly switch banks and bulky high-voltage control wiring to a minimum.

Van Laarhoven's efforts make LiteTouch 2000® a product to be utilized by programmers of varying backgrounds and experience levels. *Home Automation Basics II* should be a part of every electrical and security professional's reference library.

Audio Systems Technology, Level I

Handbook for Installers and Engineers

NSCA

This book is a one-stop information source for today's audio technician. It can be used as a study guide to prepare for NICET audio technician certification exams, as well as a comprehensive reference for the installer of audio systems—both out in the field and at the bench.

Designed to correspond with Level I work elements on the NICET tests, this valuable handbook presents the basics of audio installation as it is practiced in the industry today. Topics include: Basic Electronic Circuits; Basic Math; Basics of Microphones & Loudspeakers; Basic Wiring; Switches and Connectors; Codes, Standards and Safety; and Reading Plans and Specifications.

Additionally, information about getting certified by NICET is included, with tips and strategies to help with your success on the NICET exams.

Audio
320 pages • paperback • 7-3/8 x 9-1/4"

Audio Systems Technology, Level II

Handbook for Installers and Engineers

NSCA

Designed to correspond with Level II work elements on the NICET tests, this book presents intermediate level content on audio installation as it is practiced in the industry today. Some of the topics: Audio Calculations; Acoustical Measurements; Microphones, Loudspeakers and Mixers; Trigonometry and Geometry; Wiring and Cabling; Effective Business Communication; and Bench Test Equipment.

Information about getting certified by NICET is included, with tips and strategies for the test-taker.

Both Level I and Level II books are for you if:

- You want to be NICET-certified in audio systems.
- You are a developing audio installer or engineer.
- You want to enhance your knowledge of audio systems design and installation.
- You are experienced but want to brush up on intermediate-level audio.

PROMPT

Audio Systems Technology, Level III

Handbook for Installers and Engineers

NSCA

Audio Systems Technology Level III is an essential for the library of the advanced technician who has several years of job experience and an associate's degree or the equivalent. While each book in this series contains its own unique information, there is overlap from one level to the next, providing repetition on the most important, fundamental points. This intentional dovetailing also allows the entire series to be used as a systematic, progressive course of study from the basics through intermediate and advanced topics.

Theory and Design of Loudspeaker Enclosures

J.E. Benson

Written for design engineers and technicians, students, and intermediate-to-advanced level acoustics enthusiasts, *Theory & Design of Loudspeaker Enclosures* presents a general theory of loudspeaker enclosure systems. Full of illustrated and numerical examples, this book examines diverse developments in enclosure design, and studies the various types of enclosures as well as varying parameter values and performance optimization.

Topics examined in *Theory & Design of Loudspeaker Enclosures* include: The Synthesis of Vented Systems, Infinite-Baffle and Closed-Box Systems, Electro-Acoustical Relations, Reflex Response Relationships, System Response Formulae, Input Impedance, Circuit Parameters, System Parameters, Driver Parameters, Analogous Circuits, Terminology, And More.

Computer Networking for Small Businesses

by John Ross

Small businesses, home offices, and satellite offices have flourished in recent years. These small and unique networks of two or more PCs can be a challenge for any technician. Small network systems are vastly different from their large-office counterparts. Connecting to multiple and off-site offices provides a unique set of challenges that are addressed in this book. Topics include installation, troubleshooting and repair, and common network applications relevant to the small-office environment.

Guide to Webcams

by John Breeden & Jason Byre

Webcams are one of the hottest technologies on the market today. Their applications are endless and cross all demographics. Digital video cameras have become an increasingly popular method of communicating with others across the Internet. From video e-mail clips to web sites that broadcast people's lives for all to see, webcams have become a way for people to battle against the perceived threat of depersonalization caused by computers and to monitor areas from anywhere in the world. Projects and topics include picking a camera, avoiding obstacles, setup and installation, and applications.

The Complete RF Technician's Handbook, *Second Edition*

Cotter W. Sayre

This is THE handbook for the RF or wireless communications beginner, student, experienced technician or ham radio operator, furnishing valuable information on the fundamental and advanced concepts of RF wireless communications.

Circuits found in the majority of modern RF devices are covered, along with current test equipment and their applications. Troubleshooting down to the component level is heavily stressed. RF voltage and power amplifiers, classes of operation, configurations, biasing, coupling techniques, frequency limitations, noise and distortion are all included, as well as LC, crystal and RC oscillators. RF modulation and detection methods are explained in detail – AM, FM, PM and SSB – and associated circuits, such as AGC, squelch, selective calling, frequency multipliers, speech processing, mixers, power supplies, AFC, multiplex-

IC Design Projects

Stephen Kamichik

IC Design Projects discusses some of the most popular and practical ICs, and offers you some projects in which you can learn to create useful and interesting devices with these ICs.

Once you have read through this book and completed some of its projects, you will have a real, working knowledge of ICs, enabling you to design and build you own projects!

Topics include: how power supplies operate, integrated circuit voltage regulators, TTL logic, CMOS logic, how operational amplifiers work, how phase-locked loops work, and more!

Projects include: battery charger, bipolar power supply, capacitance meter, stereo preamplifier, function generator, DC motor control, automatic light timer, darkroom timer, LM567 tone decoder IC, electronic organ, and more!

Build Your Own Test Equipment

Carl J. Bergquist

Test equipment is among the most important tools that can be used by electronics hobbyists and professionals. Building your own test equipment can carry you a long way toward understanding electronics in general, as well as allowing you to customize the equipment to your actual needs.

Build Your Own Test Equipment contains information on how to build several pragmatic testing devices. Each and every device is designed to be highly practical and space conscious, using commonly-available components.

Projects include: Prototype Lab, Multi-Output Power Supply, Signal Generator and Tester, Logic Probe, Transistor Tester, IC Tester, Portable Digital Capacitance Meter, Four-Digit Counter, Digital Multimeter, Digital Function Generator, Eight-Digit Frequency Counter, Solid-State Oscilloscope, and more.

Exploring the World of SCSI

by Louis Columbus

Focusing on the needs of the hobbyist, PC enthusiast, as well as system administrator, *The World of SCSI* is a comprehensive book for anyone interested in learning the hands-on aspects of SCSI. It includes how to work with the Logical Unit Numbers (LUNs) within SCSI, how termination works, bus mastering, caching, and how the various levels of RAID provide varying levels of performance and reliability. This book provides the functionality that intermediate and advanced system users need for configuring SCSI on their systems, while at the same time providing the experienced professional with the necessary diagrams, descriptions, information sources, and guidance on how to implement SCSI-based solutions. Chapters include: How SCSI Works; Connecting with SCSI Devices; and many more.

Dictionary of Modern Electronics Technology

Andrew Singmin

New technology overpowers the old everyday. One minute you're working with the quickest and most sophisticated electronic equipment, and the next minute you're working with a museum piece. The words that support your equipment change just as fast.

If you're looking for a dictionary that thoroughly defines the ever-changing and advancing world of electronic terminology, look no further than the Modern Dictionary of Electronics Technology. With up-to-date definitions and explanations, this dictionary sheds insightful light on words and terms used at the forefront of today's integrated circuit industry and surrounding electronic sectors.

Whether you're a device engineer, a specialist working in the semiconductor industry, or simply an electronics enthusiast, this dictionary is a necessary guide for your electronic endeavors.

Electronic Projects for the 21st Century

Electronic Projects for the 21st Century

John Iovine

If you are an electronics hobbyist with an interest in science, or are fascinated by the technologies of the future, you'll find *Electronic Projects for the 21st Century* a welcome addition to your electronics library. It's filled with nearly two dozen fun and useful electronics projects designed to let you use and experiment with the latest innovations in science and technology. This book contains the expert, hands-on guidance and detailed instructions you need to perform experiments that involve genetics, lasers, holography, Kirlian photography, alternative energy sources and more. You will obtain all the information necessary to create the following: biofeedback/lie detector device, ELF monitor, Geiger counter, MHD generator, expansion cloud chamber, air pollution monitor, laser power supply for holography, pinhole camera, synthetic fuel from coal, and much more.

The Component Identifier and Source Book, *2nd Edition*

Victor Meeldijk

Because interface designs are often reverse engineered using component data or block diagrams that list only part numbers, technicians are often forced to search for replacement parts armed only with manufacturer logos and part numbers.

This book was written to assist technicians and designers in identifying components from prefixes and logos, as well as find sources for various types of microcircuits and other components. It will help readers cross reference component types to manufacturers, and also cross reference trade names, abbreviations, and part number prefixes to the manufacturer. Listings of the worldwide manufacturing and sales office addresses are provided, with a special listing of manufacturers who provide replacement devices and vendors who specialize in stocking and locating discontinued devices. There is not another book on the market that lists as many manufacturers of such diverse electronic components.

Internet Guide to the Electronics Industry

John J. Adams

Although the Internet pervades our lives, it would not have been possible without the growth of electronics. It is very fitting then that technical subjects, data sheets, parts houses, and of course manufacturers, are developing new and innovative ways to ride along the Information Superhighway. Whether it’s programs that calculate Ohm’s Law or a schematic of a satellite system, electronics hobbyists and technicians can find a wealth of knowledge and information on the Internet.

In fact, soon electronics hobbyists and professionals will be able to access on-line catalogs from manufacturers and distributors all over the world, and then order parts, schematics, and other merchandise without leaving home. The *Internet Guide to the Electronics Industry* serves mainly as a directory to the resources available to electronics professionals and hobbyists.

The Video Hacker's Handbook
Carl J. Bergquist
Electronic Projects for Video Enthusiasts

Desktop Digital Video

by Ron Grebler

Desktop Digital Video is for those people who have a good understanding of personal computers and want to learn how video (and digital video) fits into the bigger picture. This book will introduce you to the essentials of video engineering, and to the intricacies and intimacies of digital technology. It examines the hardware involved, then explores the variety of different software applications and how to utilize them practically. Best of all, *Desktop Digital Video* will guide you through the development of your own customized digital video system. Topics covered include the video signal, digital video theory, digital video editing programs, hardware, digital video software and much more.

The Video Hacker's Handbook

by Carl Bergquist

Geared toward electronic hobbyists and technicians interested in experimenting with the multiple facets of video technology, *The Video Hacker's Handbook* features projects never seen before in book form. Video theory and project information is presented in a practical and easy-to-understand fashion, allowing you to not only learn how video technology came to be so important in today's world, but also how to incorporate this knowledge into projects of your own design. In addition to the hands-on construction projects, the text covers existing video devices useful in this area of technology plus a little history surrounding television and video relay systems.

Gone are the days when electricians dealt only with wires, outlets, and switches. As new electronic devices extend their reach and influence into our daily lives, electricians are finding it necessary to adapt and improve their skills to meet the new demands. In *Electronics for the Electrician*, author Newton C. Braga gives electricians and other professionals a perfect way to do just that.

Electronic components in electric circuits and installations are becoming more common. Timers, dimmers, heater controls, intercoms, alarms, doorbells, battery chargers, emergency lights, illumination controls, air conditioners, washing machines, and electronic injection systems are all electric devices containing electronic circuits.

Until some years ago, electronics and electricity were independent fields. Electronics technicians fixed and repaired only electronic devices, concentrating their efforts in radio and TV, while electricians worked with cars, home and industrial installations, and energy distribution. They were entirely different fields. Now electricians must know how a timer or a dimmer works, because they need to know how to repair one if necessary.

Braga breaks his text into three sections:

- The Differences Between Electricity and Electronics
- Electronic Components
- Troubleshooting and Repair

Electronics for the Electrician isn't directed to all people; it's a book for electricians and other professionals—from construction engineers to architects. This book is intended to give professionals basic knowledge about electronics, in order to understand how electronic circuits and devices work in electric installations.

Newton C. Braga has written more than 50 books about electronics and electricity that have been published in his native Brazil, as well as Europe and the United States. The main training network of the Brazilian Federation of Industries (SENAI) recommended Braga's *Electric Installations For Beginners* and *The Basic Electronics Course*, published in Brazil, as basic texts in its courses.

FUN PROJECTS *for the* EXPERIMENTER

Newton C. Braga

PROMPT®
PUBLICATIONS

During more than 20 years, the author, as a collaborator with American, European and Latin American electronics magazines*, has published a large assortment of practical circuits using common parts.

Now many of those projects are included in this volume, most of which you can build in one evening. The projects range from fun types through practical types to amusement types. Of course, there are other devices that can be used to teach you something about circuits or components.

An important feature of theses projects are the Ideas to Explore, intended for students looking for projects in science or to use in practical research.

We can consider this book as a source book of the easiest and fun-to-make of the hundreds of projects created and published by the author during these last years.

But, as the projects are in a wide range of types, we should separate the electronics experimenters into two groups: the ones who want to improve or expand some other area of their electronics interest, such as computers, radio, instrumentation, audio, security and even games; and the ones who want to learn something about electronic circuits and devices or want new ideas to use in science projects.

Most of the projects described herein can be stand-alone as individual accessories; wherever possible the circuits have been designed so that they can be ganged with one or more other projects. For example, many projects of audio effects or generators can be ganged with audio amplifiers or high-power output stages.

All the projects are simple, with few low-cost components that can be made in one evening of work.

To make it easy for the reader to choose the projects we added codes after each title to indicate the kind of experimenter for whom they are intended: the code "P" (Practical) indicates a project built for practical use. The code "E" (Experimental) indicates that the project is intended for the experimenter to teach something about circuits or devices.

Of course, you can also find projects with both codes (E and P)which can either be mounted to teach something or/and be used for a practical end.

The presentations of the projects are practical. Electronics components are listed with each circuit diagram. But secondary parts such as sockets, chassis, enclosures, miscellaneous hardware and so on, are not specified, since the reader is free to choose these non-critical items according to his preferences and demands.

The manner in which the circuits work and can be modified is explained in practical terms so the reader can acquire some knowledge of practical electronics as he progresses through the book.

Although many of the projects we enjoyed constructing as they are described here, you may think of possible modifications. We just recommend that you go ahead and modify the circuits to your personal ends. There is a wide latitude in circuit modifications and most of them will be of value to the experimenter who wants to see how things work, even though each project's primary intent is for the builder who desires a functional item of equipment as the result of his work.

As the book includes easy-to-build projects, the author hopes it will help you to learn many of the fundamentals of electronics in an easy and fun way, and, if you're a student, provide a source for school projects.

Newton C. Braga

* Mini-Projects is the title of a column published by the author during several years in a Brazilian Electronics Magazine named Eletrônica Total (Total Electronics).

MICRO-POWER LED FLASHER (E/P)

A simple LED flasher can be built with a TLC7555 Timer used as a low-frequency oscillator and drive to an LED. IC1 runs in a low frequency determined by R2/R3 and C1. Frequency is in the range between 0.1 and 5 Hz but you can alter it by changing C1. This capacitor can range from 1 to 10 uF.

Duty cycle is determined by R2/R3 ratio and is important in applications where you need reduction of energy consumed. Though Figure 1 shows fixed resistors for R2 and R3, you can use trimmer potentiometers if you prefer. The potentiometers, of course, are handy for altering the frequency and duty cycle of the oscillator.

R1 values depend upon the power supply voltage. With power supplies between 5 and 6 volts, R1 is 470 ohms. With power supplies between 6 and 9 volts, R1 is 560 or 680 ohms. With power supplies in the range between 9 and 12 volts, R1 must be 1,000 ohms. The circuit drains only 250 uA from a 6-volt power supply.

Figure 1 shows the schematic diagram for the Micro-Power LED Flasher. At the heart of the circuit is IC1, a 555 timer.

Use the parts placement diagram as a guide when assembling the Micro-Power LED Flasher. Components placement, using a terminal strip as chassis, is shown in ***Figure 2***.

Take special care with positions of polarized components, such as the LED and electrolytic capacitor.

After you are sure that you have wired all the components correctly, put the batteries in the battery holder. The LED should flash.

Figure 2

Parts List — Micro-Power LED Flasher

IC1 - TLC7555 CMOS Integrated Circuit - Timer

LED1 - Common red, green or yellow LED

D1 - 1N914 general purpose silicon diode

R1 - 560 ohm, 1/4W, 5% resistor

R2 - 1,000,000 ohm, 1/4W, 5% resistor

R3 - 4,700 ohm, 1/4W, 5% resistor

C1 - 4,7 uF, 6 WVDC electrolytic capacitor

C2 - 10 uF, 12 WVDC electrolytic capacitor

B1 - 6 to 12V AA cells, 9V battery or power supply

Ideas to Explore

To learn more about the circuit and devices:

- Alter R2 and R3 (minimum values are 1,000 ohms for both) and see how the flashing rate changes. Of course, if you want, you can replace R2 and R3 with 1,000,000-ohm trimmer potentiometers.

- Explain how the astable 555 works in this circuit.

- Alter C1 in a range between 1 and 100 uF and observe flashing rate alteration. Explain what happens.

- What is duty-cycle?

Science experiments with the circuit:

- LED is a monochromatic light source. You can perform some experiments in optics using this kind of light source. Chromatic filters can be used in some experiments involving LEDs. Try to use LEDs of different colors (red, yellow, green and, if possible, blue).
- Light flashes, as the ones produced by this circuit, can be used in hypnotic experiments.
- The circuit can be used to indicate operation of other electronic devices. Wired to the power supply of a monitored device, the blinker LED will indicate its operation.

Remember that the theory in this book is specifically related to the associated experiments and projects. This book is designed as an introduction, not as an in-depth treatment of electronics. If you are interested in finding out more about the subjects touched on in this book, several texts can be found for further reading.

SET-RESET FLIP-FLOP (E)

With this project we can show how two NAND gates of a 7400 IC (TTL Integrated Circuit) can be wired to perform as an R-S flip-flop.

This circuit is a pulse-triggered flip-flop that needs negative-going pulses to be triggered. This circuit operates as follows: as we see, it has two outputs; a normal output called Q (LED1) and an inverted output called $\overline{Q}$ (LED2). When one output is 1 the other necessarily will be 0 and vice-versa because they are complementary.

The circuit has also two inputs named S (SET) and R (RESET) as shown in the schematic diagram, where the trigger signals are applied.

R input is wired to Q output and S input is wired to $\overline{Q}$ output, forming a closed-loop for the digital signals.

When a negative-going trigger pulse is applied to S input the output Q swings to the 1 state. As this output is wired to R input, the 1 state causes output $\overline{Q}$ to fall to a 0 level. But $\overline{Q}$ output is also wired to S input causing a feedback that makes its output remain at 1 also after the trigger pulse has disappeared. To trigger the flip-flop again, changing the output states, we should apply a negative-going pulse to R input. This pulse causes the output to go to 1, and as this output is wired to R input, the trigger pulse also causes the output Q to go to 0 level.

A zero in this output goes to R input, and also after the trigger pulse disappears the outputs remain in their states.

See that the circuit has two stable states, and we only can change these states with set or reset (S or R) negative-going pulses applied to its inputs.

Our project is a manually-triggered flip-flop and can be constructed wiring a switch to the R-S inputs as shown in ***Figure 1***.

Logic states are indicated by two LEDs. LED1 glows with a 1 at Q output and LED2 glows with a 1 at $\overline{Q}$ output.

The circuit must be powered by a 5-volt regulated power supply as it uses a TTL IC. Current requirements range typically from 5 to 15 mA.

Components placement on a small printed-circuit board is shown in ***Figure 2***.

Experiments like this can also be performed on what electronics experimenters call “breadboards”. These are boards on which the parts of experiments can be temporarily assembled. By using breadboards it is not necessary to

solder the components. This is why they are also called "solderless boards"

The circuit can be used to teach much about flip-flops, used in computers as counters and in memories and many other applications.

Observation: In digital electronics an electrical signal is either high or low. These two states are used to represent binary bits 1 and 0. Since digital logic ICs operate from a single-ended power supply, a high state represents a voltage near the supply voltage and a low state represents a voltage near 0V.

PARTS LIST — SET-RESET FLIP-FLOP

IC1	- 7400 TTL Integrated Circuit
LEDs	- Red, green or yellow common LEDs
R1, R2	- 330 ohm, 1/4W, 5% resistors
S1	- SPDT toggle switch

Ideas to Explore

To learn more about the circuit and devices:

- The common flip-flop is a fundamental counter circuit. Mount other units like this and use them to explain how counters and memories work in computer circuits. Each flip-flop can store a bit.

- Find the differences between R-S and J-K flip-flops and how they are used in logic circuits.

Science experiments and projects using this circuit:

- Replace S1 by a magnetic (reed) switch or a microswitch and use this circuit as a one-event memory in experiments. It can detect and memorize when a switch in an lure, alarm, or mechanical process is closed for a moment.

MINI-METRONOME (P)

Here is a dandy two-transistor metronome which you can build into a small plastic case. You can use an old nonworking transistor radio to house this gadget. In most case you can merely remove the main circuitry but retain some parts, such as the on-off volume control potentiometer, speaker and battery holder. If you have done this, you have just eliminated the following items: SPKR, S1, and B1.

The circuit can be powered with two or four AA cells and drains about 10 mA.

As soon as S1 is closed, the metronome starts clacking. By adjusting potentiometer P1 you find the "beat" or frequency of clacking you wish to set.

To calibrate, you have only to synchronize your metronome with a commercial type or any known source.

Figure 1 shows the schematic diagram for the Mini-Metronome. At the heart of the circuit are Q1 and Q2, as a two-stage direct-coupled amplifier, which allows the circuit to generate intervalled pulses.

Figure 2 shows a mechanical view of the metronome, using a terminal strip as "chassis" for the small components.

Position of the polarized components, such as C1, C2 and the transistor, should be observed in the mounting.

Figure 2

Parts List — Mini Metronome

Q1 - BC548 NPN transistor

Q2 - BC558 PNP transistor

S1 - SPST toggle or slide switch

B1 - 3V or 6V - two or four AA cells

SPKR - 4 or 8 ohm, 2 to 4-inch loudspeaker

P1 - 1,000,000 ohm potentiometer

R1 - 10,000 ohm, 1/4W, 5% resistor

R2 - 1,000 ohm, 1/4W, 5% resistor

C1 - 10 μF, 6 WVDC electrolytic capacitor

C2 - 10 μF, 6 WVDC electrolytic capacitor

Ideas to Explore

To learn more about the circuit and devices or to get better performance:

- Replace C1 by any capacitor in the range between 1 and 10 μF. Observe what will happen to the beat rate. Explain it.

- Replace transistor Q2 with a TIP32 on a small heatsink and power the circuit from a 9V or 12V power supply. You'll have extra power for your experimental metronome and can use it in larger places.

- Remove P1 and touch with your fingers the points where it was wired. Will the circuit operate? Can you explain what is going on?

Science experiments and different uses for the circuit:

- The metronome can be used in gymnastic exercises or in running to find the correct rhythm. The metronome can be housed in a small plastic box, powered by cells and easily carried with the runner.
- Biological experiments with sounds can be made with this device; experiments in animal conditioning, for example.

PENDULUM ALARM (E/P)

Any movement that swings the pendulum sensor triggers this alarm, enabling a relay.

The circuit can be used to protect cars, large objects, homes and other places as the sensor can be used to detect any movement. This device can also be used for scientific experiments, as suggested at the end of the section.

The relay can drive powerful sound systems, such as sirens, horns, lamps, etc. The circuit can be powered by a 12-volt battery (when used in cars, for instance) or a power supply. Current drain is very low (about 100 uA) when the relay is deenergized, extending battery life.

The schematic circuit of the Pendulum Alarm is shown in ***Figure 1.*** The circuit has as its heart an SCR (Silicon Controlled Rectifier), which energizes the relay when the sensor detects any movement.

A mechanical view of the circuit mounting, using a terminal strip as chassis, is shown in ***Figure 2***.

Relay coil voltage is chosen according to the power supply voltage. You can use a mini DPDT 1A Mini Relay (Radio Shack 275-249) or, for heavy loads, a 10A mini SPDT relay (Radio Shack 275-248). These relays are rated to 12 VDC and drain only 38 mA (their coil resistance is about 320 ohms). As equivalent types can be used, you should take care with terminal layout.

Reset can be made with a momentary-type switch (Push-On) wired between the SCR anode and catode, or by using the on-off switch.

Positions of polarized components, such as the SCR and diode, should be observed.

Sensor details are also given in ***Figure 2***. Notice that operation occurs when the vertical (or horizontal) bare wire touches the ring during any movement.

Ideas to Explore

To learn more about circuit and devices:

- Replace relay with a 12V x 200 mA incandescent lamp. Does the circuit work?
- Explain what D1 is doing in this circuit. Is it necessary if the relay is replaced by an incandescent lamp?
- Explain how an SCR works.

Science projects and different uses for this circuit:

- Replace X1 by a reed switch to get an alarm triggered by a magnetic sensor. You can also replace X1 by a microswitch or other kind of momentary switch.
- In biological experiments the alarm can be used to detect small movements in animal traps or cages.

- Replacing X1 by two metal wires enables the circuit to be triggered by water. Water level detectors can be made using this kind of sensor, and it can be used in many experiments and practical applications.

- Installed in your car, this circuit can be used as an alarm, driving the horn or a siren.

- By replacing X1 with a large metal plate, the circuit can be used to detect wind. Air flow can move the plate so that the bare wire touching the loop causes the alarm to trigger.

MEDIUM-WAVE RF PRESELECTOR (P)

The sensivity of most moderately-priced AM receivers is poor in the medium-wave band. Worse yet, selectivity also drops off sharply within the upper part of the band, making the receiver highly susceptible to images, noise and annoying heterodynes.

Even the best antenna and a good booster amplifier can't make up for these deficiencies in a common receiver's front end. But, using an RF preselector between the antenna and the receiver's antenna input terminals will give you real increase in the reception quality.

This circuit matches the antenna impedance with the receiver's antenna input according the frequency of the tuned station.

Figure 1 shows schematic diagram of the Medium-Wave Preselector.

Figure 2 shows an exploded view of the circuit, which can be housed in a small plastic box.

L1 is formed by turns of No. 28 enameled wire, wound on a 5/16-inch ferrite form. Taps are made each 15 or 20 turns and its number is not critical. The number of taps can be altered.

Attach your antenna and ground to the input terminals of the preselector. Tune to the desired station on your receiver, and, by choosing the best position of the alligator clip on the strip and by adjusting CV, find the best signal.

The required antenna will depend upon the station you want to tune. A random length of wire will give fairly good performance through the AM band. Antennas with lengths between 15 and 150 feet are recommended for best performance.

Ideas to Explore

To learn more about the circuit and devices:

- Explain the importance of a good ground connection in this circuit. What is the meaning of "impedance"?

- Use a new coil with 20 turns and taps every 3 turns to tune short-wave stations.

- Make a second coil (20 turns) on the same ferrite rod to plug the antenna and ground.

ELECTRONIC FISHING LURE (P)

This circuit imitates the sound of wet bugs milling about the surface to attract curious fish.

The circuit is basically a Hartley audio oscillator operating in a frequency between 200 and 2,000 Hertz. Powered by an AA cell, it can housed in a clean empty peanut butter jar with the buzzer circuitry mounted upside-down on the cover. You must be carefull not to drill in such a way as to allow water to leak through the cap. Silicon rubber can be used to close any water leak.

Capacitor C1 would give a resonant frequency of approximately 1,000 Hz, but P1 would give a wide variation in signal tone generated in the audio range.

You can also use a low-impedance earphone as a transducer, connecting it to the second coil (output) of the transformer.

To operate, unscrew the cap, throw S1 ON, put the cover back on, and drop the fish lure into the water in the vicinity of where you will be fishing. Allow 20 minutes before reeling them in. If necessary, adjust P1 to a new signal tone.

Figure 1 shows the schematic diagram for the Fish Lure. Observe that the secondary coil of the small audio transformer is not used in this circuit.

Construction details of the Electronic Fishing Lure, using a terminal strip as chassis, is shown in ***Figure 2***. The exact locations of components is not critical.

T1 is also not critical. Any 500:8 or 1,000:8 transistor transformer with center-tapped primary can be used. We can also suggest that any small transistor transformer can be experimented with.

P1 - 100,000 ohm trimmer potentiometer
R1 - 1,000 ohm, 1/4W, 5% resistor
C1 - 0.01 uF metal film or ceramic capacitor
S1 - SPST toggle or slide switch
BZ - Piezoelectric transducer or crystal earphone (Radio Shack273-073 or equivalent)
B1 - 1.5 V AA cell

Ideas to Explore

To learn more about the circuit:

- Replace BZ by a low-impedance tweeter or small loudspeaker connected to the transformer secondary coil.
- Change C1 values in the range between 0.001 and 0.22 uF. Observe what hapens with tone pitch. A higher-value capacitor gives a lower tone.
- The circuit also operates from a 3V or 6V power supply without making any changes.

Science and different uses for the device:

- You can make several experiments in animal conditioning, including the ones that live in the water. Try to alter the RC network (P1, R1 and C1) to get tones of different pitch. Try to use diodes, small transformer coils and other passive components in this experiment. Sounds like those produced by songbirds can be generated with a few components arranged in the correct way. Can you discover how to do it?

- Remove the piezoelectric transducer and wire electrodes in its place. The device can be use as a nerv stimulator. Experiments with animals and plants can be made. What physiological functions are affected? Can circadian rhytms or internal biological clocks be affected by continuous exposure to sounds?

- Electrodes placed into water and wired in place of the transducer will produce a current field. You can perform interesting scientific work relating how fish and other water beings react to the current field. Can the current fields affect physiological functions? If you experiment with plants, select a fast growing house plant.

FREE-POWER AM RECEIVER (P,E)

This project uses a strange way to get its power. It uses power "extracted" from the tuned station to give to the amplifier transistor. With a reasonably strong applied modulation envelope, this type of detector produces a strong demodulated output.

Naturally, the closer you are to a strong station, the more current your radio will be able to supply.

For best results, you must do everything possible to deliver a strong signal to the transistor detector. We recommend a good antenna and ground, the latter preferably being made to a water pipe or solid external ground composed of a pipe driven at least 5 feet into moist earth. This is important for ensuring maximum signal pickup.

If you have plenty of space available, the longer the antenna (up to about 100 feet), the better the results.

Figure 1 shows the schematic diagram of the Free-Power AM receiver. Observe that the heart of the circuit is a germanium transistor that works as a detector and audio amplifier.

Components placement on a terminal strip used as a chassis is shown in ***Figure 2.*** The terminal strip can be fixed on an experiment board that can be constructed using some common tools and materials.

Q1 is any germanium transistor, such as GE-2 or 2N107. You can find germanium transistors in old nonworking AM transistor radio receivers. Nonworking AM radios can also supply the variable capacitor and the loopstick (ferrite rod).

Earphone must be a high-impedance crystal type. Low-impedance earphones don't function in this circuit.

Ideas to Explore

To learn more about the circuit:

- Replace L1 by 15 turns of No. 28 wire, wound on a ferrite rod, to tune short-wave stations.
- By replacing Q1 with a germanium diode and removing R1 and C1 you'll transform this radio into a simple crystal set.
- Alter R1 in a range between 4,700 and 47,000 ohms to get better performance, depending on the transistor used.
- Replace the transistor with a silicon type, such as the BC548. What will happen with sensivity?

Science project involving the circuit and uncommon uses:

- Explain how crystal sets function and tell about radio history. If you are interested in more radio history, several texts can be found in the public library.
- If you want to learn more about radio receivers, try to find information about heterodyne and super-hereterodyne types.

DUAL-LED FLASHER (E,P)

This circuit uses a one-gate oscillator, with a 4093 CMOS IC, to produce a 50% duty-cycle flasher in two LEDs or a bi-color LED. The circuit can be powered by a 3 to 12-volt power supply and is useful in several experiments and practical applications. You can use it as part of alarms, warning systems, games, toys, and some scientific experiments, as we will describe here.

R2 and R3 values depend upon the power supply voltage, according to the following table:

Power Supply	R2, R3
3 Volts	220 ohms
5 Volts	330 ohms
6 Volts	470 ohms
9 Volts	820 ohms
12 Volts	1,000 ohms

For more output you can use a transistorized output stage driving incandescent lamps. Experiments to observe light effects on animals and plants can be conducted with this circuit.

P1 and C1 determine flash rate. Flash rate can be adjusted by P1, but C1 also can be altered in a large range of values, according to the application you intend for the device.

Schematic diagram for the Dual-Led Flasher is shown in ***Figure 1***. One gate of a 4093 IC is used as oscillator and the other two are used as inverters.

Components placement on a PC board is shown in ***Figure 2***. You can also use a breadboard or solderless board to mount it as an experimental circuit.

Position of the polarized pieces, such as LEDs, eletrolytics and IC, should be observed.

P1	- 1,000,000 ohm potentiometer
C1	- 1 uF, 25 WVDC electrolytic capacitor

Ideas to Explore

To learn more about the circuit and devices:

- Replace C1 with capacitors in the range between 1 and 47 uF. Observe how higher values alter the flash rate.

- Infrared LEDs can be used in some experiments. No change in the original circuit is necessary.

Science and different uses for the circuit:

- Remove P1 and R1 and wire at this pont a touch sensor or electrodes. You can control the flash rate by touch. A bio-feedback device can be made this way.

- By wiring the IC”s pin 1 to an external circuit, the flasher can be controlled by a logic level. CMOS circuits can be used to control the flasher.

- Mount the LEDs in place of the lenses of a set of eyeglasses. The flash rate can be adjusted to make an hypnotic or relaxing effect. Combine this with a touch sensor and you have an uncommon bio-feedback device. You can also use this circuit to make experiments in circadian rhythms or internal biological clocks, determining how they can be altered by light pulses. Various theories have been proposed about this subject.

- Psychiatrists are using phototherapy to help some patients. Can you find some application for the circuit in this field?

- P1 also can be replaced by resistive transducers, such as LDRs or NTCs, to give a light- or temperature-dependent flash-rate circuit. Experiments can be made with conductivity of materials by connecting probes in series with R1. Replace P1 with the probes in this case.

6V X 1A POWER SUPPLY (P)

In order to perform experiments and projects involving electricity you will need a source of voltage. Voltage requirements for common projects, such as the ones in this book, depend upon their applications, and typically range from a few milliamperes to one or two amperes.

Instead of using a battery you can use a circuit called a *power supply*.

The power supply we show here can be used to provide 6V x 1A regulated output to the experimental and practical circuits described in this book. The output voltage is fixed by the IC.

Figure 1 shows the schematic diagram for this power supply. IC1 is a voltage regulator, #7806. The "06" indicates that it is a 6-volt regulator.

Figure 2 shows the components layout, using a terminal strip as chassis.

The complete project can be assembled in a small plastic box. The integrated circuit should be mounted on a heatsink. You can also add an LED in series with a 470 ohm resistor, wired in the output of the circuit to indicate that it is on.

External circuits can be connected to the power supply with alligator clips.

Position of the polarized pieces, such as diodes, the IC, and electrolytic capacitors, must be observed.

The transformer isn't a critical part of this project. Types with a secondary coil ranging from 7.5 to 12 volts and currents between 500 mA and 1A can be used.

C1 - 1,000 uF, 25 WVDC electrolytic capacitor
C2 - 10 uF, 12 WVDC electrolytic capacitor
S1 - SPST switch

Ideas to Explore

To learn more about the circuit or alter the performance:

- Replace IC1 by a 7805, 7809 or 7812 if you want a 5V, 9V or 12V power supply. You may also have to change the transformer with a 117:15+15V using a 7812.
- Explain how the circuit works.
- What is the difference between an AC and a DC current?

Science and uncommon applications:

- This power supply can be used in chemical experiments, such as the ones that involve current flow through substances. Experiments involving electrolysis and electroplating are two that can be suggested. A variable wound-wire potentiometer (100 ohms, 5 watts) should be wired in series with the power supply output to limit current flow through the load. You can also use the Light Dimmer described in this book for this task.

- 6V, 200 mA small incandescent lamps can be supported by this power supply. These lamps are excellent light sources to work with microscopes.

- Small motors and lamps in experiments involving physics, mechanics and robotics can be powered from this power supply with advantages. You don't have to spend a lot of money on cells or batteries.

- All circuits described in this book which require a 6V supply can be powered by this power supply.

- The circuit can be used as an excellent power adapter for your 6V equipment, such as small radios, calculators, etc.

- 6V lamps can be used in experiments involving plant growth. Select a fast growing house plant and use a darkroom or cardboard box to cover them. Lamps with colored filters can be used in an experiment involving growth and development.

- Circadian rhythms can also be studied using animals or plants. Lamps can be powered on at night and off at day. What physiological functions could be affected?

INSECT REPELLENT (P)

Some continuous sounds can repel insects (and also attract). The frequency and intensity depends upon the application and type of insect and can be found through experimentation.

The circuit shown here generates a continuous sound that can be used to repel (or attract) some types of insects, or in scientific experiments involving animals.

Our insect repellent can be powered by 9V batteries, two AA cells or four AA cells, and its low current requirements will extend the life of those cells or batteries.

Figure 1 shows the schematic diagram of the Insect Repellent. The heart of the circuit is a 7555 IC, a CMOS timer wired as an audio oscillator and driving a piezoelectric transducer.

The components placement on a homemade printed-circuit board is shown in ***Figure 2***. Exact placement is not that critical.

All the components and the power supply can be housed in a small plastic box. Transducer BZ is a crystal earpiece or a piezoelectric transducer, such as the Radio Shack 273-073.

Position of the polarized pieces, such as C2 and the power supply, must be carefully observed.

Using the insect repellent is very easy. You only need to adjust the trimmer potentiometer P1 to produce a sound with the same pitch as the insect you intend to repel. Experimentation should be made until you find the best sound to repel a specific insect.

Ideas to Explore

To learn more about the circuit or get better performance:

- Powerful output can be obtained with a transistorized output stage as shown in ***Figure 3***. The power transistor should be mounted on a heatsink. The transducer is a low-impedance loudspeaker ranging from 4 to 8 ohms.

- Experiments with ultrasound can be made with this circuit: reduce C1 to 1200 pF and use a piezoelectric tweeter as transducer. Remove the small transformer used in these tweeters and plug the transducer directly to the circuit output. Outputs in frequencies as high as 40,000 Hz can be produced by this circuit.

- Explain how sounds can be produced by electronic transducers such as the one used in this project.

- What are ultrasounds?

Science and different applications:

- Of course, you can test the real effects of this device on several kinds of insects. An attractive biological experiment can be conducted based on this circuit.

- Effects of sounds on plant growth or development can be conducted using this circuit. Can sounds (or ultrasounds) alter the circadian rhythms of plants and insects?

- The continuous tone produced by this circuit can be used in alarms or warning systems. Mice and other small animals are repelled by powerful ultrasounds.

- Replace R2 by an LDR. The circuit now becomes a light-dependent oscillator. Experiments with light and sounds can now be conducted using the device.

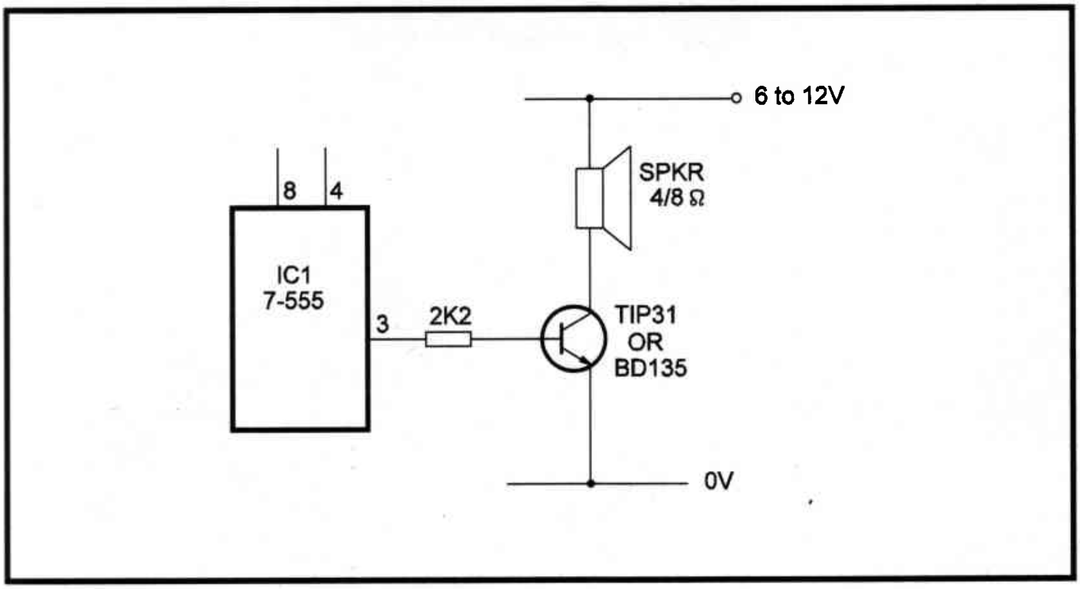

Figure 3

ULTRASONIC GENERATOR (E/P)

Dogs, mice, bats and other animals can hear sounds with frequencies up to 40,000 Hz. There are several kinds of insects that can also hear or react to these sounds. The circuit we propose here produces a continuous sound emission in frequencies above the human limit, or a range between 18,000 and 40,000 Hz. These sounds are called ultrasounds and can be used in several experimental and practical applications.

The device we describe here can be used to scare dogs and other animals, in biological experiments, and many other interesting applications.

The recommended piezoelectric transducer has its maximum output power between 700 and 3,000 Hz, but it also will operate at higher frequencies emitting less power.

The recommended power supply is four AA cells or a 9-volt battery.

Our project runs between approximately 18,000 and 40,000 Hz, but you can easily alter this range by changing C1, in a range between 470 pF and 0.001 uF. Frequency can be set by P1 in the range determined by C1.

Remember that the 4093B IC will oscillate in frequencies up to 500 kHz.

The complete circuit of the Ultrasonic Generator, using the four gates of a 4093B integrated circuit, is shown in ***Figure 1***.

Components placement on a printed-circuit board is shown in ***Figure 2***.

The circuit can be housed in a small plastic box and the transducer will be fixed in the front panel.

Take care with the position of the polarized parts, such as the transistor, electrolytic capacitor and power supply.

For continuous operation, Q1 should be mounted on a heatsink.

The transformer is not a critical part. Any transformer with a secondary coil ranging from 100 to 500 mA can be used in this project.

Ideas to Explore

To learn more about the circuit or to get better performance:

- You can replace the piezoelectric transducer by a common tweeter. Remove T1 and BZ and place the tweeter between S1 and Q1's collector. Can you measure the generated ultrasound power?

- The circuit can also generate sound in the audible range. Replace C1 by a capacitor in the range between 0.02 and 0.1 uF.

- Explain ultrasounds and how they are produced by electronic transducers.

- What is a piezoelectric material?

Science and different applications:

- Several experiments can be made using ultrasounds. You can experiment with dog conditioning. Using this oscillator you can call a dog using an inaudible sound! (inaudible to humans)

- Choose a capacitor between 0.01 and 0.047 uF to produce sounds both in the audio range and ultrasound range. You can now conduct experiments to determine the exact upper-limit frequency heard by humans. You also can conduct experiments with animals. It will be important to have a frequency counter on hand to do this work.

- Replace BZ by electrodes. The circuit will generate a high-voltage output that can be used in nerve stimulation. Use a 10,000 ohm potentiometer to adjust output voltage at this point. Pulses can reach peaks as high as 400 volts.

- To get pulses (for nerve stimulation and other experiments) you only have to replace C1 with a 1 uF capacitor and P1 with a 1,000,000 ohm potentiometer. Pulses in the rate range between 0.1 per second to 10 per second can be generated with this change.

- This circuit can also be used as a fluorescent lamp inverter. A common fluorescent lamp (4 to 20 watts) in place of the transducer will glow, even one that is weak enough to not function on the AC power line.

DC LAMP DIMMER (E,P)

This circuit can be used to control the amount of current in an incandescent lamp and also a DC motor. If you change the amount of current through a lamp you change its brightness. And if you change the amount of current through a DC motor you change its speed. Input voltage can range from 6 to 12 volts and current drain in the output is up to 2A. You can also use this circuit in the output of a 6V or 12V fixed power supply, converting it into a variable 0 to 6 volt or 0 to 12 volt supply.

The power transistor should be mounted on a heatsink. The circuit can be housed in a small plastic box and the heatsink with the transistor fixed on the outside.

The circuit can be used to control brightness of a car's panel lamps and in robotics to control DC motor speed along a wide range of values. Also, several experiments involving current flow control can be performed using this circuit.

The circuit acts as a variable resistor or rheostat with the principal current flowing through the transistor and the control current flowing through the potentiometer. Current through the potentiometer is only a few milliamperes.

The schematic diagram of the DC dimmer is shown in ***Figure 1***. Q1 is an NPN power transistor and the principal component used in this project.

Components layout is shown in ***Figure 2***. The transistor does not show on the heatsink, however.

Equivalent transistors can be used, but take care with the maximum current they can control. Types such as TIP31 and TIP41 can be used to control lamps up to 2 amperes. Also, a further modification in R1 value must be made to ensure that, when P1 is set near its minimum value, that current is flowing through the lamp.

If equivalent transistors are used, take care with their terminal positions, as they can be different.

Ideas to Explore

To learn more about the circuit or to get better performance:

- You can use a PNP power transistor, inverting input polarization. Explain why this circuit can only control DC currents.

- A Darlington transistor can be used to reduce current flow through the potentiometer. Replace P1 with a 100,000 ohm common potentiometer and R1 with a 10,000 ohm, 1/4 watt resistor when using a Darlington power transistor. TIP110 can be used in this case.

- What is a rheostat?

Science and uncommon applications:

- You can use this circuit to control brightness of microscope light sources. A 6V lamp can be used for that task and this circuit will be wired between the lamp and a 6V power supply. The 6V regulated power supply described in this book is ideal for this application.

- Experiments in electrolysis and electroplating can be current-flow controlled by using this circuit.

- This circuit can be used to control small motors in robotics or in physics experiments.

- The amount of current in current fields can be controlled by using this circuit and a DC power supply. Experiments involving electrotropism can be attempted. Try to put plants within a coil to observe the influence of the magnetic field on their growth and development. Remember that there is a magnetic field around a coil of wire that is carrying a current.

Figure 3 shows how this experiment can be arranged.

The coil is formed by 10 to 50 turns of common No.18 to 22 wire around a cardboard box or wood form. An ammeter in series with the coil circuit can be used to control the amount of current used in the experiment.

Remember that too much current will cause the coil and the transistor to overheat. It is a good idea to add a lamp in series with the coil circuit. The lamp will add resistance to the coil circuit, reducing current flow to a safe level.

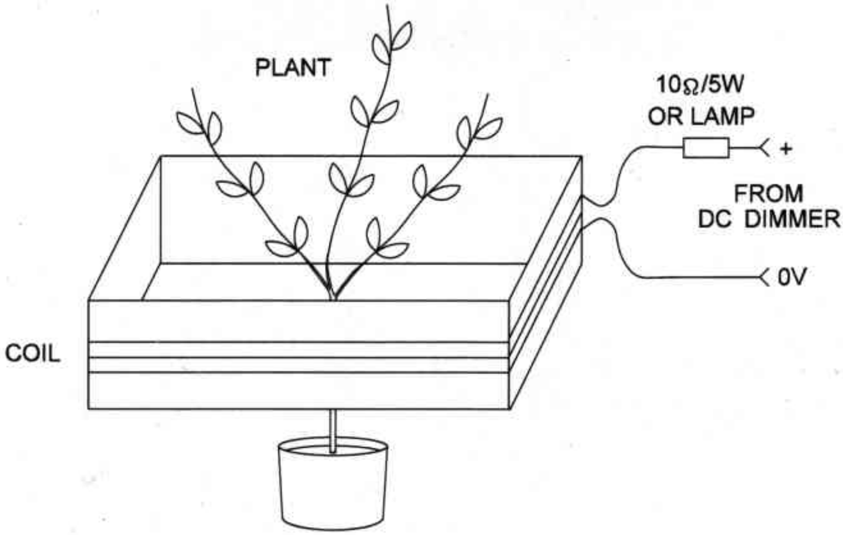

Figure 3

AUDIO OSCILLATOR (E)

This low-power experimental oscillator can generate audible signals in the range between 100 and 2,000 Hz, driving a small loudspeaker or a low-impedance earphone. The circuit can be powered by 2 two or four AA cells or a fixed 6 volt power supply. Current requirements for this circuit depend upon the power supply voltage and the loudspeaker impedance and range typically from 10 to 300 mA.

Potentiometer P1 adjusts the operating frequency and can be set within a large range of values. Potentiometers up to 1,000,000 ohms can be used, changing the frequency range lower limit to about 10 Hz.

C1 can also be altered, and values between 0.01 and 0.22 uF are suitable for experimentation. Large C1 values will produce frequencies in the lower part of the range.

The circuit can be used as part of alarms, games, toys and to learn more about transistorized oscillators.

Figure 1 shows the schematic diagram of the Audio-Oscillator. Q1 and Q2 form a directed-coupled amplifier and R1/C1 is the closed loop that takes the signal back from the output to the input.

Figure 2 shows the layout of the components, using a terminal strip as chassis. All the components and power supply can be housed in a small plastic box.

The key is a telegraph homemade-type switch, but you can also use an SPST toggle or slide switch for continuous operation. A key is recommended if you want to use the oscillator as a Morse Code sender in demonstrations or practice. You can wire the points A and B to the contacts of a relay to use the circuit as part of an alarm.

Parts List — Audio Oscillator

Q1 - BC548 general purpose NPN transistor

Q2 - BC558 general purpose PNP transistor

SPKR - 4 or 8 ohm small loudspeaker

K - Telegraphic key - see text

B1 - 3 to 6 volts - two or four AA cells

R1 - 10,000 ohm, 1/4W, 5% resistor

R2 - 1,000 ohm, 1/4W, 5% resistor

C1 - 0.047 uF metal film or ceramic capacitor

Ideas to Explore

To learn more about the circuit or to get better performance:

- Change C1 for a capacitor in the range between 0.01 and 0.22 uF. The frequency range of the produced tone will be altered. With 0.01 uF or lower values for C1, the circuit will produce ultrasounds. Use a tweeter or a piezoelectric transducer in this case.

- Replace Q1 with a TIP32 or TIP42 and power the circuit with a 12 volt supply. You'll get much more power in the output.

- Explain why oscillators need a closed loop to the signal to work.

Science projects and other applications:

- Experiments in acoustics can be made with this device. The circuit can produce any tone between 10 and 20,000 Hz, and even higher.

- A telegraph station can be simulated with this circuit. You can find Morse Code in any book about telegraphy.

- By replacing K with a reed swich wired to points A and B, the circuit will operate as an alarm.

- Experiments involving conductivity of materials can be made with probes plugged to points A and B.

- Connect resistive transducers as LDRs and NTCs at points A and B to get a light-dependent or temperature-dependent oscillator.

- Using two metal rods as sensors, the circuit can be use as a lie detector or bio-feedback device. Replace C1 with a 0.22 or 0.47 uF capacitor and adjust P1 to get separated pulses at the speaker. The pulse rate will be altered when the skin conductivity of the interrogated person changes while in a state of strain due to a lie or stress.

- A 117V—6V x 250 mA transformer can replace SPKR to produce high-voltage pulses in nerve stimulation experiments. The generated pulses can reach voltages as high as 400Vpp.

- Experiments in animal physiology can be conducted using sounds or high voltage as described in other projects. Growth of plants submitted to high-power sounds or high-voltage fields can be observed using this circuit with practical experiments.

- AC fields can be generated by replacing the speaker with a 20-turn coil. The plants or animals can be positioned within the coil's electric field. See the same experiment using the DC Dimmer for coil and experiment details.

AUDIO SWITCH (E/P)

This audio controlled relay has a large number of applications and is interesting to the experimenter who wishes to explore the working universe of relays and audio or sound controlled circuits.

An audio signal in the amplitude range between 1 Vpp and 5 Vpp triggers the relay, powering on the device, wired between points A and B.

Relay value is determined by power supply voltage. For a 12 volt power supply you must use a 12 volt relay. Current drain depends upon the power supply voltage and also the relay used. Using a 12V x 38 mA (Radio Shack 275-248) relay, the current drain is low enough to allow the use of common cells in the power supply.

C1 can range between 0.01 and 1.0 uF, and determines the sensitivity of the circuit in the audio range. Large values give more sensitivity at low frequencies.

This circuit has a high-impedance input and needs a strong audio signal to operate.

Figure 1 shows the schematic diagram of the Audio Switch. Observe that the heart of the circuit is a common general-purpose NPN transistor that acts as a DC amplifier.

In ***Figure 2*** we show layout of components for this project. The components can be soldered on a terminal strip used as chassis. The terminal strip can be fixed on a wooden board.

Position of the polarized components, such as the diodes, power supply and capacitor C2, must be observed.

To use this audio relay you have to wire ponts A and B to the output of an audio amplifier (minimum power required is 5 watts) and adjust the volume control for best operation.

A small transistor output transformer should be used to operate the relay with low-impedance signals, such as the ones from the output of audio amplifiers.

R_x depends on the output power of the amplifier and is given below:

Output Power	R_x
0 to 1 watt	-
1 to 10 watts	47 ohms, 1/4 watt
10 to 25 watts	100 ohms, 1/4 watt
25 to 50 watts	220 ohms, 1/2 watt

Parts List — Audio Switch

Q1	- BC548 general-purpose NPN silicon transistor
D1	- 1N914 general-purpose silicon diode
D2	- 1N4002 silicon rectifier diode
K1	- 6V or 12V relay - see text
R1	- 10,000 ohm, 1/4W, 5% resistor
C1	- metal film or ceramic capacitor - see text
C2	- 100 uF, 12 WVDC electrolytic capacitor
B1	- 6V or 12V cells, power supply or battery

Ideas to Explore

To learn more about the circuit and devices or to get better performance:

- Replace Q1 with a Darlington transistor (such as a BC517) and resistor R1 with 100,000 ohms. The circuit will increase in sensitivity.
- Explain how C1 functions in this circuit.

Science and different applications:

- Connect the circuit to an audio amplifier output, with a microphone plugged to the amplifier input. You'll have a sound-operated switch.
- This circuit with a microphone and an audio amplifier can be used to close a trap with sound activation or to activate a recording with sounds.

You can also use it to photograph an explosion or the crash of an object by triggering a flash with the produced sound.

- The audio output of a multimedia system in a computer can be used to control external devices with this circuit.

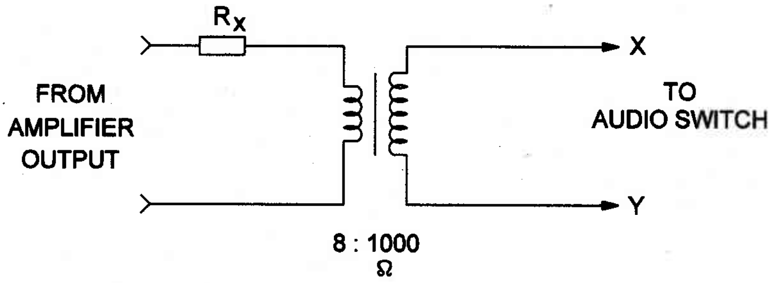

Figure 3

6 VOLTS FROM 12V BATTERIES (P)

With this adapter you can power 6 volt (up to 1A) devices, such as recorders, CD players, calculators, radios, battery chargers, etc., from your car battery. The current adapter is plugged into the vehicle lighter socket and is small enough to be housed in a very compact plastic box.

Only four components are used. The IC determines the output voltage and should be mounted on a heatsink. Capacitors are polarized components, so you must observe their position when mounting. The fuse is very important in order to protect the device and car wiring against shorts.

Output varies according to the device you are applying power to. DC extension cables with plugs to fit the device to be powered should be used. Take care with the output poles. Check if your device has a positive or negative pole in the central terminal.

The schematic diagram of the 12V to 6V x 1A converter is shown in ***Figure 1***. The principal component is IC1, a 6V voltage regulator that operates with input voltages ranging from 8 to 35 volts.

Components layout is shown in ***Figure 2***. All the components can easily be housed in a plastic box.

The integrated circuit can be changed to alter the output voltage. You can use a 7809 for 9V x 1A output or a 7805 for 5V x 1A output.

It is very important that no parts of the components used in this circuit touch one another. The IC has short-circuit and thermal protection.

IC1	- 7806 Integrated circuit
C1	- 1,000 uF, 16 WVDC electrolytic capacitor
C2	- 100 uF, 12 WVDC electrolytic capacitor
F1	- 2A fuse

Ideas to Explore

To learn more about the device or to get better performance:

- Replace the integrated circuit (IC1) with a 7805 or 7809 to get output voltages of 5V and 9V.
- Explain the difference between this linear voltage regulator and a switch-mode regulator used in computer power supplies.
- This circuit can also be used in nonregulated power supplies to get a regulated 6V x 1A output.
- It's possible to get a negative regulated power supply by replacing the 7806 with a 7906 IC. Do a search for information about this change in the project.

Science projects and uncommon uses:

- You can use this downconverter to power four AA cell-powered circuits from a 12V battery in science experiments.
- 6V lamps used as light source for microscopes can be powered from the car battery using this downconverter. Fieldwork using a microscope can be conducted using this circuit.

ONE-COMPONENT TRANSMITTER (E)

Here is a project that should be constructed by those with no patience for electronics building. Only one component is used to build a complete wireless transmitter!

Of course, this is the simplest way to generate radio signals. It is a CW (continuous wave) transmitter and is powerful enough to plunk down a signal anywhere on the 550 kHz to 7 MHz band.

The fundamental frequency depends upon power supply voltage and is in the range between 100 kHz and 1 MHz, but there are strong harmonics reaching up to 7 MHz.

Figure 1 shows the schematic diagram of this simple tramsmitter. As you can see, we have only one component: a 4049 CMOS IC that is formed by six inverters. In this project only five inverters are used.

The circuit is powered from AA cells or battery, and current drain is very low.

As an experimental project you can place the IC on a universal solderless board. The antenna is a single wire 2 to 5 feet long.

A common AM (medium wave or short wave) receiver is placed near the transmitter. A signal can be tuned in from distances up to some feet away.

There are two ways to tune the transmitter, shown in ***Figure 2***.

In the first case, as the frequency is voltage-dependent, we change the power supply voltage. Use a 12 volt power supply and adjust the voltage in the IC with P1. In the second case, we include a variable capacitor in the feedback loop to alter the frequency.

Parts List — One-Component Transmitter

Ideas to Explore

To learn more about the circuit and device:

- Explain how radio signals are generated and why we don't need a tuned circuit.
- Why should an even number of gates be used in this circuit? Will an odd number work?
- Why can you tune in the signals on more than one point of the dial?

Science projects:

- Send telegraph signals through a wall using this circuit as transmitter and an AM radio as receiver.
- Explain how computer circuits can generate radio signals (noise), using this circuit as an example.

WIRELESS FM TRANSMITTER (E/P)

These circuits have always been popular for both utility and entertainment purposes.

The FM transmitter described here is built with few components to save space and cost. The circuit has only one transistor and is powered by two or four AA cells.

The broadcasting frequency of the unit, in the range between 88 and 108 MHz (FM band), is determined by L1 and the variable capacitor CV (a 20 or 30 pF trimmer capacitor). L1 consists of four turns of No. 22 wire, wound in a single close-spaced layer on a 1/2-inch form. The coil is center tapped where it is wired to the antenna terminal.

Any piece of stiff wire will serve as the antenna and will give good coverage. For better operation, antenna length should be between 5 and 15 inches.

Try out your unit at any convenient dead spot on the the FM band. Adjust CV to the best signal. The signals can be tuned in distances up to 150 feet.

A schematic diagram of the FM transmitter is shown in ***Figure 1***. Only one transistor as used as a high-frequency oscillator. Any small RF NPN transistor can be used for the task.

Components placement on a printed-circuit board is shown in ***Figure 2***. Capacitors are critical components and should be the types indicated in the parts list. Don't use metal film capacitors instead of the ceramic capacitors which are called for in the parts list.

You can also use a terminal strip as chassis as shown in ***Figure 3***, but keep all the component terminals and wiring short to avoid instability.

The circuit can be housed in a small plastic box along with the power supply. Avoid the use of metal boxes to house the circuit.

Take care with position of the polarized pieces, such as the electret microphone, electrolytic capacitor and power supply.

Figure 3

Place the circuit inside a false book on a desk to pick up conversations.

- Explain how the transmitter works.
- What are radio waves or electromagnetic waves?
- What is Frequency Modulation (FM) and Amplitude Modulation (AM)? Explain the differences.

Science projects using this transmitter:

- The transmitter can be used to pick up remote sounds. You can fix it in animal pens or jails to monitor them remotely.
- The mike can be placed in the focus of a parabolic reflector to concentrate sounds. Birds and other animals in the forest or other places can be heard using this system, as suggested in ***Figure 4***. An interesting study can be made involving local songbirds.
- You can use this transmitter for an experimental broadcast in your school. However, ***don't use long antennas because FCC rules are severe regarding strong illegal radio emissions in the FM band.***

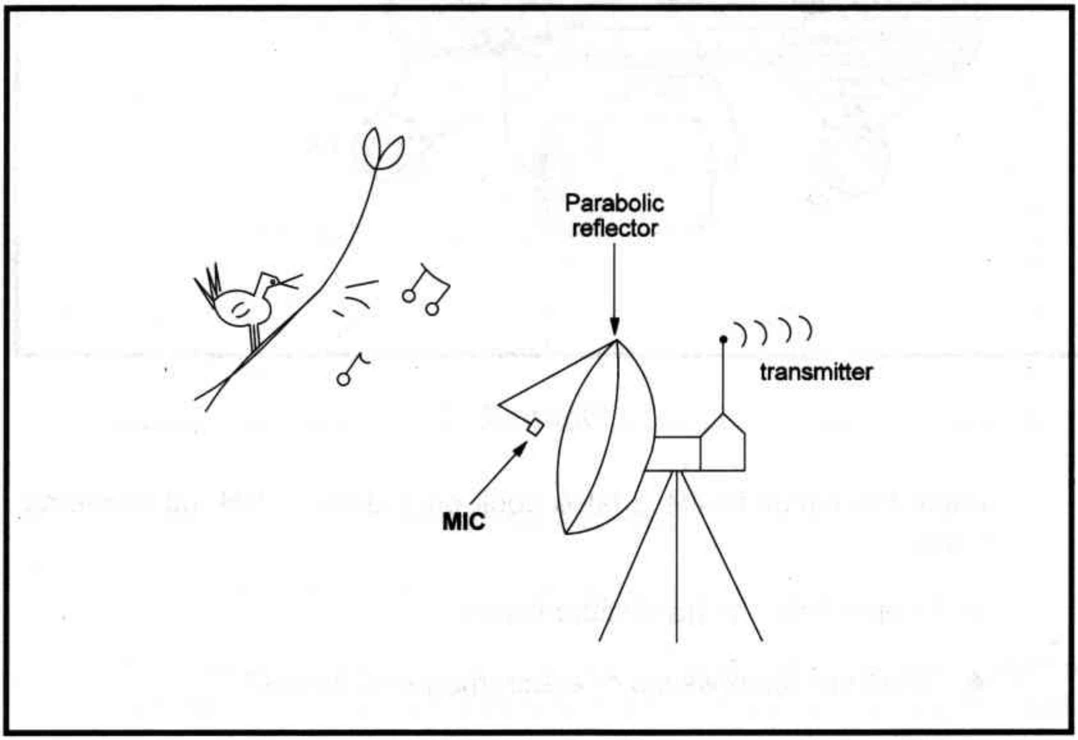

Figure 4

HIGH-POWER AUDIO OSCILLATOR (E)

This high-power version of an audio oscillator produces a strong audible tone using a piezoelectric transducer. All four gates existing in the 4093 IC are used in this project to drive the transducer with a good audio signal.

The circuit can be used in alarms, toys, as a standalone project to teach about oscillators specifically, or in experiments using continuous sounds in the frequency range between 100 and 10,000 Hz.

The recommended piezoelectric transducer emits maximum output power between 700 and 3,000 Hz, but it will also operate in other frequencies with less power.

Power supply voltage range is between 5 and 12 volts. Current requirements depend upon the power supply voltage, ranging from 10 to 50 mA typically.

P1 adjusts the tone frequency. C1 can be altered within a large range of values as indicated in the schematic diagram, shown in ***Figure 1***.

Components placement on a printed-circuit board is shown in ***Figure 2***. You can also mount the circuit using a solderless board for experimental applications.

All the components and the batteries (if used as power supply) can be housed in a small plastic box.

BZ can be replaced with a common piezoelectric tweeter. But, in this case, you should open the tweeter and remove the small transformer from inside it. Then the output of the circuit should be connected directly to the small piezoelectric transducer.

P1	- 100,000 ohm potentiometer
R1	- 10,000 ohm, 1/4W, 5% resistor
C1	- 1200 pF to 0.047 uF ceramic or metal film capacitor

Ideas to Explore

To learn more about components and devices:

- This circuit can also produce sound in the ultrasound band. Using a 1,200 pF capacitor for C1, the range will reach an upper limit of about 100,000 Hz.

- Explain how a push-pull output stage operates.

Science and uncommon applications:

- This circuit can be used for animal conditioning or in experiments involving sounds.

- By replacing P1 with sensors, such as LDRs (Light Dependent Resistors) or NTCs (Negative-Temperature Coefficient resistors), tone frequency will be light-dependent or temperature-dependent.

- By replacing P1 with touch sensors or electrodes, we can use the circuit as lie detector or bio-feedback devices. The sound pitch will depend upon skin resistance.

- The circuit can also be used as a fish attractor or in experiments involving water animals and sounds. Replacing BZ with wires immersed into water will generate electric current fields for experimental works involving the influence of these fields on fish or other beings.

- Some animals, such as mice and rats, are scared off by ultrasounds. The circuit can be used in experiments to determine the frequencies that are more effective for this task.

See other projects involving sounds for new ideas to explore.

TIMER (E/P)

Small home appliances and circuits can be turned on after a time delay ranging from seconds to minutes using this simple timer. School and hobbyist experiments can be time-controlled by using this circuit.

The unit has a constant-current source to charge C1. C1 and P1 adjust the time range. You can alter C1 within a range of 100 and 1000 uF to change the time range.

Using a 1 ampere relay you can control AC loads up to 100 watts wired to the 117 VAC power line.

To operate the unit, connect the load to the relay contacts (points A and B, used as a switch) and adjust P1 to the desired time delay. Press S2 do discharge C1 completely . Then close S1 to start. After the adjusted time delay, the relay will close, and the load will be powered ON.

Conversely, by using the NC (Normally Closed) contacts of the relay you can turn a device OFF after the adjusted time.

To use the unit again you must press S2 to discharge C1 before starting.

Figure 1 shows the schematic diagram of the timer. Observe the different components used in this project: a unijunction transistor (UJT) and an SCR (Silicon Controlled Rectifier).

An mechanical view is shown in ***Figure 2,*** using a terminal strip as chassis. All the components and power supply can be housed in a small plastic box. Take care with positions of critical components, such as the UJT, SCR, diodes and electrolytic capacitors.

The relay depends upon the power supply voltage and voltage drop through the SCR. This drop is about 2 volts, so you need to use 6 to 7.5-volt relays with a 9-volt power supply.

The SCR needn't be mounted on a heatsink, as the current drain is low.

Parts List — Timer

Q1 - BC548 NPN general-purpose silicon transistor

Q2 - 2N2646 unijunction transistor

SCR - TIC106 silicon controlled rectifier

D1, 2 - 1N4002 silicon diodes

R1 - 47,000 ohm, 1/4W, 5% resistor

R2 - 120 ohm, 1/4W, 5% resistor

R3 - 100 ohm, 1/4W, 5% resistor

P1 - 100,000 ohm potentiometer

C1, 2 - 100 uF, 12 WVDC electrolytic capacitors

K1 - Relay - see text

S1 - SPST slide or toggle switch

S2 - Normally Open momentary switch

B1 - 9V - six AA cells

Ideas to Explore

To learn much about circuit and devices or to get better performance:

- Explain how a constant-current source operates.
- Explain how a UJT and SCR operate.
- Alter C1 to get higher time delays. Try values up to 1,000 uF.

Science projects and uncommon uses for this device:

- All experiments that need time-delay control can use this device, as long as the time delay needed falls in the range of this timer (between a few seconds and minutes). Use a common watch as reference to make a scale for the potentiometer.
- The circuit can be used to activate dangerous experiments with a safe time-delay allowing the experimenter to reach safe distance.
- Traps can be armed after a time-delay, so the experimenter can avoid the trap himself.
- Chemical processes can be controlled using this timer. Any audio oscillator described in this book can be use as warning circuit when wired to the relay output.

MICRO AM RADIO (E/P)

This micro AM radio will tune strong stations in the frequency range between 530 and 1,600 kHz.

The circuit uses only one transistor as the amplifier and with a transformer drives a small loudspeaker. As the circuit is very poor in amplification, it needs a long wire antenna. The antenna should be from 15 to 50 feet long for best results. A good ground connection is also important.

Of course, this is a small inexpensive transistor radio with low listening volume, particularly on a weak station. If the station is too weak, replace the SPKR by a low-impedance earphone.

The power supply is formed by two or four AA cells and current drain is very low, extending their life. The circuit drains only few microamperes.

L1 is a tapped loopstick, connected to variable capacitor CV. These items can often be found in non-working transistor radios, as well as the speaker and transformer.

Figure 1 shows the schematic diagram for this project. Diode D1 acts as a detector and Q1 as an audio amplifier. T1 is a common transistor output transformer.

In ***Figure 2*** we show the components layout. All the components can be housed in a small plastic box. A terminal strip is used as chassis in an experimental version.

T1 is a transistor transformer (1,000:8) and the SPKR is a miniature type. But, if you have an unworking AM radio you can get these parts without spending any money.

To use, close S1 and tune to the desired station by adjusting CV. You can adjust R1 for the best results according to your transistor gain.

Parts List — Micro AM Radio

Q1 - BC548 general-purpose NPN transistor

D1 - 1N34 general-purpose germanium diode

L1 - loopstick - see text

CV - 365 pF variable capacitor

T1 - Transistor transformer 1,000:8

SPKR - 8 ohms x 2 in. miniature speaker

R1 - 2,200,000 ohm, 1/4W, 5% resistor

C1 - 0.1 uF ceramic or metal film capacitor

S1 - SPST toggle or slide switch

B1 - 3 or 6V - two or four AA cells

Ideas to Explore

To learn more about the circuit or to get better performance:

- Replace Q1 with a Darlington transistor, such as a BC517, and find a better value for R1. Values in the range between 2,200,000 and 10,000,000 ohms can be used.

- Replace L1 by 20 turns of No. 28 wire on a ferrite rod and try tuning short-wave stations. Use a long wire as antenna. Position of the L1 tap must be carefully studied to get best selectivity and sensibility.

- Experiment with a crystal earpiece in the place of T1 and SPKR. A 10,000 ohm resistor should be wired in parallel with the earpiece.

- Explain how crystal sets or direct-detection receivers operate.
- Define the term "selectivity".
- What is a galena-crystal?

Science projects:

- This receiver can be used to demonstrate how antique radio receivers operated when radio was first invented. It can be presented as a "modern version" of a crystal or galena receiver in a demonstration. An interesting exhibit can be made with this set, the free-power AM receiver (described in this book), and a crystal set.
- The circuit can also be used as an RF "sniffer", detecting radio signals produced by experimental circuits in the AM or short-wave band. Replace L1 with a 1,000 uH choke and remove C1 to get a sensitive RF sniffer.

TOUCH SWITCH (E)

Small appliances, lamps and motors can be controlled by a simple touch with this experimental circuit. Loads are ON during the time adjusted by P1 for a few seconds to more than 10 minutes. Conversely, by using the NC (normally closed) contacts you can also turn off an appliance after the adjusted time.

The sensor is formed by two small metal plates, and shouldn't be placed far from the circuit. The metal plates are finger-touched at the same moment.

The circuit can be powered from a 6- or 12-volt power supply, depending on the relay used. Do not use transformeless power supplies with this project, to avoid shocks or dangerous shorts. Transformerless power supplies are not isolated from the AC power line and represent a dangerous shock hazard.

K1 is a relay with 6- or 12-volt coil and is energized by current up to 50 mA. With relays in this range you can power the touch switch from AA cells (6 volts) or small power supplies.

A schematic of the Touch Switch is shown in ***Figure 1***. The circuit uses a 555 IC timer as its heart, and time delay is determined by adjusting P1.

Circuit mounting, using a small homemade printed-circuit board, is shown in ***Figure 2***. If you'd like to etch your own board use this parts placement diagram as guide.

In ***Figure 3*** we show the sensor that can be made with two small metal plates on a plastic or wood base. Wires to the sensor shouldn't be long. A maximum lenght of 10 feet is recommended to avoid erratic operation.

Position of the polarized components, such as the electrolytic capacitors and diodes, should be observed. Load is connected to terminals A and B. Remember that the relay acts as a switch.

Don't power this circuit from transformerless power supplies to avoid dangerous shocks and shorts.

A sensitivity control can be added to this circuit in a simple manner. Use a 1,000,000 ohm potentiometer for this task.

Parts List — Touch Switch

IC1	- 555 integrated circuit, timer
Q1, 2	- BC548 general-purpose NPN transistors
D1	- 1N914 silicon diode
K1	- relay - see text
R1	- 100,000 ohm, 1/4W, 5% resistor
R2	- 47,000 ohm, 1/4W, 5% resistor
R3	- 10,000 ohm, 1/4W, 5% resistor
R4	- 1,000 ohm, 1/4W, 5% resistor
P1	- 1,000,000 ohm, 1/4W, 5% resistor
C1	- 10 to 470 uF, 12 WVDC electrolytic capacitor - see text
C2	- 100 uF, 16 WVDC electrolytic capacitor
S1	- SPST toggle or slide switch
B1	- 6 or 12V - AA cells, battery or power supply

Ideas to Explore

To get more performance or to learn more about the circuit:

- Sensitivity can be increased by replacing Q1 with a Darlington transistor, such as a BC517.
- By connecting a reed switch between points Y and X you can use this circuit do detect movement. Fix a small magnet on the piece to act on the reed switch.

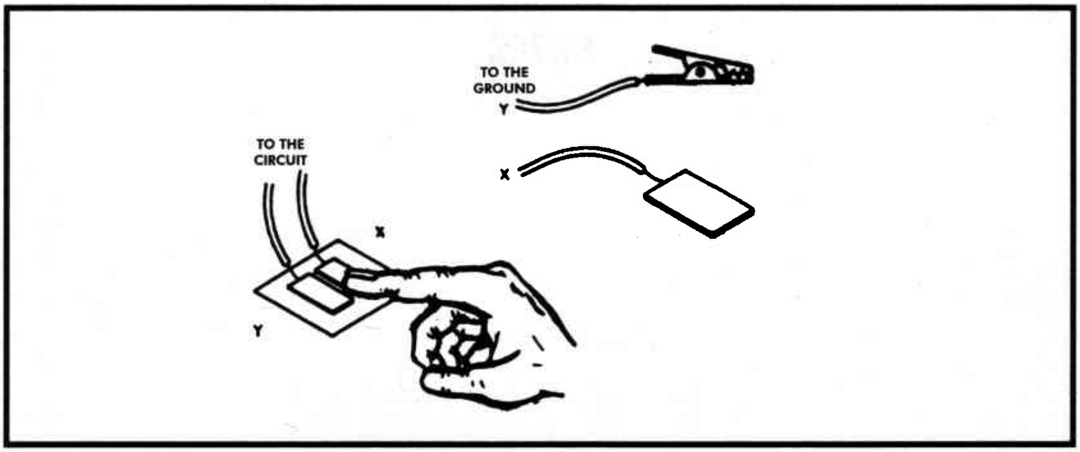

Figure 3

Science and uncommon applications:

- This circuit can be used to close a trap. The touch sensor will detect when the animal enters the trap.

- Projects that need a way to detect movements, switching any load, can be made with this circuit. Several kind of sensors, like microswitches, pendulum sensors or any other momentary-type switch can be used in this circuit.

- Connect an LDR between points A and B. Also connect a 100,000 ohm potentiometer between X and the negative pole of the power supply. You'll have a light-operated relay or remote control. A flash of light produced by a lantern or even a cigarette lighter can close the relay, powering the load. The circuit can be used to detect flashes of light in science experiments. Fix the LDR into a telescope and you can detect meteor fallings.

- Experiments involving thunderstorms at night can be conducted automatically using this circuit. The first flash of lightning can be used to power ON the equipment.

SIMPLE FLUORESCENT LAMP INVERTER (E/P)

This circuit will light a common fluorescent tube (from 7 to 40 watts) from a 6- or 12-volt power supply, such as ni-cad cells, D cells, car battery or other source, without need of a choke or starter. Even the old tubes which no longer function at all on AC power lines will light when used for this purpose. (Some of them, though, may be too weak to light when the circuit is powered from 6 or 12 volts. You should experiment beforehand.)

You can use the device as an emergency light, in trailers, signaling, etc.

By powering the fluorescent lamp with a transformer power supply you increase safety factor of an experiment, avoiding dangerous shocks or shorts.

Current drain, typically ranging from 100 to 800 mA, depends on the characteristics of the lamp used, the power supply voltage, and the transformer.

The lamp will brighten according to the drained current. Experiments should be done with some different transformers and oscillator frequencies to get better performance out of the circuit.

Basicaly, the circuit is a low-frequency oscillator driving a transformer. High voltage is obtained from the transformer to light a fluorescent light.

The trimmer potentiometer allows frequency adjustment to get better performance.

Schematic diagram of the Fluorescent Lamp Inverter is displayed in ***Figure 1.*** As you see, the circuit consists of a low-frequency oscillator with a pair of complementary transistors.

Components layout, using a terminal strip as chassis, is shown in ***Figure 2***. Components placement is not critical.

Transistor Q2 should be mounted on a large heatsink. T1 is a 6V x 450 mA or 12V x 450 mA transformer. If a CT (center-tapped secondary coil) transformer is you should use only two of the three secondary's wires.

Experiments with transformers with secondary currents from 300 to 800 mA and voltages betweeen 9 and 15V can be made to get better performance.

Warning: The fluorescent lamp is powered with high voltages that can be dangerous. Take care of the wires' insulations and when handling connections to the device.

Parts List — Simple Fluorescent Lamp Inverter

Q1	- BC548 - general purpose NPN silicon transistor
Q2	- TIP42 - PNP power transistor
T1	- Transformer: 117 VAC; 6V x 450 mA or 12V x 450 mA
X1	- Fluorescent lamp - see text
P1	- 470,000 ohms - trimmer potentiometer
R1	- 10,000 ohms, 1/4-watt, 5% - resistor
R2	- 1,000 ohms, 1/4-watt, 5% - resistor
C1	- 0.047 uF - metal film capacitor

Ideas to Explore

To learn more about the circuit or to get better performance:

- Try to use a ferrite transformer in place of T1. The circuit performance will increase.
- Explain how transformers work in this kind of circuit and why transformers do not work in DC circuits.

Science projects and uncommon applications:

- Replace X1 by an small ultraviolet fluorescent lamp and you'll have a mineral or fluorescent materials searcher. Many materials, including the ones with a high percentage of calcium, will glow when illuminated by ultraviolet. Many experiments and demonstrations can be made involving minerals, plants and fluorescent materials .

- An interesting experiment with plants is to study the effect of ultraviolet radiation on different plants' growth or germination. Irradiate several batches of various seeds, such as tomato, been, squash, etc., with UV, and then plant. Because of increasing UV radiation reaching the earth due to depletion of the ozone layer, the effect of this radiation on plant life is of concern to us all.

- Compare effects of different light wavelengths to seed germination. The wavelenghts of incoming solar radiation range from 200 to 3,000 nanometers (nm). UV radiation is between 380 and 400 nm. Select seeds from common plants and expose differrent batches to UV and/or common light (red to blue). What happens with the diferent seeds during germination? You also can conduct the experiment not only with seeds, but plants and insects.

- High voltage present in the 117V transformer coil can be used in nerve stimulation experiments. *Please add a 10,000 ohm potentiometer to control the applied voltage if the circuit is intended to be used on humans! The voltage in the transformer has peaks as high as 400V!*

- Fluorescent light can also be use in experiments with insects. Some kinds of insects are attracted by light (visible and ultraviolet!). Insect traps can be constructed using this circuit as base.

- Fish and other animals can be attracted by fluorescent light. A circuit powered by cells or battery is important for fieldwork.

- Alternate methods of farm pest control can use light, visible as well as radiation in the ultraviolet part of the spectrum. Insect traps can be constructed with fluorescent lamp inverters. For further information:

Minneapolis, MN 55414 (612) 331-1099

TOUCH ON/TOUCH OFF RELAY (P)

AC-powered appliances, such as lamps, small home appliances, tools and other items, can be controlled by your fingertips using this circuit. Also, test equipment and experiments can be controlled by this circuit. You can turn on any load by first touching time sensor X1, then turn it off by touching X1 again. There is no shock hazard, as the control circuit is completely isolated from the AC power line.

The control circuit is powered from four or eight AA cells, or, if you prefer, a power supply ranging from 6 to 12 volts according to the relay coil.

Don't use transformerless power supplies because they are not isolated from the AC power line and can cause severe shocks and shorts.

The schematic diagram of the Touch On/Touch Off Relay is given in ***Figure 1***. The circuit uses two ICs. The 555 timer works as a monostable, producing one control pulse when the sensor is touched. The 4013 is a flip-flop that controls the relay by a transistor.

Components placement on a homemade printed-circuit board is as shown in ***Figure 2***. Component layout should be altered if the relay used in the project is an equivalent of the type indicated in parts list.

Relay coil voltage is determined by the power supply voltage and the load current requirement. You can use a mini 1A DPDT (Radio Shack 275-249) 12V, 280 ohm, 43 mA, and wire it as shown in the figure, or use another type of relay, depending on the load requirements.

A 10A SPDT mini-relay (Radio Shack 275-278) is suitable for heavy duty appliances.

As a simple rule, you can use a 6- or 12-volt relay with coil currents ranging from 10 to 100 mA and contacts up to 10A, according to the task you have in mind.

Positions of the polarized components, such as the diode, electrolytic capacitors and transistor, should be observed.

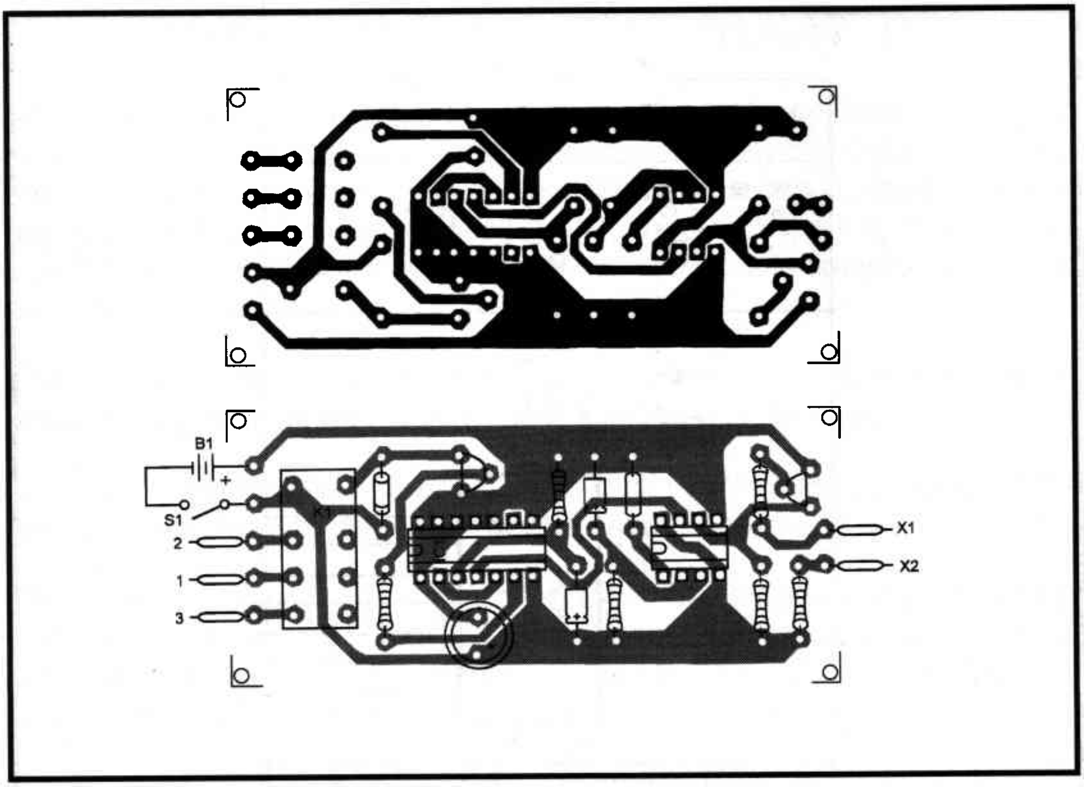

Figure 2

Sensor are the same as the "Touch Switch" project described in this book.

Don't use metallic box to house the device, as there are parts connected directly to the AC power line. Be sure that there are no power line contacts with the low voltage circuit to avoid shocks and dangerous shorts.

The load is connected as shown in ***Figure 3,*** to be ON when the relay coil is energized. You can also use the normally closed contacts to turn off a load when the relay coil is energized.

Remember that current requirements are high when the relay coil is energized and low when the transistor Q2 is off (relay coil nonenergized). That is an important factor to consider if you are using batteries to power the unit.

After you are sure that you have wired all parts of the circuit correctly, plug the power cord into the wall socket. You can now test the circuit.

Connect a load to the output (relay contacts) and touch the sensor. The load should be powered ON if all is OK.

Parts List — Touch On/Touch Off Relay

IC1 - 555 Integrated circuit - timer
IC2 - 4013B CMOS integrated circuit - dual flip-flop
Q1, 2 - BC548 General-purpose NPN silicon transistors
D1 - 1N914 General-purpose silicon diode
K1 - Relay - see text
R1, 2, 5 - 100,000 ohm, 1/4W, 5% resistors

C3 - 4.7 uF, 12 WVDC electrolytic capacitor
C4 - 100 uF, 16 WVDC electrolytic capacitor
S1 - SPST toggle or slide switch
B1 - 6 or 12V (according to relay) - see text
X1, 2 - sensor - see text

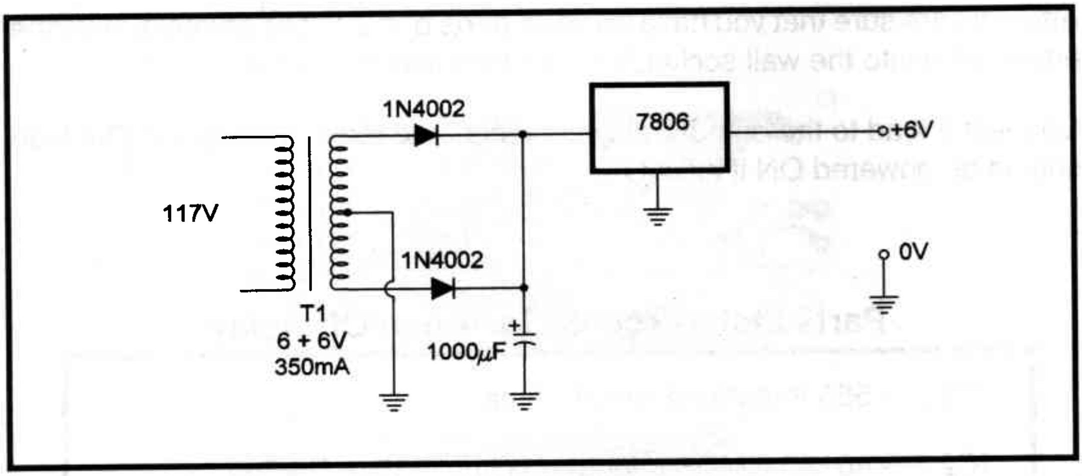

Figure 3

Ideas to Explore

To learn more about the circuit or to get better performance:

- Better performance can be obtained by replacing Q1 with a Darlington transistor, such as a BC517.
- A 100,000 ohm potentiometer placed between the base of Q1 and the negative pole of the power supply will give a sensitivity adjustment for the circuit.
- Explain how a flip-flop, as used in this circuit, works, and the function of the C3/R5 network in this project. Explain why the current flowing through the fingers when the sensor is touched doesn't cause any shock hazard.
- Depending upon the application, you can power ON the load when relay is not energized (to reduce power consumption). That is possible using the normally closed contacts of the relay.

Science projects and uncommon uses:

- By connecting a reed switch between points X1 and X2 you can use the circuit to detect movement of mechanical items in experiments or projects. Just affix a magnet on the moving item to act on the switch.
- Experiments with animals can be conducted with this circuit by using appropriate transducers connected between X1 and X2.
- An LDR can be used to control the circuit with a flash of light. A lantern, cigarette lighter, etc., can be used to turn appliances on or off.

EXPERIMENTAL GALVANOMETER (E)

The experimental galvanometer described here can detect currents as low as few microamperes and uses unusual parts. This galvanometer operates as common commercial galvanometers found in multimeters and several other analog instruments.

One purpose of this experiment can be to demonstrate that there is a magnetic field around a coil that that is carrying electricity (Oersted Experiment).

The operating principle is very simple to understand: an electric current flowing across a coil (or a wire) produces a magnetic field. The field can act on a mobile magnetic metal piece, such as a compass pointer or a blade, as shown in the figures herein. The compass or blade movement indicates the presence of a current.

Figure 1 shows the two basic versions of the experimental galvanometer, using a common compass and using a blade. Is very important to observe the correct path for the current flow in the coil. The coil should be wired exactly as shown in the figure.

In ***Figure 2*** we have a circuit to operate the galvanometer. The resistor can range from 100 to 100,000 ohms. The higher the resistor, the more sensitive is the galvanometer. Experiment to find the highest resistor value that can cause the pointer to move.

The coil is made with 50 to 200 turns of No. 28 to 32 wire on a paper form. Number of turns determines sensitivity. The higher the number of turns, the more sensitive is the galvanometer.

Currents as low as a few microamperes can be detected with a carefully made prototype.

Ideas to Explore

To get better performance or to learn more about the circuit:

- Experiment with several coils with different numbers of turns and compare sensitivity.

Science projects:

- Demonstrate how Oersted discovered the magnetic field around a wire that is carrying electricity and how modern galvanometers are constructed.
- Where can galvanometers can be used? What are voltmeters and ammeters?
- Determine the sensitivity of your galvanometer by connecting it in series with a multimeter (DC mA or uA scale) and a 100,000 ohm potentiometer.

OVER-TEMPERATURE ALARM (E/P)

This circuit will produce intermittent beeps by a piezoelectric transducer when the temperature rises over a preadjusted value. You can use this circuit in greenhouses, heaters, etc. The sensor is a common silicon diode but an NTC can also be used if you change some components' values.

Exchanging positions of R1 and P1 with D1 will cause the device to operate as an under-temperature alarm.

The intermittent signal is generated by two oscillators. IC1a (pins 1,2 and 3) is an inverter that controls IC1b and IC1c (oscillators). IC1c (pins 8, 9 and 10) is a very-low-frequency oscillator that provides the modulation rate for the second oscillator. The second oscillator (pins 5,6 and 4) has its frequency determined by R2 and C1. The produced audio tone can be altered by adjusting both C1 and R2 within a large range of values.

Power comes from a 3- to 15-volt power supply. For portable use a small 9-volt battery is recommended. Current drain is very low, about 0.5 mA when the tone is off. When the tone is on, current drain rises to about 5 mA.

A schematic of the Over-Temperature Alarm is shown in ***Figure 1***. IC1, a 4093B, has two gates operating as oscillators and two as buffer-inverters.

Components placement on a homemade printed-circuit board is shown in ***Figure 2***. You can made your prototype using a single-sided PC board.

Position of the polarized components, especially diode D1 (used as sensor), should be observed. This sensor can be placed far from the device by using common wiring. You must take some care to avoid humidity or water falling onto the sensor, which will cause adversely affect the alarm operation.

BZ is a piezoelectric transducer (Radio Shack 273-073 or equivalent) or a crystal earpiece.

Operation is adjusted by P1. Set this potentiometer to get sound at the desired temperature. To get a more precise adjustment you can replace the common trimmer potentiometer by a multi-turn potentiometer.

Get the sensor between your fingers to see how it works: when the temperature rises some degrees the circuit will produce a serie of beeps. Isolate the sensor, and after some seconds sound emission will stop.

Parts List — Over-Temperature Alarm

IC1	- 4093 CMOS integrated circuit
D1	- 1N914 or 1N4148 general purpose silicon diode
BZ	- Piezoelectric transducer or crystal earphone (Radio Shack 273-073 or equivalent)
R1	- 100,000 ohm, 1/4W, 5% resistor
R2	- 33,000 ohm, 1/4W, 5% resistor
R3	- 2,200,000 ohm, 1/4W, 5% resistor
P1	- 10,000,000 ohm trimmer potentiomer
C1	- 0.047 uF metal film or ceramic capacitor
C2	- 0.47 uF metal film or ceramic capacitor
C3	- 100 uF, 16 WVDC electrolytic capacitor

Ideas to Explore

To learn more about the circuit or to get better performance:

- Alter both R2 and C1 to change tone pitch or both R3 and C2 to alter modulation rate.

- Replace D1 with a 10,000 to 100,000 ohm NTC, R1 with a 2,200 ohm resistor, and P1 with a 100,000 to 1,000,000 ohm potentiometer, to get a new kind of sensor.

- Try to add a powerful output audio stage using a transistor, such as a BD135 and a small loudspeaker. See other projects in this book for suggestions about the configuration.

Science projects and other applications:

- Chemical processes that involve heat changes can be controlled using this alarm. The sensor should be protected against moisture and water in experiments involving liquids.

- Replace D1 by an LDR or photodiode. The circuit will operate as a light alarm or dark alarm, depending upon sensor position. With an LDR it would be better to replace P1 with a 1,000,000 ohm potentiometer and R1 with a 10,000 ohm resistor. Lenses placed in front of the LDR or phototransistor can be used to increase sensitivity.

- The circuit can also operate as a water-level alarm by using a two-wire sensor to replace D1. The sensor is made with two bare wires. The wires are separated by a distance of about 2 or 3 inches. The water completes the circuit while the wires are immersed. When the water level falls below the wires, the circuit is opened and the alarm is triggered.

- Temperature in greenhouses, animal pens, incubators and aquariums can be monitored using this device. And if working with an LDR as the sensor, experiments involving light can be conducted.

CAPACITOR TESTER (P)

This circuit can be used to test metal film ceramic capacitors and other types of capacitors in a range of values between 470 pF to 10 uF.

The device is formed by an audio-oscillator that produces a tone determined by the capacitor under test. Probes connect the capacitor to the circuit. The frequency of the produced tone is higher for lower-value capacitors. A falling tone indicates a bad capacitor.

Testing capacitors in the range between 1 and 10 uF, the oscillator will produce separated audio pulses, working like a metronome.

The circuit is powered by two or four AA cells, and current drain is very low. P1 is adjusted to set an audible tone at the speaker, according the value of the capacitor being tested.

You can also use this device to compare capacitor values. Two capacitors with the same value will give the same tone.

The schematic diagram of the Capacitor Tester is shown in ***Figure 1***. The circuit has as its heart two complementary transistors working as a direct-coupled amplifier. Feedback is provided by resistor R1 and the capacitor under test.

Components placement on a terminal strip is shown in ***Figure 2***. Use this parts placement as a guide when assembling the terminal strip and when housing the circuit into a box.

Termination components should be short as possible to avoid instability.

Position of the polarized components, such as the electrolytic capacitor and power supply, should be observed when mounting. The capacitor under test is placed in the circuit by two alligator clips as shown in Figure 2.

The circuit can be housed in a small plastic box.

S1 - SPST toggle or slide switch

B1 - 3 or 6V - 2 or 4 AA-cells

SPKR - 4 to 8 ohms - 2 to 4 in. loudspeaker

Ideas to Explore

To get better performance or to learn more about the circuit:

- Replace P1 with 10,000,000 ohms to test capacitors under 470 pF. Don't touch the alligator clips or probes when testing small capacitors bellow 1,000 pF.
- Explain how capacitors function in this circuit. What is feedback?

Science projects and uncommon uses:

- Mount an experimental capacitor using aluminum foil and paper as dielectric. Test the capacitor using this device and compare the value with known capacitors.

- Experiments involving capacitive transducers can be conducted with this circuit. The circuit can be used as an analog-to-digital (A/D) converter. These circuits can convert capacitances (an analog quantity) into frequencies (a digital quantity). With an appropriate conversion scale it will be possible to use a frequency counter to measure capacitances.

CONTINUITY TESTER (E/P)

This circuit can be used to test electronic components such as diodes, resistors, coils, transformers, lamps, fuses, switches, loudspeakers and many others. The state of the component under test is indicated by an LED.

When the probes are separated or when the resistance between them is very high (more than 1,000,000 ohms) the LED is off. When the resistance is low (the transistor is in a conduction state) the LED is on.

The circuit is powered from a 6- or 9-volt supply (AA cells or battery). Current drain is less than 10 mA with the LED on. R2 value depends on the power supply voltage. For a 9V supply we recommend 820 or 1,000 ohms for R2.

A schematic diagram of the Continuity Tester is given in ***Figure 1***. Two transistor are wired as a Darlington pair. The configuration reduces the current flow between probes to microampere values.

Components placement on a terminal strip, used as chassis, is shown in ***Figure 2***. It is very important to observe positions of the transistors and LED.

House the device in a small plastic box and use probes or alligator clips to connect the components under test.

Ideas to Explore

To get better performance or to learn more about circuit and devices:

- Invert power supply poles and LED position and use NPN transistors. Will the circuit operate as the original version? A transistor such as the BC548 can be used in this experiment. You can also replace the LED and R1 with a 6-volt x 50 mA small incandescent lamp.

- Determine the highest resistance that can be connected between probes that causes the LED to illuminate.

Science projects:

- Conductability of chemical substances can be detected or demonstrated with this circuit. Use two bare wires as probes.

- By replacing the LED with a 0-200 uA microammeter you can use this circuit as a lie detector. Small changes in skin resistance can be detected in this way. Skin resistance alters with stress or by the strain caused by an interrogation session.

- Experiments with plants can be conducted involving alteration in the resistance between electrodes placed on their leafs . An interesting study about this subject is found in the book *The Secret Life of Plants* by Peter Tompkins and Christopher Bird. The authors associate electrical phenomena in plants to a rudimentary nervous system.

LED BARGRAPH (E/P)

This circuit drives ten LEDs in response to an analog voltage applied to its input and can be used to provide a visual indication of the instantaneous power being developed by an audio amplifier. It can also be used to provide visual indication of variable events in science experiments.

You can extend the project by using two chips and you'll be able to continuously monitor the audio output power of both channels of your stereo system.

The circuit can be used with amplifiers ranging from 0.1 to 100 watts.

In some cases you should use a small transformer, wired as in ***Figure 1***, to isolate the input and match impedances. This is necessary when the amplifier has a low-output impedance. Resistor R_x is chosen according to the output power of the amplifier. Values are given in Table 1.

Table 1

Amplifier Output Power	Rx
0.1 to 1 watt	-
1 to 5 watts	10 ohms, 1/2 watt

50 to 100 watts	100 ohms, 2 watts

A schematic diagram of the LED bargraph is shown in ***Figure 2***. The circuit uses an LM3914 IC to drive the LEDs, converting voltages into one of ten outputs.

The components are placed on a printed-circuit board as shown in ***Figure 3***. If you'd like to build your circuit the same way, you can etch your own board using the solder and component-side templates shown in this figure.

Figure 2

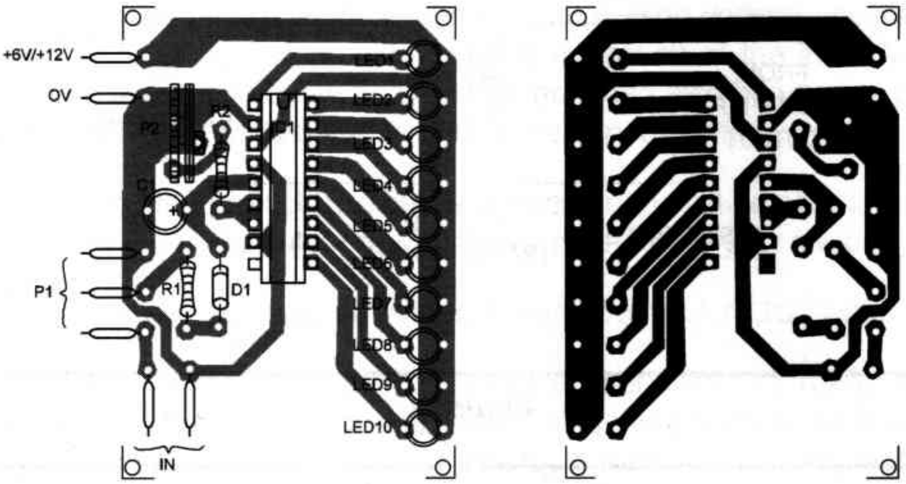

Figure 3

P2 adjusts the dynamic range in which the circuit operates. P1 adjusts sensitivity and depends on the application. You can set the value to a fixed point by using a trimmer potentiometer.

Audio comes from the loudspeaker output of the amplifier. Any small transformer with a high-impedance coil and a low-impedance coil can be used. Any small transformer with a 117 VAC primary, secondary rated from 5 to 12.6 volts, and current ratings between 100 and 500 mA can be used.

Position of the polarized components, such as LEDs, diode, and electrolytic capacitor, should be observed.

Bass response is provided by C1. You can alter this component within the range given in the schematic diagram to achieve best performance.

Remember that the highest applied voltage to the input shouldn't exceed the power supply voltage.

Parts List — LED Bargraph

IC1	- LM3914 Integrated circuit (National)
LEDs	- Common red, yellow or green
D1	- 1N914 or 1N4148 general purpose silicon diode
R1	- 10,000 ohm, 1/4W, 5% resistor
R2	- 470 ohm, 1/4W, 5% resistor
P1	- 10,000 ohm potentiometer
P2	- 4,700 ohm trimmer potentiometer
C1	- 1 to 10 uF, 12 WVDC electrolytic capacitor - see text

Ideas to Explore

To learn more about the circuit or to get better performance:

- Determine the voltage level that turns on each LED using a DC power supply plugged to the input of the device.
- By wiring probes at the positive power supply line and the input you can use this circuit as a digital resistance or conductance meter.

Science projects:

- This circuit can replace the common multimeter to indicate voltage variations in experiments. The visual effect is better.
- It can also be used in the output of a lie detector or bio-feedback.
- Conect an LDR between the input and (+) for a digital photometer. For a digital thermometer wire an NTC between (+) and the input.
- This circuit can also replace the LED and resistor in the Continuity Tester and the same experiments, with advantages, can be performed.

LIQUIDS SHAKER (P/E)

A toy's small DC motor can be used to mount a liquids shaker. The shaker can be used in chemical experiments to mix substances quickly and efficiently.

The circuit is powered from the power supply line (to avoid the expense of batteries), but there is no shock hazard because an isolation transformer is used. Of course, for fieldwork you can also power your mixer from common AA cells.

The transformer is chosen according to the motor voltage. A four-AA-cell DC motor requires a 6+6 volt x 500 mA transformer (a 6-volt center tapped transformer). A two-AA-cell DC motor requires a 3V x 500 mA transformer.

Secure the motor into a small cylindrical plastic box. Use a long shaft to attach a small plastic screw propeller.

Figure 1 shows the schematic diagram of the electronic part of the circuit: a power supply. The diodes are common 50V x 1A silicon rectifiers, and C1 is not critical. C1 should be in the range between 100 and 1,000 uF.

Figure 2 shows a mechanical view, using a small terminal strip as chassis. The fuse is important to avoid severe troubles if shorts occur.

R1 is a current-limiting resistor and can be altered according to the motor. Values between 4.7 and 100 ohms can be experimented with for better performance.

Position of the polarized parts, such as the diodes and electrolytic capacitor, should be observed. Remember that the motor rotates clockwise or not according to the voltage polarization.

Ideas to Explore

To learn more about circuit and devices or to get better performance:

- Alter R1 to achieve better performance according to the DC motor used. Try values between 4.7 and 100 ohms.
- Use the DC Lamp Dimmer described in this book to get a speed control for the motor. Remove R1 if the dimmer is used.
- Use the 6V DC converter to get a regulated output from the circuit.

Science projects and uncommon uses:

- This power supply can be used in electro-chemical experiments, such as electrolysis and electroplating.
- Replace the screw propeller with a fan blade. Experiment.
- The device can be used in experiments involving water currents in small places, such as aquariums.
- Other applications that require controlled movement of a small DC motor can use this circuit.

SIGNAL TRACER (P)

Signal tracing by means of a signal tracer offers a valuable method for servicing a variety of electronic equipment. This method is often employed when a circuit is not completely dead, but rather malfunctioning. AM and FM receivers, CD players, multimedia amplifiers, TV sets, etc., can be serviced using this simple signal tracer.

The circuit we show here consists of a two-stage direct-coupled transistor amplifier. The circuit has two inputs. When the probe is used in the RF mode the detector diode is inserted into the circuit. When the probe is used in the audio mode the signal is applied directly to the base of the first transistor (Q1).

As the circuit has a low-power output, a gain control is not used.

The circuit is powered from two AA cells, and current drain is only few milliamperes. Since the circuit draws such low current, long battery life can be expected.

Figure 1 shows the schematic diagram of the signal tracer. R1 determines the gain of the amplifier stage and can be altered to get better performance depending on the transistors used.

Figure 2 shows the signal tracer mounted on a terminal strip, which is used as a chassis. Take care with the transistors; one is an NPN and the other is a PNP. If you switch one with the other the circuit will not work.

This project can be housed in a small plastic box. The size of the plastic box is determined by the speaker size. Position of the polarized pieces should be observed.

C2 - 100 uF, 6 WVDC electrolytic capacitor

SPKR - 4/8 ohms - 2 or 4 in. small loudspeaker

S1 - SPST slide or toggle switch

B1 - 3V - two AA cells

Ideas to Explore

To learn more about the circuit or to get better performance:

- Explain how signal tracers are used for service work.
- Change R1 value to achieve better performance.
- Use the tracer in a small AM radio to study its operation.
- Replace the speaker by a low-impedance earphone to get a portable unit that can be housed in a very small plastic box.

Science projects:

- The tracer can be used to detect signals produced in experiments involving current fields, as described in this book.
- The tracer can be used as an experimental audio amplifier with transducers such as piezoelectric pickups or microphones.

ONE-EVENT REGISTER (P/E)

This is a one-bit memory that can be used to store a simple bit of information, such as a remote power-failure or closed-trap detector, or a touch sensor.

The circuit operates as follows: When the resistance between the alligator clips falls, the SCR is triggered, powering ON the LED.

The SCR and LED stay in the ON state even after the applied pulse to the input is gone. So the device “memorizes” the event.

The sensor can be a magnetic switch (reed switch), a microswitch, or a touch switch. A simple touch switch is a metal plate wired to G2. To get best sensitivity, G1 needs a good ground. You can also use as sensor two metal plates that are touched at the same time to trigger the circuit ON.

The circuit is powered by four AA cells and current drain is very low when the LED is off. When the LED is on, current drain is less than 10 mA.

To reset the device you only have to toggle S1. Another way to reset the circuit is to wire a momentary switch between the anode and cathode of the SCR. Sensors can be wired to the device with long unshielded wires.

The schematic of the One-Event is shown in ***Figure 1.*** Though R2 and R3 are shown as fixed, you can use a 1,000,000 ohm potentiometer if you prefer. A sensitivity adjustment will get better performance from the register.

Figure 2 shows the One-event Register, on terminal strip mounting. As it is an experimental circuit you can also use a solderless board to install the components.

The circuit can easily be housed into a small plastic box. Observe the positions of all the polarized components, such as the LED, SCR and power supply.

Resistor R3 is only necessary if TIC106 is used. Other SCRs, such as the MCR106 and C106, don’t require R3.

R3	- 47,000 ohm, 1/4W, 5% resistor - see text
S1	- SPST slide or toggle switch
B1	- 6 V - four AA cells
G1, 2	- Alligator clips

Ideas to Explore

To get better performance or to learn more about the circuit:

- You can replace R1 and the LED with a buzzer or audio oscillator to get an alarm. But, remember that there a voltage drop of about 2 volts when current flows through the SCR. This voltage drop can be compensated by adding two or three volts to the power supply. For instance, if you use a 6-volt relay, the recommended voltage for the power supply is 8 or 9 volts.

- As current drain is very low when the LED is off, depending on the intended use, S1 can be removed.

- Explain how the SCR operates in this circuit.

Science and uncommon applications:

- You can connect an LDR between G1 and G2 for a light-operated one-event memory or alarm. A single short pulse of light can trigger the circuit.
- Use this circuit to know when someone touches an object when you leave it unattended. You can also know if someone entered your room when you were out.
- By using two bare wire as sensors, you have a water-level alarm. The LED will glow when the water touches the two bare wires at the same time.

NOISE GENERATOR (E)

The purpose of this simple experiment is to produce noise in the AM radio band. The circuit can be used to show how brush motors and general appliances with motors can generate noise in the radio band, interfering in radio, TV, and radio communication services.

The circuit is very simple and the produced noise is too weak to cause any problem to radio receivers. (FCC rules about noise and radio interference are severe.) The noise produced by this experiment will interfere only in receivers just a few feet away.

The schematic diagram of the device is shown in ***Figure 1***. The heart of the circuit is a small DC motor that works as a automatic key, producing rapid variation in the current flow.

A mechanical view of the circuit, using a terminal strip as chassis, is shown in ***Figure 2***. All the components, including the power supply, can be fixed on a plastic board.

Any small DC motor obtained from a nonworking toy can be used in this project. The power supply depends upon the motor used.

CV and L1 can be obtained from any nonworking AM radio.

You can get more power for the RF noise by wiring a piece of wire to the antenna (A) terminal, but limit this wire to no longer than 6 feet. L1 is formed by 100 turns of No. 28 wire wound on a ferrite rod (diameter and length are not critical).

By adjusting CV, you can try to tune the signal to be stronger on a dead point of the AM radio band.

L1	- loopstick - see text
M	- 3 to 6V DC motor

Ideas to Explore

To learn more about the circuit or to get more performance:

- Try to produce RF noise in the high-frequency band by replacing L1. With a 30-turn coil on a ferrite rod you can produce signals in the range between 2 and 7 MHz.
- Explain how RF noise is produced.
- Find out through reference books how Marconi and other radio pioneers generated radio waves from their transmitters.

Science and uncommon applications:

- You can show how antique radio transmitters operated using this circuit. Morse coded messages can be transmitted using a key in place of S1.
- Explain why this noise generator can be used to transmit voice-modulated signals.

EXPERIMENTAL OHMMETER (E)

As commercial ohmmeters are cheap and easy to find, anyone who wants a good instrument for his own use will not build one. But you can build a simple ohmmeter to demonstrate how it works or study how the big ones are made.

The simple ohmmeter described here can easily be made from a milliammeter or microammeter, and can be used in experiments, demonstrations and many other applications.

Our ohmmeter is also a voltmeter. And since this ohmmeter can measure a large range of voltages and resistances we can say that it is, in practice, a multimeter. Voltages can be measured in the range between 0 and 12 volts (the range used to power almost all circuits in this book), and resistances between 0 and infinite.

If using a 200 uA microammeter, the sensitivity will be 5,000 ohms per volt. This value is typical of several commercial types of common multimeters.

But you can use any other ammeter with a full-scale value ranging from 100 uA to 1 mA. Simply change R1 to achieve best performance.

The schematic of the experimental ohmmeter is shown in ***Figure 1***. Note that we use only four components that can easily be housed in a small plastic box.

Layout is shown in ***Figure 2***. Components mounting is not critical, and you can replace the banana jacks by probes or any other method to make external connections.

Probes are connected to the external banana jacks depending on the measurement you intend to make. To measure voltage, the red probe is connected to J1 and the black probe is connected to J2. To measure resistance, connect the red probe to J1 and the black probe to J3. Put the probes together and adjust P1 to get an indication of zero at the instrument scale.

By using a series of known resistors, it is possible to calibrate the meter scale to read ohms directly. Start from 0 (with J1 and J2 shorted), and note the meter readings when 1k, 2k, etc, resistors are connected across J1 and J3.

Figure 2

After calibrating the device to read ohms, use a variable power supply to calibrate the voltage scale.

Position of the polarized components, such as the ammeter and power supply (cells), must be observed.

Parts List — Experimental Ohmmeter

B1	- 3V - two AA cells
R1	- 10,000 ohm, 1/4W, 5% resistor
P1	- 47,000 ohm, 1/4W trimmer potentiometer
M1	- 0-200 uA microammeter - see text
J1-3	- banana jacks

Ideas to Explore

To learn more about the circuit or to get better performance:

- Explain how resistance and voltage scales operate in this ohmmeter.
- Calibrate the scales of your ohmmeter using a variable power supply and some known-value resistors, as described above.
- Calculate the resistance values read in the meter and compare with the real values of used resistors. Do your calculated results confirm previous studies?

Science and uncommon applications:

- You can use the ohmmeter to determine sensor and media resistances in several experiments if you don't have a commercial multimeter.
- By wiring a 47,000 ohm potentiometer between J1 and J3 you can use this device as a position indicator. Cursor positions can be directly converted into current as indicated by the meter. A scale of angles can be arranged to read degrees directly.

TEST YOUR NERVES (P/E)

This circuit puts your manual skills to a lively test. As shown in the schematic diagram, the circuit has a small loop that you must navigate around a wire. The object of the game is to guide the loop over the weaving course without touching the wire.

A slight misdjudgement or quiver of the hand and the ring will contact the weaving wire, enabling the circuit that will produce a noticeable (but inoffensive) shock!

The skill required to play the game depends largely on the size of the loop and the degree of twist and turn in the wire.

Scoring is a matter of counting the number of times the player is affected by a shock! The person with the lowest total (or no touch) wins.

The circuit is powered from a D cell, as the current drain is high when the loop touches the wire. When not in use, don't leave the ring and wire together. This will cause the battery to run down in a short time.

A circuit diagram of the device is shown in ***Figure 1***. The heart of the project is the transformer that converts 1.5 VDC into high-voltage pulses up to 400 volts.

A mechanical view of the mounting is shown in ***Figure 2***.

All the components can be housed in a small plastic box. Wires to the loop and weaving wire should be 2 or 3 feet long to prevent pull-outs when the player is struck.

Observe the isolation between the points where the player touches and the weaving wire. The two wires that connect X2 should be twisted.

T1 is any small transformer with a 117 VAC primary, and secondary coil ranging between 3 and 9V. Current drain can range from 100 to 500 mA when the wire touches the loop.

X2	- Weaving wire - see text

Ideas to Explore

To get better performance or to learn more about the circuit:

- Explain why the transformer does not operate with DC but that this project is able to generate high voltage using that device.
- What happens if the loop is placed together with the weaving wire? Why it is necessary to avoid this condition?

Science projects:

- Changes in the project can be made to generate high voltage from cells in experiments. Nerve stimulation can be tried using this simple circuit.
- Neon or fluorescent lamps wired between the loop and wire will flash when the loop and wire touch. This experiment can be used to prove that high voltage is generated by the circuit.

WIRELESS BEEPER (E)

This FM wireless transmitter produces a beep that can be tuned on any dead point of the FM broadcast band. The circuit can be used as a localizer when attached to objects or persons. You also can use it as a wireless alarm.

The signal can be tuned on common FM radios in a range up to 150 feet. Alterations for a far-reaching version are given below.

The circuit produces an intermittent beep of about 1 Hz. An audio tone is generated by IC1b (pins 5, 6 and 4) and its frequency is determined by R2 and C2. You can easily alter this frequency by adjusting R2. Resistor values between 22,000 and 100,000 ohms can be experimented with or, if you prefer, 100,000 ohms in series with 10,000 ohms can replace R1.

Repetition rate is per R1 and C1. Values are variable. For C1, values between 0.15 and 1 uF can be tried. It is important to test for the ideal value of this component, depending on the intended application.

The schematic diagram of the wireless beeper is shown in ***Figure 1.*** Three gates of a 4093 IC are used to generate the low-frequency signals, and one RF transistor is used to generated the high-frequency signal.

Components placement on a homemade printed-circuit board is shown in ***Figure 2.*** Placement is critical for the high-frequency stage. Capacitors in this stage should be ceramic.

L1 consists of four turns of No. 18 or 20 wire on a 1/2 in. form without a ferrite core.

The antenna is formed by a piece of bare wire between 5 and 10 inches long. It can be connected to any tap on the coil. Experiment to get better performance.

The power supply current drain is about 10 mA. You can use four AA-cells or a 9V battery to power the transmitter.

For a wireless alarm, S1 can be replaced by the contacts of a relay. The relay is used to interface the alarm with the transmitter in this application.

Parts List — Wireless Beeper

IC1 - 4093 CMOS Integrated Circuit

Q1 - BF494 or equivalent NPN RF silicon transistor

L1 - coil - see text

CV - trimmer capacitor - 20 to 40 pF maximum

R1 - 2,200,000 ohm, 1/4W, 5% resistor

R2 - 39,000 ohm, 1/4W, 5% resistor

R3 - 8,200 ohm, 1/4W, 5% resistor

R4 - 6,800 ohm, 1/4W, 5% resistor

R5 - 47 ohm, 1/4W, 5% resistor

C1 - 0.22 uF ceramic or metal film capacitor

C2 - 0.047 uF ceramic or metal film capacitor

C3 - 0.01 uF ceramic or metal film capacitor

C4 - 4,700 pF ceramic capacitor

C5 - 4.7 pF ceramic capacitor

C6 - 0.1 uF ceramic capacitor

A - antenna - see text

S1 - SPST slide or toggle switch

B1 - 6 to 9V - four AA cells or 9V battery

Ideas to Explore

To get better performance or to learn more about the circuit:

- You can control the beeper oscillator by IC1, pins 1 and 5. Put these pins together. When in a high logic level the circuit produces intervalled beeps. When in a low logic level the circuit stops.
- Replace Q1 by a 2N2218. Power the circuit with a 12V power supply. Signals can now be tuned from distances up to 1,500 feet. A 5- to 6-foot antenna will increase the range of the transmitter.

Science projects or uncommon applications:

- House this circuit in a box and tell someone to hide it. You'll find it by using a small FM receiver.
- The transmitter can be used to track animals by fixing it on a collar.
- You also can use the transmitter to monitor remote sensors in experiments. The circuits can power ON the transmiter or trigger the oscillator as indicated above.

ELECTROSCOPE (E/P)

An electroscope is an instrument that can be used for detecting the presence of an electric static charge. We describe here an electronic version of the traditional electroscope—one that is made with gold foils placed into a glass jar. This circuit can also be used for "sniffing" high voltage without actually making contact with dangerous circuitry.

A metal ring, which constitutes the sensor, is simply poked into the electric field. This operation must be done with caution to avoid contact with the conductors carrying the high voltage.

You can use the device in experiments with high voltage generators (Van de Graaff accelerator) and in many other applications at home or school.

The circuit is portable, powered from four AA cells or a 9V battery.

Presence of a static charge or a strong field created by high-voltage lines is indicated by an LED.

The schematic diagram of the Electroscope is shown in ***Figure 1***. The circuit uses four gates of a 4093 IC that work as buffers and inverters, driving the LED. The high-impedance input of the CMOS integrated circuits results in high sensivity to detect static charges.

All the components are mounted on a homemade printed-circuit board as shown in ***Figure 2***.

Sensor X1 is a small bare wire lop. The completedcircuit can be housed into a small plastic box with the batteries. The LED should be placed in a visible point of the box.

To use:

Bring a charged source close to the sensor. A piece of paper or plastic stroked with a rod of insulating material will do. Adjust P1 to get better sensitivity. The LED will glow according to the electric charge movement.

Parts List — Electroscope

IC1 - 4093B CMOS Integrated Circuit

LED - Common red, yellow or green LED

X1 - Sensor - see text

P1 - 1,000,000 ohm potentiometer

R1 - 22,000,000 ohm, 1/4W, 5% resistor

R2 - 100,000 ohms, 1/4W, 5% resistor

R3 - 1,000 ohms, 1/4W, 5% resistor

S1 - SPST slide or toggle switch

B1 - 6V or 9V - four AA cells or 9V battery

Ideas to Explore

To learn more about the circuit or to get better performance:

- Connect the sensor to an external antenna. You can detect clouds' electrical charge as they pass overhead.
- Explain how the circuit works.
- An interesting study or experiment could be performed to show how static charges are produced and how they can be detected.

Science and uncommon applications:

- In all the experiments that can be conducted with a common electroscope, the electronic version can replace it.

- Determine the polarity of the charge that makes the LED to glow.

- Static charges could have some influence on animals and plants. An experiment to support this affirmation can be conducted. This project, of course, will involve some special equipment such as a high-voltage generator (Van de Graaff or other) and an electroscope. Select seeds from common plants such as tomatoes and beans, and expose several batches of seeds to a static high-voltage field. What are the effects on seed germination? Is plant growth also affected by electric fields?

UNIVERSAL PROBE (P)

This ultra-simple probe can be used to test almost every electronic component. Capacitors, resistors, fuses, switches, coils, transformers, diodes, wires, etc., can be tested with this simple circuit.

Only three components are used and they can easily be housed in a small plastic box, performing as a portable unit.

The circuit consists basically of a continuity tester with a visual indication by an LED. If current can flow between the probes the LED glows; if not, the LED remains off.

Current flowing between probes is very low to avoid overloading the tested components.

A schematic diagram of the Universal Probe is shown in ***Figure 1***. As you can see, only three electronic components are used in this project.

A components layout view is shown in ***Figure 2***. The components can be housed in a small box and no ON-OFF switch is necessary.

When mounting, take care with position of the two polarized components, the LED and power supply.

The power supply consists of two AA cells.

An ON-OFF switch is not necessary, as the circuit is off when the probes are separated.

Current through the component under test is determined by the voltage drop across the LED (about 1.6V for red LEDs and 1.8V for yellow LEDs), and resistance of R1.

Parts List — Universal Probe

LED - Common red, green or yellow LED

R1 - 470 ohm, 1/4W, 5% resistor

PP1, 2 - Red and black probes

B1 - 3V - two AA cells

Ideas to Explore

Science projects:

- Use this probe in to find materials that conduct or do not conduct electric current. Several other simple experiments in electricity can be conducted using this probe: for example, show how a switch works, or how a potentiometer used as a rheostat controls the current flow accross an LED.

- Explain how the LED produces its light.

- Use this probe to explain how a diode works. (Remember that DC is used in the probes and diodes, allowing the current to flow only in one direction.)

- This circuit can also be used as a monochromatic source of light in experiments involving optics.

TONE-ACTIVATED RELAY (E)

This circuit can be used to recognize a tone by its frequency. When this tone is present in a circuit the relay is energized, which could supply power to a selected appliance.

Wired to the output of a receiver, the circuit can be used as part of a tone-modulated wireless remote control. The receiver can be a common FM radio or an infrared receiver, depending on the intended application.

The circuit can be used with tones ranging up to 100,000 Hz. The circuit is tuned by P1.

Inputs of other units can be wired in parallel to get a multi-channel remote control system. Take care to avoid using harmonic frequencies.

The schematic diagram of the Tone Activated Relay is shown in ***Figure 1***. The heart of the circuit is the LM567 IC, a National Semiconductor PLL (Phase-Locked Loop) that drives the relay through transistor Q1.

Components placement on a homemade printed-circuit board is shown in ***Figure 2***. Placement is not critical, but when operating in frequencies above 50,000 Hz it is important to avoid long connections.

The relay is any type with a 6V coil and current rated for values between 10 and 100 mA.

Position of the polarized components, such as the diode and electrolytic capacitor, should be observed.

To use:

Wire the output of an audio generator or audio oscillator to points X and Y. The signal should have amplitude in a range between 100 mV and 1 V peak-to-peak for best results. Adjust P1 to trigger the relay. Reduce the signal amplitude and trim P1 for the best performance.

Ideas to Explore

To get better performance or to learn more about the circuit:

- Explain how a PLL (Phase-Locked Loop) works.
- What are harmonics of a signal?

Science and uncommon uses:

- Remote sensors can be used to close the relay. Using an oscillator to produce the tone, the wires used can be very long, reaching distances up to 5 miles.

- You can use a small oscillator as transmitter and this circuit as part of a receiver to activate devices by telephone line.

- Connect the input of this circuit to the output of an audio amplifier. Plug a microphone to the input of the amplifier. With some practice you can control the relay by whistling.

- You can also use this tone-activated relay to control appliances from your computer, using the multimedia audio output. Write a program to produce a tone when an icon on your Windows screen is clicked with the mouse.

- The tone can be used to turn on the relay if the circuit is plugged to the audio output of your computer. Three modes of operation are possible:

a) By adjusting the length of the tone pulse you can turn on any appliance connected to the relay during this time interval. The appliance will turn off after the pulse ends.

b) Using a monostable with a 555 timer, for instance, a short pulse can turn on the appliance after a preadjusted time interval.

c) Using the turn-on-and-off circuit, described in this book, you'll have a bistable operation: a click on the icon turns on the appliance controlled by the relay, and the next click turns it off.

LIGHT COMPARATOR (E)

This device can be used to compare two light sources by their intensities. Several optical experiments can be conducted using this. You can compare colors of surfaces by reflected light or compare colors using special filters.

The sensors used are CdS photoresistors or LDRs (Light Dependent Resistors) that have peak sensitivity in the red part of the spectrum (7350 angstroms or 735 nm).

As the name suggests, the LDR has a resistance which varies as light falls on its sensitive surface. As the light intensity increases, resistance falls. In total darkness resistance can be high as 1,000,000 ohms or more. Illuminated by direct solar light, the resistance falls to 100 ohms or less.

Our circuit is a simple Wheatstone Bridge equilibrated by two LDRs and an adjustable potentiometer (P1).

When the two LDRs are receiving the same amount of light, P1 can be adjusted to get a null indication on the ammeter (M1).

If we use one LDR as reference, we can compare another source of light with this by using the other LDR as sensor. A new adjustment of P1 can reveal the difference between the two light sources.

The schematic diagram of the light comparator is shown in ***Figure 1***. No transistors are used in this project—only resistors.

Components layout, using a terminal strip as chassis, is shown in ***Figure 2***. The terminal strip can be fixed in the plastic box using screws. Wires to the sensor can be as long as 6 feet without instability problems.

The LDRs should be mounted into two small opaque tubes to receive light from different sources without outside interference. M1 should be a zero-center microammeter. A 50-0-50 uA microammeter would be suitable.

The circuit can be powered from two or four AA cells, and current drain is very low, extending battery life to many months.

B1	- 3 to 6V - two or four AA cells

Ideas to Explore

To learn more about the circuit or to get better performance:

- Use other types of sensors, such as phototransistors in the circuit. What is the difference?
- Explain how an LDR or CdS cell operates.
- Use a convergent lens in front of the cells for more sensitivity.

Science projects:

- Several experiments involving light sources in optics can be made using this circuit.
- Compare the reflections from paper using different but equal-power light sources, such as incandescent and fluorescent. Which of them has the better performance?
- It is possible to change this circuit into a temperature comparator. Just replace the LDRs with NTCs.

ELECTRONIC ORGAN (E/P)

This is an interesting experiment in audio which would make a nice toy for children.

This circuit produces a musical note by pressing a key on a keyboard. The sound is produced by a small speaker.

The electronic organ will play only one note at a time, but the number of notes is unlimited.

Different tones can be selected by pressing different keys, as in a common electronic organ. Tonal range is determined by C1, which can be altered within a large range of values. Values between 0.022 uF (for higher notes) and 1 uF (for lower notes) can be experimented.

You can also use this circuit as a multi-tone bell in your home or to monitor several places at the same time. Replacing the keys with different sensors (reed switches, for instance) will produce different tones when closed.

A schematic diagram of the simple Electronic Organ is given in ***Figure 1***. The circuit consistis of a simple two-transistor oscillator. The transistors are direct- coupled and drive a small loudspeaker.

Components layout, using a terminal strip as chassis is, shown in ***Figure 2***. The circuit can be housed in the same box as the keyboard.

In ***Figure 3*** we show the layout of the keyboard. Each trimmer potentiometer is used to adjust individual notes.

The circuit can be powered from AA cells or a power supply ranging from 3 to 6 volts.

The keyboard can also be made from a printed-circuit board or with small metal plates. When each metal plate is touched by a probe the corresponding circuit closes and a musical tone is produced.

R1 - 10,000 ohm, 1/4W, 5% resistor

C1 - 0.047 uF ceramic or metal film capacitor

C2 - 100 uF, 12 WVDC electrolytic capacitor

S5 - SPST toggle or slide switch

B1 - 3 or 6V - AA cells

SPKR - 4/8 ohm, 2 to 4 in. - small loudspeaker

Ideas to Explore

To learn more about the circuit or to get better performance:

- Alter C1 in the range given in the text to produce a different range of sounds.
- Explain how the circuit works.
- Try to replace R1 with a network formed by small transformers, diodes, resistors, capacitors and other components. Modifications in the tone pitch could be found this way.

Science and uncommon applications:

- Replace S1, S2, etc., with different kinds of switches. You can identify the closed switch by the tone.
- Use only one potentiometer coupled to a cursor. You can produce music by rapidly changing cursor position and pressing the series switch.
- The same keyboard can be used in other audio oscillators, resulting in different configurations of electronic organ.

EXPERIMENTAL LIGHT-ALARM (E)

This circuit consists of a simple but effective light-activated alarm which uses only a half dozen components. A light falling on the LDR turns on the SCR. The lamp will remain on until the power is off or S1 is used to reset the circuit.

P1 adjusts sensitivity according to the application. To get better performance the LDR can be housed in an opaque tube with a convergent lens.

A 6-volt lamp can be used without problems since there is a voltage drop of about 2 volts when in the ON state.

The schematic diagram is shown in ***Figure 1***. S1 is optional, as you can reset the circuit by turning off the power supply.

Components layout, using a terminal strip, is shown in ***Figure 2***. The lamp can be replaced by an LED in series with a 470 ohm resistor or a buzzer. You also can control an audio oscillator, replacing the lamp with it.

The lamp isn't a critical component. Any 6V lamp ranging from 50 to 250 mA can be used.

The LDR is a common CdS photoresistor. The SCR needn't be mounted on a heatsink as the current is very low.

Figure 2

Ideas to Explore

To learn more about the circuit or to get better performance:

- Replace X1 with a 6V relay to control external loads. Wire a 1N914 diode in parallel with the relay coil to prevent high-voltage kick from damaging the SCR. You can also control small audio oscillators or other devices.
- Change position of the LDR with P1 to get a dark-activated alarm.
- Explain how LDRs (Light Dependent Resistors) work.
- Replace the LDR with a phototransistor. Will the circuit operate as you want?

Science projects:

- This circuit can be used to monitor traps or events that involve object or animal movements.
- Several LDRs can be wired in parallel to monitor more than one place at the same time. In a dark-activated alarm, when P1 switches position with the LDR, more than one LDR can also be used. But, in this case, you must wire the LDRs in series.

PHOTOMETER (E/P)

Some of the most common applications for LDRs are as sensing elements in alarms, photo-relays, counters, light meters for photography and also experiments in optics.

The project described here is a simple light meter made from an LDR (Light Dependent Resistor or Photoresistor), a 0-200 uA microammeter, and a 3V battery formed by two AA cells.

Use any general-purpose LDR with a high dark-to-light resistance ratio.

Since the circuit is operating for short durations you don't need an ON-OFF switch. Just put the cells in the battery holder when using the unit.

P1 adjusts sensitivity to the range of your working light intensity.

Figure 1 shows the schematic of the Photometer. The ammeter is not critical. Any type with full scale ranging from 100 uA to 1 mA can be used.

Figure 2 shows a mounting view, using a terminal strip as chassis. The device can be housed in a small plastic box. The meter and LDR are placed on the front panel.

If the ammeter used is out of specification, you need to adjust P1. Try values between 10,000 and 100,000 ohms. The LDR can be housed in a small opaque tube, depending on the application.

Ideas to Explore

To get better performance or to learn more about the circuit:

- Try to use a phototransistor in place of the LDR.
- Replace the ammeter by a common multimeter.
- You can replace the LDR by an NTC and convert the device into a temperature meter.

Science projects using the device:

- Any experiment that involves light measurement can be conducted using this device.
- You can calibrate the meter scale using a common photography photometer as reference.

SEQUENCE GENERATOR (E/P)

An astable multivibrator, put to work by using it as a source of clock pulses for a 4017 counter, is the basis for this circuit.

We can use it to generate random numbers in a range of one-of-ten or as a 0-to-9 counter in science projects or in other applications.

You can also adjust the clock so that it supplies one pulse each second for using the circuit as a timer in scientific experiments or at home. If you alter the clock pulse frequency, time range can be changed so that it supplies one pulse each minute or ten minutes. In this case, the time range will rise to 9 minutes or 90 minutes (in 1- or 10-minute steps)!

As a sequence generator in logic circuits demonstrations, you can change the astable operation of the 555 to monostable, connecting a momentary switch or any sensor that can be used to trigger it.

The circuit can be powered from 6 to 12V supplies, and R3 depends upon the voltage of the power supply. Use a 470 ohm resistor if the supply voltage is 6V. Use a 1,000 ohm resistor if the power supply used is 12V.

Capacitor C1 determines the pulse rate range and can be altered. Values between 1 and 1,000 uF can be used. Remember that higher values mean lower pulse rate.

P1 adjusts the pulse rate within 100:1, depending on the capacitor used.

Figure 1 shows the schematic diagram of the Sequence Generator. The circuit uses a 555 IC timer to generate the clock pulses and a 4017 CMOS IC, a counter and 1-of-10 decoder to drive ten LEDs as indicators.

Components placement on a homemade printed-circuit board is shown in ***Figure 2***. You can also use a solderless board or breadboard to mount it.

Positions of the polarized pieces, such as the LEDs and electrolytic capacitor, should be observed.

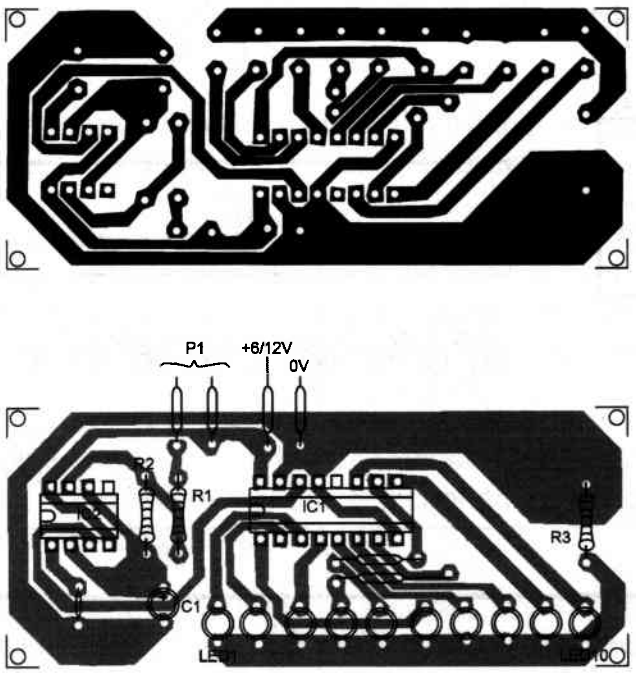

Figure 2

Ideas to Explore

To learn more about the circuit or to get better performance:

- Wire a momentary switch between IC1's pin 3 and IC2's pin 14 to control the counter. You can stop the counter any time with this switch.
- Explain how counters such as the 4017 work.
- Could you alter the circuit so that it counts to any value between 2 and 9?

Science and uncommon uses:

- Wire the 555 as a monostable multivibrator and use an LDR as sensor to trigger it. The circuit will operate as a pulse-of-light counter.
- Use this circuit in a project about computers. You can produce pulses to be counted using the experimental flip-flop described in this book.
- Experiments on ESP (Extra-Sensory Perception) can be conducted using this circuit. Random numbers in a scale of 1-to-10 can be generated using this circuit.

SIGNAL INJECTOR (E/P)

If you're interested in doing some servicing on your audio equipment (multimedia, for instance) you will undoubtedly find this square wave generator to be a handy tool. You can also use this circuit in RF stages in AM/FM receivers, since the oscillator harmonics are strong in frequencies as high as 100 MHz.

In this arrangment, frequency is determined by capacitor C2, resistors R1 and R2, and D1. The frequency can be altered by the values of resistors and/or capacitors selected. In our circuit the oscillator runs at about 1,000 Hz.

The output signal waveform is square and the output swings the full power supply voltage, which can be anything between 3 and 12 volts (we recommend a 3-volt power supply if you want a portable unit). Supply current is typicaly 10 uA, extending battery life.

Figure 1 shows the complete schematic diagram of the Signal Injector. IC1 is a 555 timer, wired as an audio oscillator. Frequency is determined by C2, R2 and R1. You can change C2 within a large range of values.

Figure 2 shows the homemade PC board where the components are mounted. A small 3V battery can also be used if you want a very compact mounting.

A signal injector is used from the "back" to the "front" of an audio (or RF) circuit. For instance, to use the signal injector with an AM receiver, apply the signal from the probe at the base of the output transistor. If that stage and everything after it operates correctly the signal will be heard in the speaker. If the output stage proves to be OK, move back to the base of the driver transistor. The output signal will be higher if everything is working. Then, apply the signal progressively towards the front of the circuit by injecting it at the volume control, detector stage, IF stages and the mixer.

The circuit can be housed in a small plastic box and connected to the external circuit through a probe and an alligator clip. ***Figure 3*** represents a possible housing arrangement.

To test the signal injector, apply the signal to the input of any audio amplifier.

C3	- 0.01 uF ceramic or metal film capacitor
S1	- SPST toggle or slide switch
B1	- 3V - two AA cells
PP1	- Probe
G1	- Alligator clip

Ideas to Explore

To learn more about the circuit or to get better performance:

- What happens with the wave shape if D1 is removed?
- Why can the circuit be used in frequencies as high as 100 MHz if it generates a 1,000 Hz signal?
- Replace the IC with a common 555 (bipolar). The circuit will work, but the current drain is higher than in the original version.
- Remove C3 and power the circuit from a 5V power supply. The signal injector can now be used in TTL logic circuits.

- R1 and R2 are shown as fixed resistors in this project. You can change these resistors to a potentiometer (1,000,000 ohms, for instance) in series with a 1,000 ohm resistor to generate signals within a large range of frequencies and duty-cycles.

Science projects using the signal injector:

- The circuit can be used as a simple bio-stimulator in biological experiments. Stimulation levels as high as the power supply voltage can be achieved. These levels can be used in direct nerve stimulation.
- Wire a piezoelectric transducer or crystal earphone to the output of this signal injector. A tone of about 1,000 Hz will be produced and can be used in experiments.

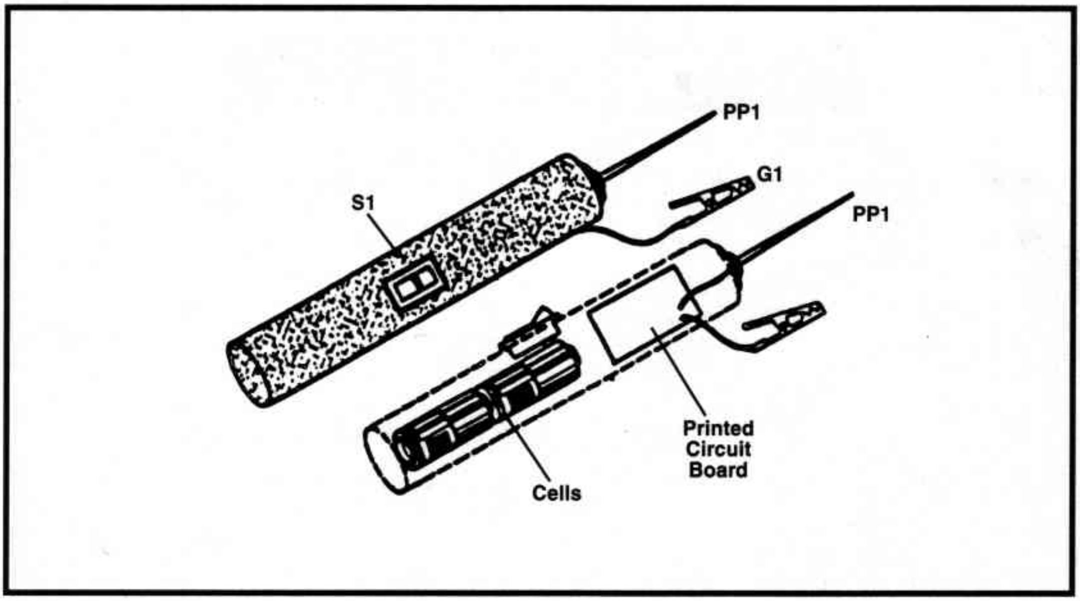

Figure 3

METAL DETECTOR (E)

You can use this simple metal detector to locate plumbing pipes, electrical wiring inside walls, find a lost watch or coin at the beach or even a treasure with gold coins buried years ago by pirates.

You can also use the circuit in experiments where you can show the magnetic properties of materials. The differences between paramagnetic, diamagnetic, and nonmagnetic materials can be shown. Interesting experiments can be conducted using the metal detector described here.

This circuit will detect the presence of metallic objects through any nonconductive material such as dirt, wood, stone, plaster or plastic.

With a little practice, you will be able to detect metallic objects to depths of over several inches and will give you a fairly good idea of their size.

Our circuit uses the beat-frequency method to detect an object.

The frequency of the search coil oscillator changes when the conductance in the field of the search coil changes. Therefore, when metals come within a short distance of the coil, the frequency is changed, which in turn changes the pitch of the audible sound.

The sound is produced by the speaker of a common AM receiver that tunes the coil oscillator.

A schematic diagram of the Metal Detector is shown in ***Figure 1***. Observe that the circuit is a very simple one-transistor oscillator. You can also use a general-purpose PNP silicon transistor, inverting the power supply polarity.

The physical arrangment of the electronic components, using a terminal strip as chassis, is shown in ***Figure 2***. The critical part of this project is the search coil.

The search coil is wound in a large 6-inch plastic Frisbee. Begin by securing one end of the enameled magnet wire form (18 to 22 AWG) with masking tape. On the tenth wrap (halfway) form a loop in the magnet wire for the center tap, then continue until you complete the 20 turns of wire.

Figure 2

It is very important to secure the coil wire firmly, as one loose loop in the coil will cause the detector to be unstable.

To use:

Fix a small portable radio close to the oscillator as shown in ***Figure 3***.

Tune the radio to a free point of the range between 550 and 1,600 kHz. Adjust CV in the search coil oscillator to tune this signal as a whistle. If you can't find the oscillator signal in the AM band, reduce or enlarge the search coil by a few turns.

Passing the search coil over a metallic object will change the pitch of the whistle. When the most pronounced change occurs, you should be directly over the metal object.

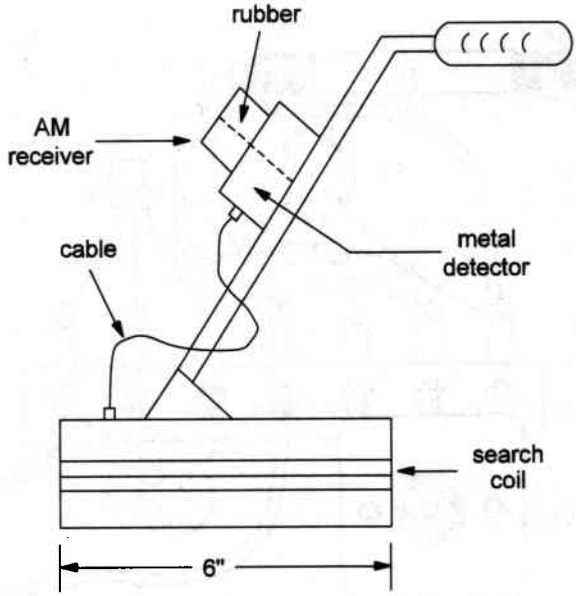

Figure 3

Parts List — Metal Detector

Q1 - BC548 general-purpose NPN silicon transistor

L1 - Search coil - see text

CV - 365 pF - any variable capacitor (from nonworking AM radio)

C1 - 2,200 pF ceramic capacitor

C2 - 0.1 uF ceramic capacitor

R1 - 10,000 ohm, 1/4W, 5% resistor

S1 - SPST slide or toggle switch

B1 - 6 or 9V - four AA cells or 9V battery

Ideas to Explore

To get better performance or to learn more about the circuit:

- Make experiments with different kinds of materials to see how the detector works with each one.
- Explain what happens when a metal object is introduced in a magnetic field. Is there any way to identify the metal being detected?
- The circuit can also be used as an RF signal generator. To get the signal from this oscillator, connect a probe to the collector of the transistor with a 1,000 pF capacitor and an alligator clip to the emitter.

Science projects and uncommon applications:

- Several experiments involving metal detection can be conducted using this simple metal detector. An example would be a work to show the differences between paramagnetic, diamagnetic and non-magnetic materials, as suggested earlier.

- The search coil can be modified to apply RF signals to plants or animals. Experiments to find the effects of RF (Radio Frequency) on seed germination or plant growth can be made with this circuit.

CRYSTAL SET (E)

A complete radio AM receiver which requires no battery power at all can be created with a few components. The classic circuit of the well-known crystal radio or crystal receiver can be based on a germanium diode as detector, or if you prefer, the original galena crystal.

Figure 1 shows the classic circuit. L1 is a proprietary antenna tuning coil wound on a paper tube and C1 is a matching variable capacitor (365 to 500 pF). A variable capacitor can be found in old non-working transistor radios. You can also find the diode in these sets and use it for this project.

Virtually any diode can be used, and the only other circuit component is capacitor C1, connected across the output. The earphones must be a high-impedance type (headphones).

An external aerial and good physical ground connection is essential for good reception.

The circuit will tune AM band radio stations not far from your home.

Component layout is shown in ***Figure 2***.

L1 is formed by 100 turns of No. 22 to 28 AWG enamelled wire on a 1-inch diameter paper tube.

Ideas to Explore

To learn more about the circuit or to get better performance:

- Use an audio amplifier to get better reception.
- Replace the coil by 100 turns of No. 22 to 28 wire on a ferrite rod.

Science projects:

- This set can be used to demonstrate how old-time radio receivers operated. Explain how a galena detector works.

TEMPERATURE-CONTROLLED OSCILLATOR (E)

You can conduct interesting experiments with this temperature-dependent oscillator. Tone pitch depends upon the temperature of a sensor. The sensor is a common general-purpose silicon diode. The reverse resistance of this diode is slight, dependent on the junction temperature. The circuit can operate in a temperature range typically between -20 and +100 degrees Celsius.

Frequency range depends upon C1. This component can be altered in a large range of values. Values between 0.01 and 0.47 uF can be substituted to produce tones in the audio range.

If you want to produce “clicks” with a rate dependent upon the temperature of the sensor, try capacitors with values between 0.47 and 1 uF. Metal film or ceramic capacitors can be used in this circuit.

By adjusting P1 you can put the oscillator near the point where it begins to run. Then, any temperature rise will trigger the oscillator, making it operate as a temperature alarm.

The circuit can be powered from two or four AA cells, and current drain is low.

The sensor is any general-purpose silicon diode. The diode can be protected against moisture and water.

The schematic diagram of the Temperature-Controlled Oscillator is shown in ***Figure 1***. The sensor can be wired to the circuit by a long twisted-pair wire for remote operation.

Components layout, using a terminal strip as chassis, is shown in ***Figure 2***. As the circuit is intended for experimental purposes, you can also mount it on a solderless board.

Position of polarized components, such as the diode and power supply, should be observed.

Ideas to Explore

To learn more about the circuit or to get better performance:

- By replacing D1 with an LDR or phototransistor the circuit will operate as a light-controlled oscillator.
- Explain why the resistance of the sensor varies with temperature, controlling this circuit.
- Replace the diode with a transistor (conection is made using collector and emitter terminals). Explain why this device can also be used as a temperature sensor.

Science projects or uncommon uses:

- You can use this circuit as a biofeedback device by replacing the sensor with two electrodes. The subject, holding the sensor in hand, can learn how to control the tone through stress and breathing management. The circuit also operates as a lie detector using this configuration.

- Any experiment involving temperature variations can be conducted using this circuit.

FREQUENCY-MODULATION SIREN (E/P)

Acting on a capacitor charging, one oscillator (pins 1,2 and 3 of IC1) can modulate another oscillator in frequency, as described in this project. The produced tones thus run from high to low and vice-versa at a rate determined by the first oscillator frequency and also by P1 and P2 adjustments.

The circuit can be used as a siren, part of alarms, games and many other applications. With a 12V power supply the output power is up to a wattage representing an excellent audio level in a loudspeaker.

The basic circuit has tone, modulation rate and depth adjusted by trimmer potentiometer. There are also some components that can be changed to alter the performance of the siren. C1, for instance, determines modulation rate and can range from 1 to 47 uF. C2 determines modulation depth and rate and can also be altered within a large range of values. C3 determine tone frequency, ranging from 0.01 to 0.1 uF.

Power supply can range from 6 to 12V. With a 12V power supply current drain is as high as 2 or 3 amps. F1 is important to prevent problems with shorts.

Q1 is a power FET and equivalents can be used. You also can replace this transistor with a Darlington NPN power transistor such as TIP110, but you must also add a series resistor with base terminal. Use a 10,000 ohm resistor for this task.

The schematic for the Frequency-Modulation Siren is shown in ***Figure 1***. Observe that two gates are used as oscillators and the other two of a 4093B IC are used as buffer-inverters.

Components placement on a homemade printed-circuit board is shown in ***Figure 2***. For experimental purposes the circuit can also be mounted on a solderless board, and it is important to place the transistor on a large heatsink.

Position of the polarized components, such as electrolytic capacitors, should be observed.

The speaker should be a high-power type for better performance. Installing it in an enclosure will provide better sound level.

Ideas to Explore

To learn more about the circuit or to get better performance:

- Explain how Power FETs work.
- Alter C1, C2 and C3 to create new sounds.

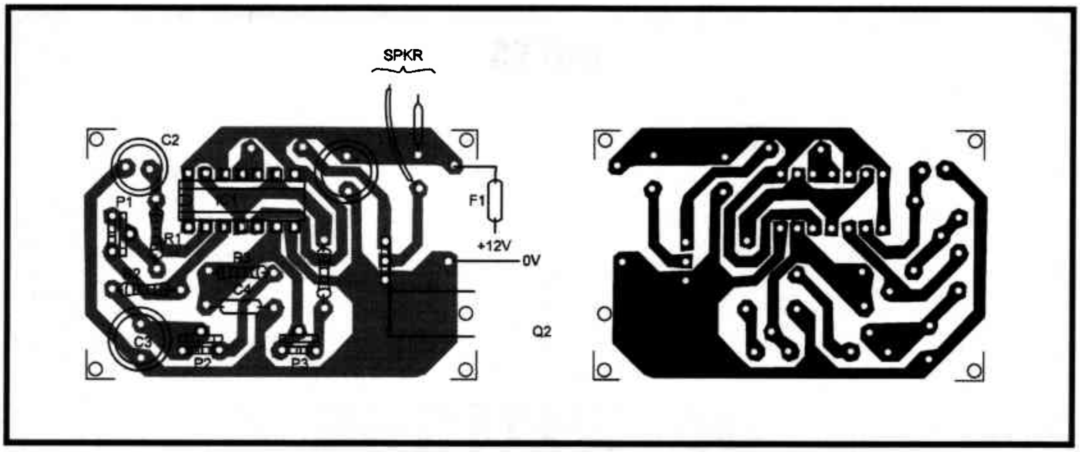

Figure 2

- Wire pins 1 and 5 together and to an external control circuit. The siren can be controlled by external logic circuits.

- Determine the logic level in pins 10 and 11 when pins 1 and 5 go low. What will happen with current drain in this case?

- Replace Q1 by a TIP31 or BD135 to operate with less power. The power supply should be reduced to 6 or 9V in this case.

Science projects and uncommon applications:

- Replace R1 with an LDR and experiment with a light-controlled siren.

- Use this siren as part of alarms.

- Using this siren you can generate special sounds to experiment with animal conditioning.

- Modulated ultrasounds can be produced by reducing C4 to values as low as 2,200 or 4,700 pF.

COIN TOSSER (E/P)

This circuit simulates the flipping of a coin by merely pressing S1. Of course, the electronic version, if used for important decisions (or experiments), can't be loaded or weighted and is 100% random.

The circuit has two LEDs that flick alternatingly, in a frequency rate determined by C1, when power is ON. When you press S1 the circuit stops immediately and only one LED remains ON.

Power supply can range from 5 to 12 volts, and this means that you can use AA cells in a portable version.

Some components can be altered according to the intended application: C1, for instance can be altered in a range from 0.01 to 0.47 uF. You can also use a touch sensor to stop the tosser or increase R1's value to up to 10,000,000 ohms.

The schematic diagram for the coin tosser is shown in ***Figure 1***. Only one gate a 4093 IC is used as oscillator to produce random pulses in this circuit.

Components placement on a homemade printed-circuit board is shown in ***Figure 2***. The circuit can easily be housed in a small plastic box.

Position of the polarized components, such as the LEDs and electrolytic capacitor, should be observed.

Ideas to Explore

To learn more about the circuit or to get better performance:

- Instead of using LEDs, transistors can be used to drive incandescent lamps.

- S1 can be placed as far as you want from the circuit. Common parallel wire can be used for this task.

- Explain how a flip-flop works and how you can guarantee that the circuit is 100% random.

Science and uncommon applications:

- You can conduct ESP (Extra-Sensory Perception) experiments using this circuit. S1 can be placed far from the LEDs for better results.
- Experiments with probability theory can be conducted using this circuit.
- Try to couple a sequence generator to the oscillator used in this circuit to get a 1-to-10 raffle circuit.

PLASMA OSCILLATOR (E)

A flame is a conductive medium that can be used in an uncommon feedback loop to control the frequency of an audio oscillator. This configuration can be used as a confirmation of the conductivity of a flame.

The audio oscillator described in this project is controlled by the "fourth" matter state, the "plasma" or an ionized gas, and can be used as part of an interesting experiment in physics.

The flame can be produced by a simple match or a candle and the flickering effect will modulate the generated sound.

The circuit runs in frequencies between 1 and 500 Hz, depending on the electrodes and flame positions.

A schematic diagram of the Plasma Oscillator is shown in ***Figure 1.*** The high input impedance of a 4093B is fundamental in this project. A flame typically has a resistance in the range of tenths of megohms.

The printed circuit board for the components positioning is shown in ***Figure 2***.

Sensor details are also given in that figure. Two wires, one placed near the other, with about 1 inch of bared length as shown in the figure, form the "plasma sensor". The flame should involve the two bared wires at the same time to allow the feedback current to flow and the oscillator to operate.

An output stage using a piezoelectric transducer can replace the transistor and loudspeaker. With a lower current drain this configuration can be powered from four AA cells or a 9V battery.

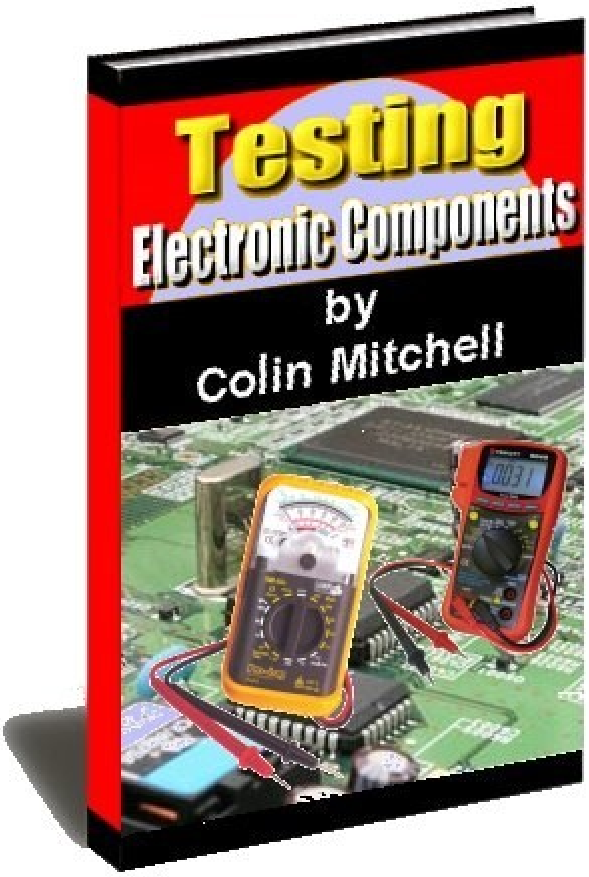
Ideas to Explore

To get better performance or to learn more about the circuit:

- Explain why the circuit doesn't operate using a neon or fluorescent lamp as a plasma medium.
- Explain what "plasma" is.
- You can alter this circuit to use it as a flame alarm.

Science applications:

- Off course, the basic idea of this project is to use it in an experiment involving plasma. Plasma is produced when an ionized gas loses electrons. The the gas converts in a "soup" of free electrons and ionized atoms.
- Use different kinds of flames, such as those produced by matches, gas, paper, etc., and compare their conductivity by the tone pitch.



This eBook shows you how to TEST COMPONENTS.
To do this you need "TEST GEAR." The best item of Test Gear is a MULTIMETER. It can test almost 90% of all components. And that's what we will do in this eBook:

MULTIMETERS

There are two types:

DIGITAL and ANALOGUE

A **Digital Multimeter** has a set of digits on the display and an Analogue Multimeter has a scale with a pointer (or needle).

You really need both types to cover the number of tests needed for designing and repair-work. We will discuss how they work, how to use them and some of the differences between them.

024
UNI-T
6.43

DIGITAL AND ANALOGUE MULTIMETERS

BUYING A MULTIMETER

There are many different types on the market.
The cost is determined by the number of ranges and also the extra features such as diode tester, buzzer (continuity), transistor tester, high DC current and others.
Since most multimeters are reliable and accurate, buy one with the greatest number of ranges at the lowest cost.
This article explains the difference between a cheap analogue meter, an expensive analogue meter and a digital meter. You will then be able to work out which two meters you should buy.

Multimeters are sometimes called a "meter", a "VOM" (Volts-Ohms-Milliamps or Volt Ohm Meter) or "multi-tester" or even "a tester" - they are all the same.

USING A MULTIMETER

Analogue and digital multimeters have either a rotary selector switch or push buttons to select the appropriate function and range. Some Digital Multimeter (DMMs) are auto ranging; they automatically select the correct range of voltage, resistance, or current when doing a test. However you need to select the function.

Before making any measurement you need to know what you are checking. If you are measuring voltage, select the AC range (10v, 50v, 250v, or 1000v) or DC range (0.5v, 2.5v, 10v, 50v, 250v, or 1000v). If you are measuring resistance, select the Ohms range (x1, x10, x100, x1k, x10k). If you are measuring current, select the appropriate current range DCmA 0.5mA, 50mA, 500mA. Every multimeter is different however the photo below shows a low cost meter with the basic ranges.

AC10V
dB
2kΩ/V DC AC
0dB:1mW600Ω

The most important point to remember is this:
You must select a voltage or current range that is bigger or HIGHER than the maximum expected value, so the needle does not swing across the scale and hit the "end stop."
If you are using a DMM (Digital Multi Meter), the meter will indicate if the voltage or current is higher than the selected scale, by showing "OL" - this means "Overload." If you are measuring resistance such as 1M on the x10 range the "OL" means "Open Loop" and you will need to change the range. Some meters show "1' on the display when the measurement is higher than the display will indicate and some flash a set of digits to show over-voltage or over-current. A "-1" indicates the leads should be reversed for a "positive reading."
If it is an AUTO RANGING meter, it will automatically produce a reading, otherwise the selector switch must be changed to another range.

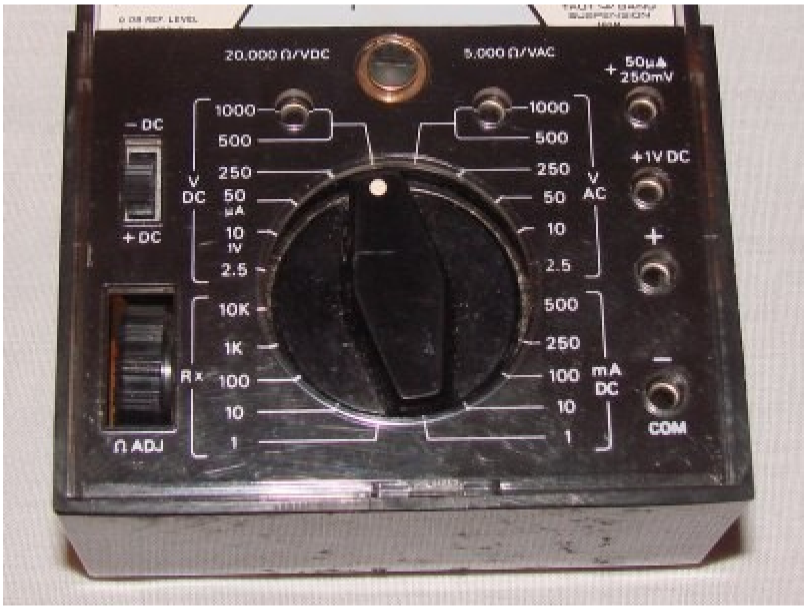
The Common (negative) lead ALWAYS fits into
the "COM" socket. The red lead fits into the
red socket for Voltage and Resistance.
Place the red lead (red banana plug)
into "A" (for HIGH CURRENT "Amps")
or mA,uA for LOW CURRENT.

The black "test lead" plugs into the socket marked "-" "Common", or "Com," and the red "test lead" plugs into meter socket marked "+" or "V-W-mA." The third banana socket measures HIGH CURRENT and the positive (red lead) plugs into this. You DO NOT move the negative "-" lead at any time. The following two photos show the test leads fitted to a digital meter. The probes and plugs have "guards" surrounding the probe tips and also the plugs so you can measure high voltages without getting near the voltage-source.

FLUKE
600.0
COM
10ADC

Analogue meters have an "Ohms Adjustment" to allow for the change in voltage of the battery inside the meter (as it gets old).



"Ohms Adjust" is also called "ZERO SET"
The sensitivity of this meter is 20,000ohms/volt
on the DC ranges and 5k/v on the AC ranges

Before taking a resistance reading (each time on any of the Ohms scales) you need to "ZERO SET" the scale, by touching the two probes together and adjust the pot until the needle reads "0" (swings FULL SCALE). If the pointer does not reach full scale, the batteries need replacing. Digital multimeters do not need "zero adjustment."

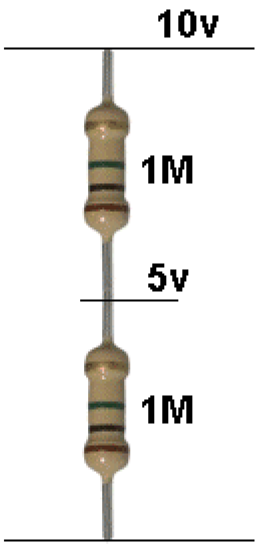
MEASURING VOLTAGE

Most of the readings taken with a multimeter will be VOLTAGE readings.
Before taking a reading, you should select the highest range and if the needle does not move up scale (to the right), you can select another range.
Always switch to the highest range before probing a circuit and keep your fingers away from the component being tested.
If the meter is Digital, select the highest range or use the auto-ranging feature, by selecting "V." The meter will automatically produce a result, even if the voltage is AC or DC.
If the meter is not auto-ranging, you will have to select V⎓ if the voltage is from a DC source or V~ if the voltage is from an AC source. DC means Direct Current and the voltage is coming from a battery or supply where the voltage is steady and not changing and AC means Alternating Current where the voltage is coming from a voltage that is rising and falling.
You can measure the voltage at different points in a circuit by connecting the black probe to chassis. This is the 0v reference and is commonly called "Chassis" or "Earth" or "Ground" or "0v."
The red lead is called the "measuring lead" or "measuring probe" and it can measure voltages at any point in a circuit. Sometimes there are "test points" on a circuit and these are wires or loops designed to hold the tip of the red probe (or a red probe fitted with a mini clip).
You can also measure voltages ACROSS A COMPONENT. In other words, the reading is taken in PARALLEL with the component. It may be the voltage across a transistor, resistor, capacitor, diode or coil. In most cases this voltage will be less than the supply voltage.
If you are measuring the voltage in a circuit that has a HIGH IMPEDANCE, the reading will be inaccurate, up to 90% !!!, if you use a cheap analogue meter.

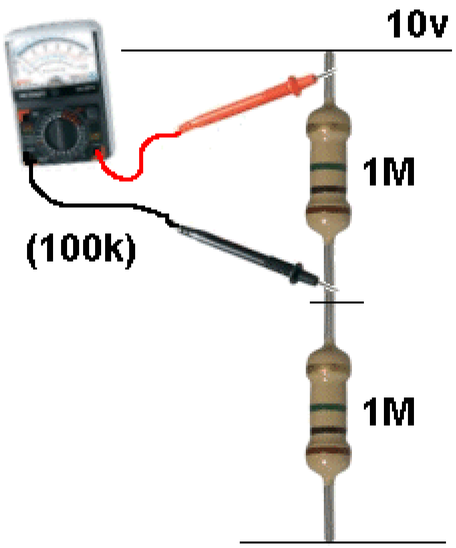
Here's a simple case.

The circuit below consists of two 1M resistors in series. The voltage at the mid point will be 5v when nothing is connected to the mid point. But if we use a cheap analogue multimeter set to 10v, the resistance of the meter will be about 100k, if the meter has a sensitivity of 10k/v and the reading will be incorrect.
Here how it works:
Every meter has a sensitivity. The sensitivity of the meter is the sensitivity of the movement and is the amount of current required to deflect the needle FULL SCALE.
This current is very small, normally 1/10th of a milliamp and corresponds to a sensitivity of 10k/volt (or 1/30th mA, for a sensitivity of 30k/v).
If an analogue meter is set to 10v, the internal resistance of the meter will be 100k for a 10k/v movement.
If this multimeter is used to test the following circuit, the reading will be inaccurate.

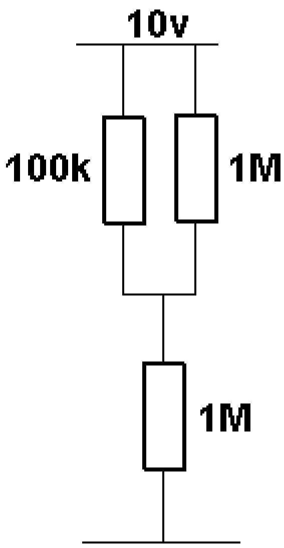
The reading should be 5v as show in diagram **A**.
But the analogue multimeter has an internal resistance of 100k and it creates a circuit shown in **C**.
The top 1M and 100k from the meter create a combined PARALLEL resistance of 90k. This forms a series circuit with the lower 1M and the meter will read less than 1v
If we measure the voltage across the lower 1M, the 100k meter will form a value of resistance with the lower 1M and it will read less than 1v
If the multimeter is 30k/v, the readings will be 2v. See how easy it is to get a totally inaccurate reading.



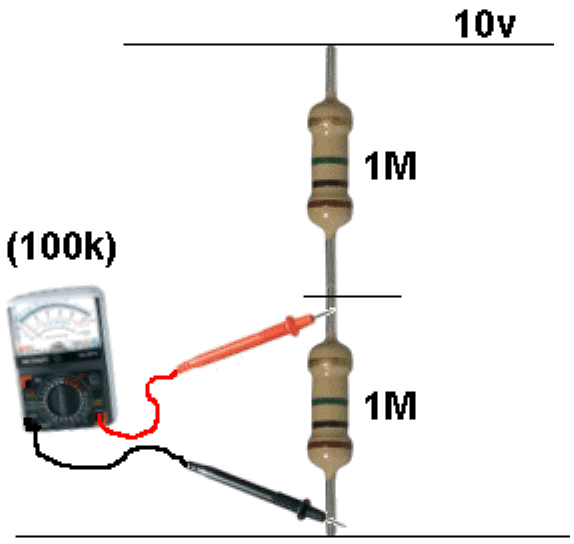
A



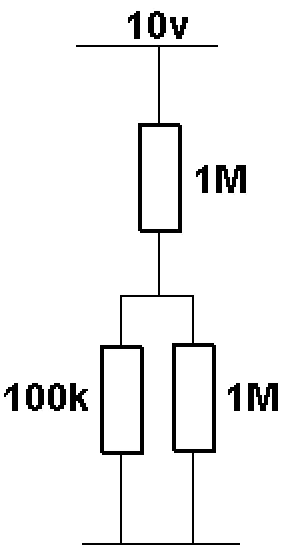
B



C



D



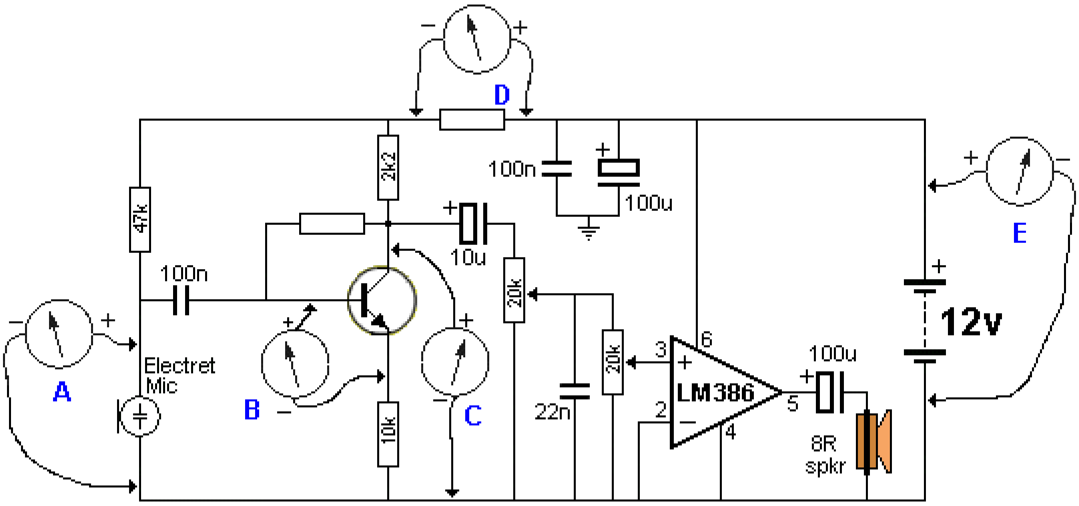
E

This introduces two new terms:
HIGH IMPEDANCE CIRCUIT and "RESISTORS in SERIES and PARALLEL."

If the reading is taken with a Digital Meter, it will be more accurate as a DMM does not take any current from the circuit (to activate the meter). In other words it has a very HIGH input impedance. Most Digital Multimeters have a fixed input resistance (impedance) of 10M - no matter what scale is selected. That's the reason for choosing a DMM for high impedance circuits. It also gives a reading that is accurate to about 1%.

MEASURING VOLTAGES IN A CIRCUIT

You can take many voltage-measurements in a circuit. You can measure "across" a component, or between any point in a circuit and either the positive rail or earth rail (0v rail). In the following circuit, the 5 most important voltage-measurements are shown. Voltage "A" is across the electret microphone. It should be between 20mV and 500mV. Voltage "B" should be about 0.6v. Voltage "C" should be about half-rail voltage. This allows the transistor to amplify both the positive and negative parts of the waveform. Voltage "D" should be about 1-3v. Voltage "E" should be the battery voltage of 12v.

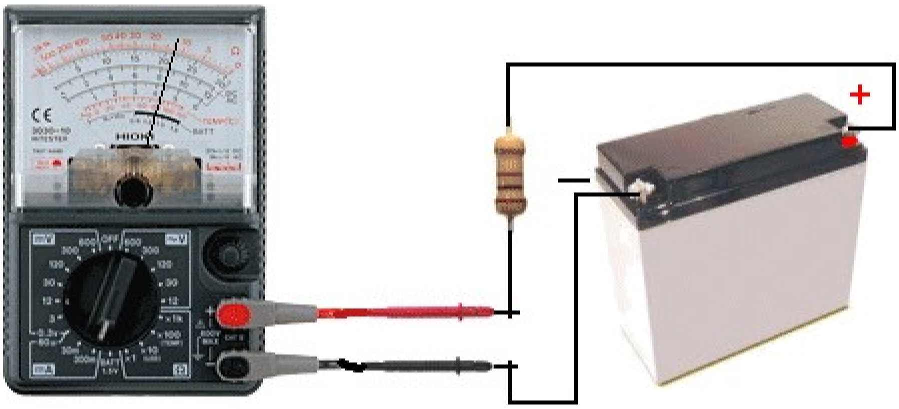


MEASURING VOLTAGES IN A CIRCUIT

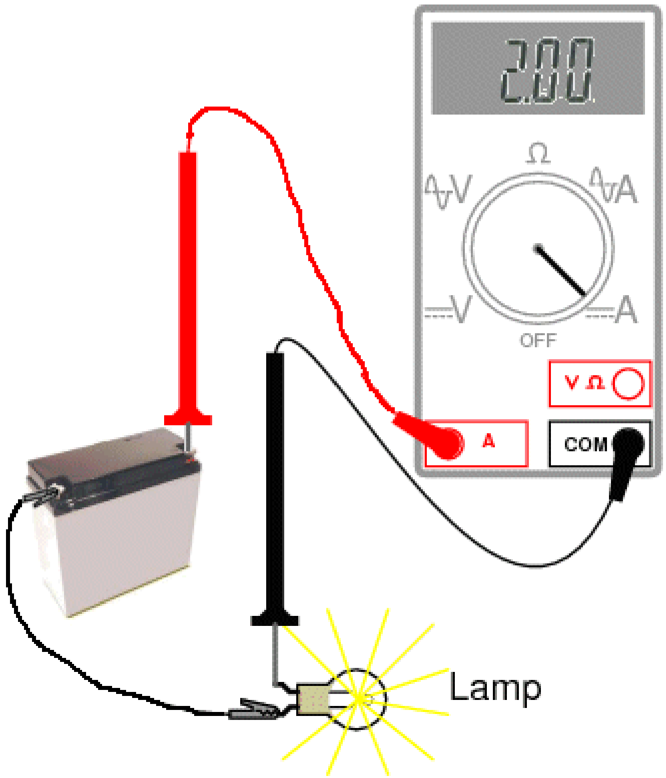
MEASURING CURRENT

You will rarely need to take current measurements, however most multimeters have DC current ranges such as 0.5mA, 50mA, 500mA and 10Amp (via the extra banana socket) and some meters have AC current ranges. Measuring the current of a circuit will tell you a lot of things. If you know the normal current, a high or low current can let you know if the circuit is overloaded or not fully operational.

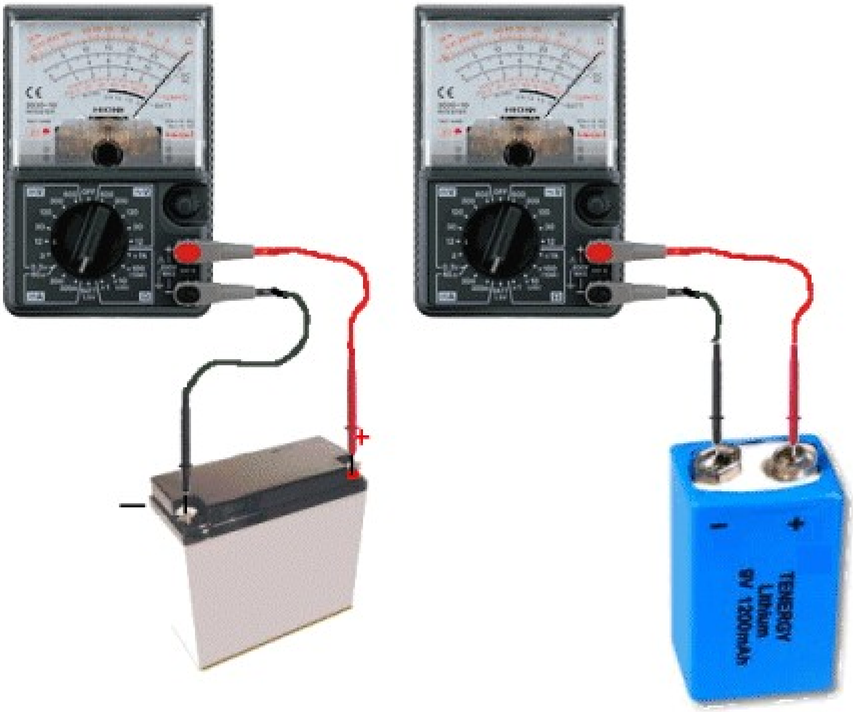
Current is always measured when the circuit is working (i.e: with power applied).
It is measured IN SERIES with the circuit or component under test.
The easiest way to measure current is to remove the fuse and take a reading across the fuse-holder.
Or remove one lead of the battery or turn the project off, and measure across the switch.
If this is not possible, you will need to remove one end of a component and measure with the two probes in the "opening."
Resistors are the easiest things to desolder, but you may have to cut a track in some circuits. You have to get an "opening" so that a current reading can be taken.
The following diagrams show how to connect the probes to take a CURRENT reading.
Do not measure the current ACROSS a component as this will create a "short-circuit."
The component is designed to drop a certain voltage and when you place the probes across this component, you are effectively adding a "link" or "jumper" and the voltage at the left-side of the component will appear on the right-side. This voltage may be too high for the circuit being supplied and the result will be damage.



Measuring current through a resistor



Measuring the current of a globe



Do NOT measure the CURRENT of a battery
(by placing the meter directly across the terminals)
A battery will deliver a very HIGH current
and damage the meter

Do not measure the "current a battery will deliver" by placing the probes across the terminals. It will deliver a very high current and damage the meter instantly. There are special battery testing instruments for this purpose.
When measuring across an "opening" or "cut," place the red probe on the wire that supplies the voltage (and current) and the black probe on the other wire. This will produce a "POSITIVE" reading. A positive reading is an UPSCALE READING and the pointer will move across the scale - to the right. A "NEGATIVE READING" will make the pointer hit the "STOP" at the left of the scale and you will not get a reading. If you are using a Digital Meter, a negative sign "-" will appear on the screen to indicate the probes are around the wrong way. No damage will be caused. It just indicates the probes are

connected incorrectly.
If you want an accurate CURRENT MEASUREMENT, use a digital meter.

MEASURING RESISTANCE

Turn a circuit off before measuring resistance.
If any voltage is present, the value of resistance will be incorrect.
In most cases you cannot measure a component while it is in-circuit. This is because the meter is actually measuring a voltage across a component and calling it a "resistance." The voltage comes from the battery inside the meter. If any other voltage is present, the meter will produce a false reading.
If you are measuring the resistance of a component while still "in circuit," (with the power off) the reading will be lower than the true reading.

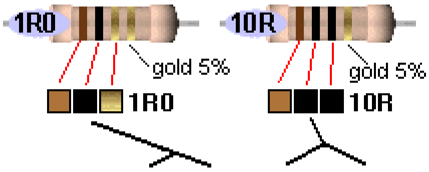
Do not measure the "Resistance of a Battery"

1. Do not measure the "resistance of a battery." The resistance of a battery (called the Internal impedance) is not measured as shown in the diagrams above. It is measured by creating a current-flow and measuring the voltage across the battery. Placing a multimeter set to **resistance** (across a battery) will destroy the meter.
2. Do not try to measure the resistance of any voltage or any "supply."

Resistance is measured in OHMs.
The resistance of a 1cm x 1cm bar, one metre long is 1 ohm.
If the bar is thinner, the resistance is higher. If the bar is longer, the resistance is higher.
If the material of the bar is changed, the resistance is higher.
When carbon is mixed with other elements, its resistance increases and this knowledge is used to make RESISTORS.
Resistors have RESISTANCE and the main purpose of a resistor is to reduce the CURRENT FLOW.
It's a bit like standing on a hose. The flow reduces.
When current flow is reduced, the output voltage is also reduced and that why the water does not spray up so high. Resistors are simple devices but they produce many different effects in a circuit.
A resistor of nearly pure carbon may be 1 ohm, but when non-conducting "impurities" are added, the same-size resistor may be 100 ohms, 1,000 ohms or 1 million ohms.
Circuits use values of less than 1 ohm to more than 22 million ohms.

Resistors are identified on a circuit with numbers and letters to show the exact value of resistance - such as 1k 2k2 4M7
The letter Ω (omega - a Greek symbol) is used to identify the word "Ohm."
but this symbol is not available on some word-processors, so the letter "R" is used. The letter "E" is also sometimes used and both mean "Ohms."



A one-ohm resistor is written "1R" or "1E." It can also be written "1R0" or "1E0."
A resistor of one-tenth of an ohm is written "0R1" or "0E1." The letter takes the place of the decimal point.
10 ohms = 10R
100 ohms = 100R
1,000 ohms = 1k (k= kilo = one thousand)
10,000 ohms = 10k
100,000 ohms = 100k
1,000,000 ohms = 1M (M = MEG = one million)

The size of a resistor has nothing to do with its resistance. The size determines the wattage of the resistor - how much heat it can dissipate without getting too hot.
Every resistor is identified by colour bands on the body, but when the resistor is a surface-mount device, numbers are used and sometimes letters.
You MUST learn the colour code for resistors and the following table shows all the colours for the most common resistors from 1/10th of an ohm to 22 Meg ohms for resistors with 5% and 10% tolerance.

If 3rd band is gold, Divide by 10
If 3rd band is silver, Divide by 100
(to get 0.22ohms etc)

COLOR CODES FOR THE WHOLE E12/E24 RANGE OF RESISTORS

The twelve odd rows - 1, 3, 5... - represent values available in the E12 range only, plus 10M

Reading 4-band resistors

The most "common" type of resistor has 4 bands and is called the 10% resistor. It now has a tolerance of 5% but is still called the "10% type" as the colours increase by 20% so that a resistor can be 10% higher or 10% lower than a particular value and all the resistors produced in a batch can be used.
The first 3 bands produce the resistance and the fourth band is the "tolerance" band. Gold = 5% (Silver =10% but no modern resistors are 10%!! - they are 5% 2% or 1%)

RESISTORS LESS THAN 10 OHMS

When the **third** band is gold, it indicates the value of the "colors" must be divided by 10.
Gold = "divide by 10" to get values 1R0 to 8R2
When the **third** band is silver, it indicates the value of the "colors" must be divided by 100.
(Remember: more letters in the word "silver" thus the divisor is "a larger division.")
Silver = "divide by 100" to get values R1 to R82
e.g: 0R1 = 0.1 ohm   0R22 = point 22 ohms
See 4th Column above for examples.

The letters "R, k and M" take the place of a decimal point.
e.g: 1**R**0 = 1 ohm   2**R**2 = 2 point 2 ohms   22**R** = 22 ohms
2**k**2 = 2,200 ohms   100**k** = 100,000 ohms
2**M**2 = 2,200,000 ohms

HOW TO REMEMBER THE COLOUR CODE:

Each colour has a "number" (or divisor) corresponding to it.
Most of the colours are in the same order as in the spectrum. You can see the spectrum in a rainbow.
It is: ROY G BIV and the colours for resistors are in the same sequence.

black
brown - colour of increasing temperature
red
orange
yellow
green
blue
(indigo - that part of the spectrum between blue and violet)
violet

gray
white

colour	**value**	No of zero's
silver	-2	divide by 100
gold	-1	divide by 10
black	0	No zeros

Bad Beer Rots Our Young Guts, But Vodka Goes Well
Bright Boys Rave Over Young Girls But Violet Gets Wed
Bad Boys Rave Over Young Girls But Violet Gets Wed with Gold and Silver.

Reading 5-band resistors:

5-band resistors are easy to read if you remember two simple points. The first three bands provide the digits in the answer and the 4th band supplies the number of zero's.

Reading "STANDARD VALUES" (on 5-band resistors)

5-band resistors are also made in "Standard Values" but will have different colours to 4-band "common" resistors - and will be confusing if you are just starting out. For instance, a 47k 5% resistor

with 4-bands will be: yellow-purple-orange-gold. For a 47k 1% resistor the colours will be yellow-purple-black-red-brown. The brown colour-band represents 1%.
The first two colour-bands for a STANDARD VALUE or "common value" in 1% or 5% will be the SAME. These two bands provide the digits in the answer.
It's the 3rd band for a 5% resistor that is expanded into two bands in a 1% resistor. But it's easy to follow.
For a standard value, the 3rd band in a 1% resistor is BLACK. This represents a ZERO in the answer. (For 5-band resistors BLACK represents a ZERO when in the third band. This is different to 4-band resistors where black represents the word OHMS! If the third band is BROWN, the answer will be 1). So the 4th band has to represent one-less ZERO and is one colour UP THE COLOUR CHART! In other words the 3rd and 4th bands (combined) on a 1% resistor produces the same number of zero's as the 3rd band on a 5% resistor!

Resistors come in a range of values and the two most common are the E12 and E24 series. The E12 series comes in twelve values for each decade. The E24 series comes in twenty-four values per decade.

E12 series - 10, 12, 15, 18, 22, 27, 33, 39, 47, 56, 68, 82

E24 series - 10, 11, 12, 13, 15, 16, 18, 20, 22, 24, 27, 30, 33, 36, 39, 43, 47, 51, 56, 62, 68, 75, 82, 91

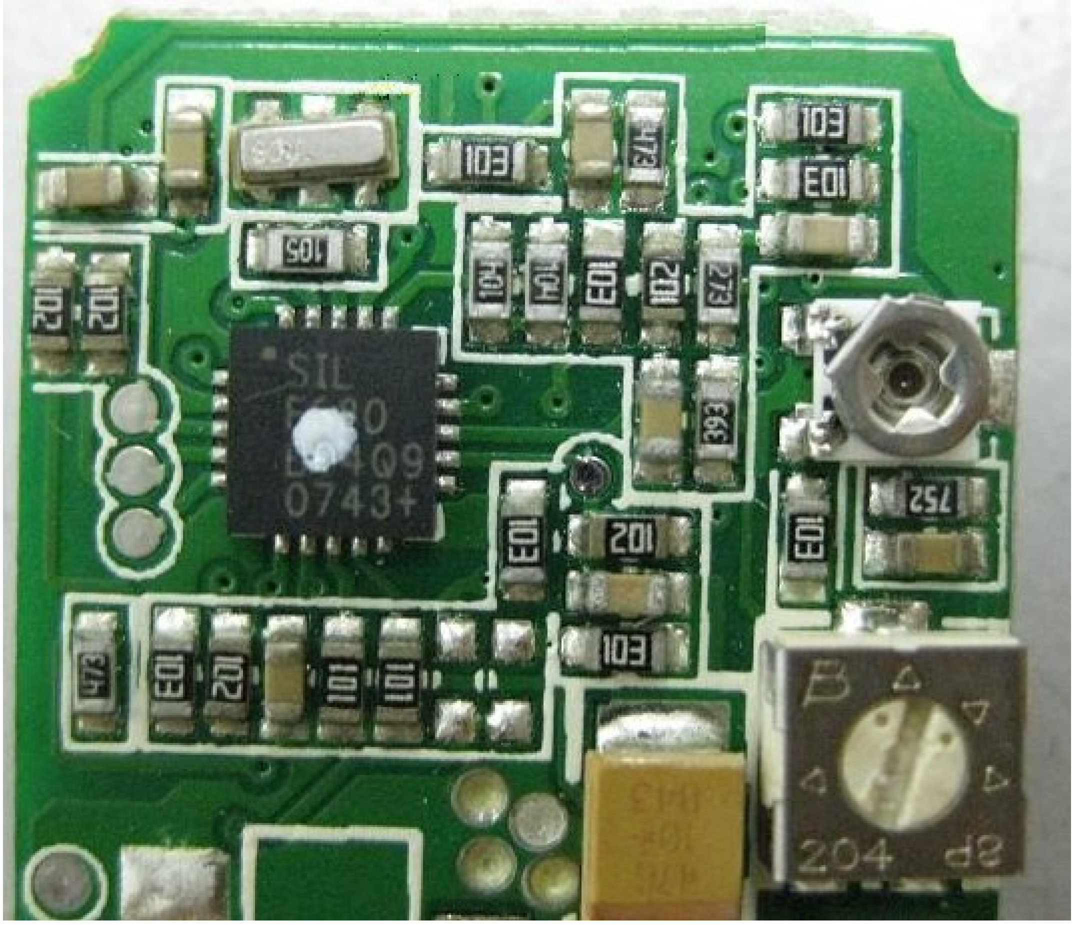
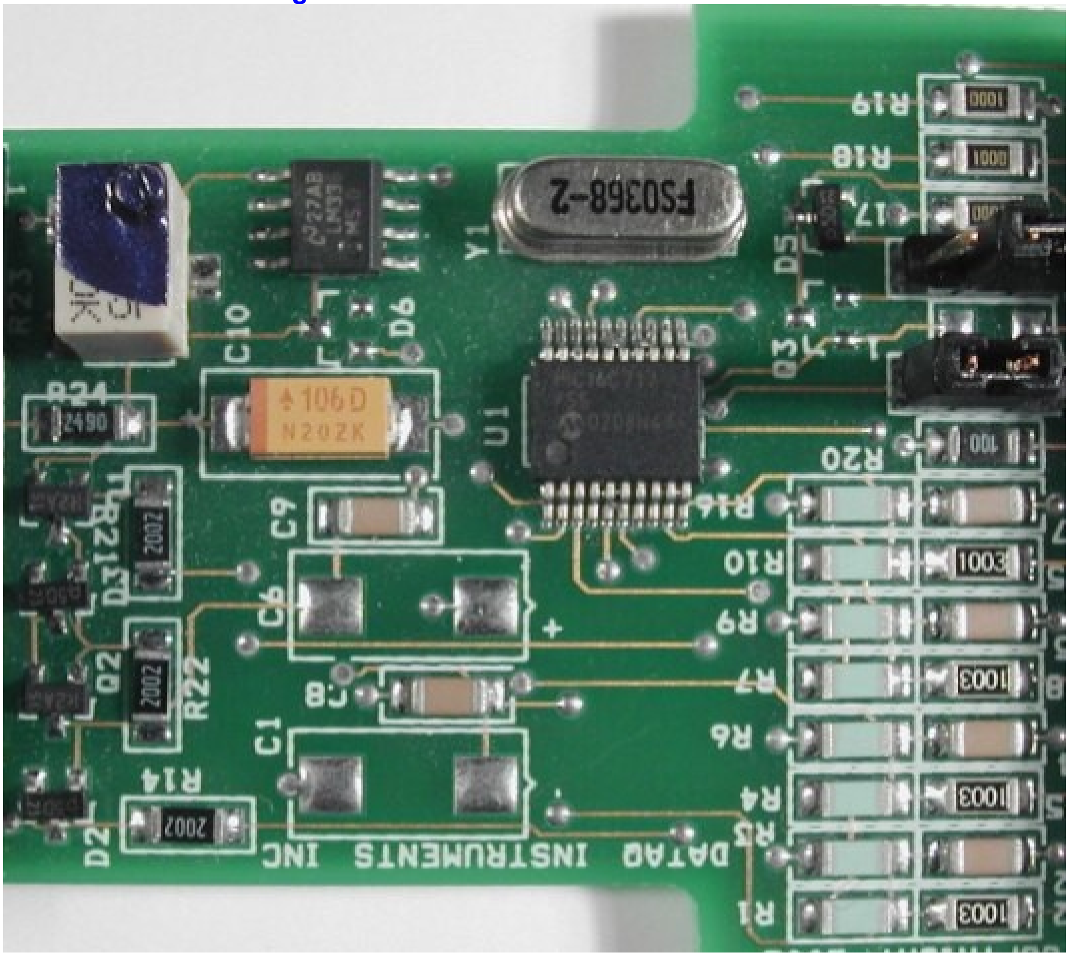
1206 and 0805 SURFACE MOUNT RESISTORS



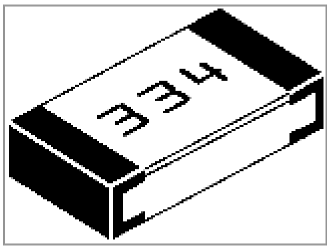
3-digit Surface Mount resistors on a PC board



4-digit Surface Mount resistors on a PC board

The photo above shows surface mount resistors on a circuit board. The components that are not marked are capacitors (capacitors are NEVER marked).
All the SM resistors in the above photos conform to a 3-digit or 4-digit code. But there are a number of codes, and the 4-digit code caters for high tolerance resistors, so it's getting very complicated.

Here is a basic 3-digit SM resistor:



A 330k SM resistor

The first two digits represent the two digits in the answer. The third digit represents the number of zero's you must place after the two digits. The answer will be OHMS. For example: 334 is written 33 0 000. This is written 330,000 ohms. The comma can be replaced by the letter "k". The final answer is: 330k.
222 = 22 00 = 2,200 = 2k2
473 = 47 000 = 47,000 = 47k
474 = 47 0000 = 470,000 = 470k
105 = 10 00000 = 1,000,000 = 1M = one million ohms
There is one trick you have to remember. Resistances less than 100 ohms are written: 100, 220, 470. These are 10 and NO zero's = 10 ohms = 10R
or 22 and no zero's = 22R or 47 and no zero's = 47R. Sometimes the resistor is marked: 10, 22 and 47 to prevent a mistake.

Remember:
R = ohms
k = kilo ohms = 1,000 ohms
M = Meg = 1,000,000 ohms
The 3 letters (R, k and M) are put in place of the decimal point. This way you cannot make a mistake when reading a value of resistance.

THE COMPLETE RANGE OF SM RESISTOR MARKINGS

Click to see the complete range of SM resistor markings for 3-digit code:

Click to see the complete range of SM resistor markings for 4-digit code:

0000 is a value on a surface-mount resistor. It is a zero-ohm **LINK**!
Resistances less than 10 ohms have 'R' to indicate the position of the decimal point.
Here are some examples:

Three Digit Examples	Four Digit Examples
330 is 33 ohms *- not 330 ohms*	**1000 is 100 ohms *- not 1000 ohms***
221 is 220 ohms	**4992 is 49 900 ohms, or 49k9**
683 is 68 000 ohms, or 68k	**1623 is 162 000 ohms, or 162k**
105 is 1 000 000 ohms, or 1M	**0R56 or R56 is 0.56 ohms**
8R2 is 8.2 ohms	

A new coding system has appeared on **1% types**. This is known as the EIA-96 marking method. It consists of a three-character code. The first two digits signify the 3 significant digits of the resistor value, using the lookup table below. The third character - a letter - signifies the multiplier.

code	value	code	value	code	value	code	value	code	value	code	value
01	100	17	147	33	215	49	316	65	464	81	681
02	102	18	150	34	221	50	324	66	475	82	698
03	105	19	154	35	226	51	332	67	487	83	715
04	107	20	158	36	232	52	340	68	499	84	732
05	110	21	162	37	237	53	348	69	511	85	750
06	113	22	165	38	243	54	357	70	523	86	768
07	115	23	169	39	249	55	365	71	536	87	787
08	118	24	174	40	255	56	374	72	549	88	806
09	121	25	178	41	261	57	383	73	562	89	825
10	124	26	182	42	267	58	392	74	576	90	845
11	127	27	187	43	274	59	402	75	590	91	866
12	130	28	191	44	280	60	412	76	604	92	887
13	133	29	196	45	287	61	422	77	619	93	909
14	137	30	200	46	294	62	432	78	634	94	931
15	140	31	205	47	301	63	442	79	649	95	953
16	143	32	210	48	309	64	453	80	665	96	976

The **multiplier** letters are as follows:

letter	mult	letter	mult
F	100000	B	10
E	10000	A	1
D	1000	X or S	0.1
C	100	Y or R	0.01

22A is a 165 ohm resistor, **68C** is a 49900 ohm (49k9) and **43E** a 2740000 (2M74). This marking scheme applies to 1% resistors only.

A similar arrangement can be used for **2% and 5%** tolerance types. The multiplier letters are identical to 1% ones, but occur **before** the number code and the following **code** is used:

2%				5%			
code	value	code	value	code	value	code	value
01	100	13	330	25	100	37	330
02	110	14	360	26	110	38	360
03	120	15	390	27	120	39	390
04	130	16	430	28	130	40	430
05	150	17	470	29	150	41	470
06	160	18	510	30	160	42	510
07	180	19	560	31	180	43	560
08	200	20	620	32	200	44	620
09	220	21	680	33	220	45	680
10	240	22	750	34	240	46	750
11	270	23	820	35	270	47	820
12	300	24	910	36	300	48	910

With this arrangement, **C31** is 5%, 18000 ohm (18k), and **D18** is 510000 ohms (510k) 2% tolerance. Always check with an ohm-meter (a multimeter) to make sure.

Chip resistors come in the following styles and ratings:

Style: 0402, 0603, 0805, 1206, 1210, 2010, 2512, 3616, 4022

Power Rating: 0402(1/16W), 0603(1/10W), 0805(1/8W), 1206(1/4W), 1210(1/3W), 2010(3/4W), 2512(1W), 3616(2W), 4022(3W)

Tolerance: 0.1%, 0.5%, 1%, 5%

Temperature Coefficient: 25ppm 50ppm 100ppm

If you want an accurate RESISTANCE measurement, remove the resistor from the circuit and use a Digital meter.

SURFACE MOUNT COMPONENTS - PACKS

Talking Electronics has packs of components for the repairman. The following packs are available:

SURFACE MOUNT RESISTOR PACK consists of 1 off each standard value
10 ohms to 1M & 2M2 (60 resistors)
$14.20   including pack and post

SURFACE MOUNT CAPACITOR PACK consists of:
2 - 10p   5 - 47p   5 - 100p   5 - 470p   5 - 1n   5 - 10n   5 - 22n   5 - 100n
5 - 1u 16v electrolytic   5 - 10u 16v electrolytic
(40 components)
$23.80 including pack and post

SURFACE MOUNT DIODE PACK consists of:
5 - 1N 4148 (marked as "A6")
$10.00   including pack and post

SURFACE MOUNT TRANSISTOR PACK consists of:
5 - BC 848 (marked as "1K") NPN
5 - BC858 PNP
$10.00   including pack and post

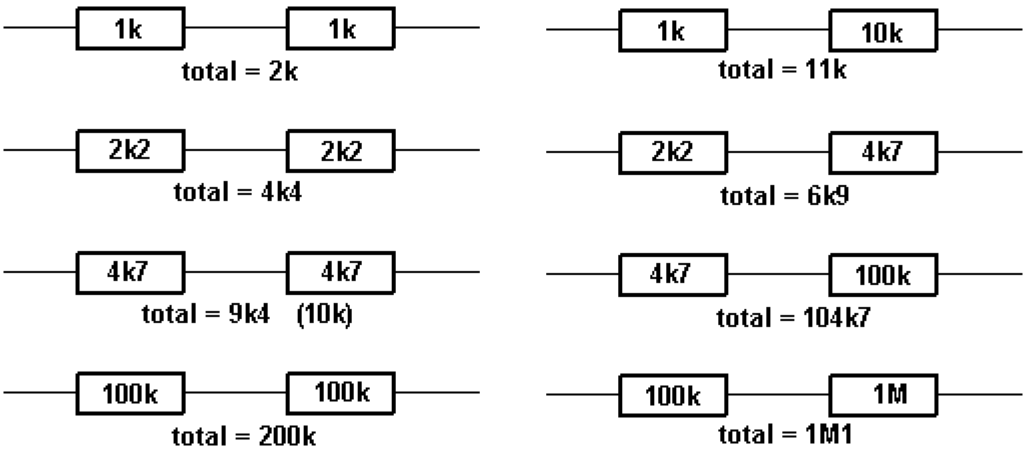
email **Colin Mitchell** for details on how to pay by credit card or PayPal.

CREATING ANY VALUE OF RESISTANCE

Any value of resistance can be created by connecting two resistors in PARALLEL or SERIES.
You can also create a higher wattage resistor by connecting them in SERIES OR PARALLEL.
We are only going to cover two EQUAL VALUE resistors in SERIES or in PARALLEL.
If you want to create a "Special Value," simply connect two resistors and read the value with a Digital Meter. Keep changing the values until you get the required value. We are not going into series or Parallel formulae. You can easily find a value with a multimeter.

TWO EQUAL-VALUE RESISTORS IN SERIES

Two equal-value resistors IN SERIES creates a value of DOUBLE. You simply ADD the values.
This can be done with any to two values as shown. Three equal-value resistors in series is three times the value.



1k
1k
total = 2k
1k
10k
total = 11k

If you want a particular value and it is not available, here is a chart.
Use 2 resistors in series or parallel as shown:

Required Value	R1	Series/ Parallel	R2	Actual value:
10	4R7	S	4R7	9R4
12	10	S	2R2	12R2
15	22	P	47	14R9
18	22	P	100	18R
22	10	S	12	22
27	22	S	4R7	26R7
33	22	S	10	32R
39	220	P	47	38R7
47	22	S	27	49
56	47	S	10	57
68	33	S	33	66
82	27	S	56	83

There are other ways to combine 2 resistors in parallel or series to get a particular value. The examples above are just one way. 4R7 = 4.7 ohms

TESTING A RESISTOR

To check the value of a resistor, it should be removed from the circuit. The surrounding components can affect the

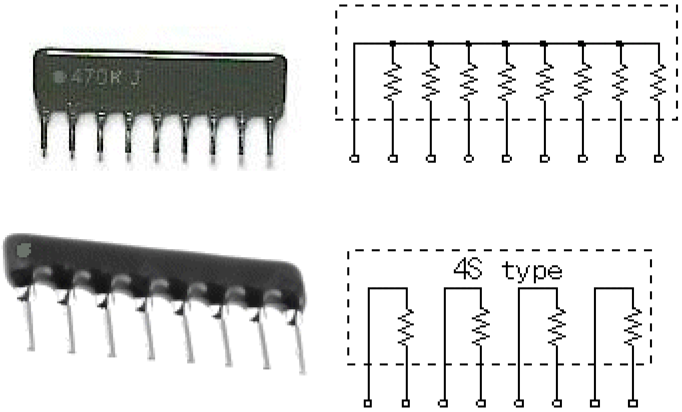
reading and make it lower.
Resistors **VERY RARELY** change value, but if it is overheated or damaged, the resistance can increase. You can take the reading of a resistor "in-circuit" in one direction then the other, as the surrounding components may have diodes and this will alter the reading.
You can also test a resistor by feeling its temperature-rise. It is getting too hot if you cannot hold your finger on it (some "metal film" resistors are designed to tolerate quite high temperatures).

TESTING AN "AC" RESISTOR

There is no such thing as an "AC" resistor. Resistors are just "resistors" and they can be in AC circuits or DC circuits. Resistors can be given names such as "Safety Resistor" "Ballast Resistor" "LOAD Resistor" "Feed Resistor" "Dropper Resistor" or "Supply Resistor." These are just normal resistors with a normal resistance - except a "Safety Resistor."
A safety resistor is made of a flame-proof material such as metal-oxide-film and not carbon-composition. It is designed to "burn out" when too much current flows BUT NOT CATCH FIRE.
It is a low-value resistor and has a voltage-drop across it but this is not intentional. The voltage-drop is to create a "heating-effect" to burn out the resistor. In all the other types of resistor, the voltage-drop is intentional.
A Ballast resistor is a normal resistor and can be called a Power resistor, Dropper resistor, Supply resistor or Feed resistor. It is designed to reduce the voltage from one source and deliver a lower voltage. It is a form of: "in-line" resistor.
A Load Resistor is generally connected across the output of a circuit and turns the energy it receives, into heat.

RESISTOR NETWORKS

To reduce the number of resistors in a circuit, some engineers use a set of identical resistors in a package called a Single-In-Line (SIL) resistor network. It is made with many resistors of the same value, all in one package. One end of each resistor is connected all the other resistors and this is the common pin, identified as pin 1 and has a dot on the package.
These packages are very reliable but to make sure all the resistors are as stated, you need to locate pin 1. All values will be identical when referenced to this pin.



RESISTOR NETWORKS

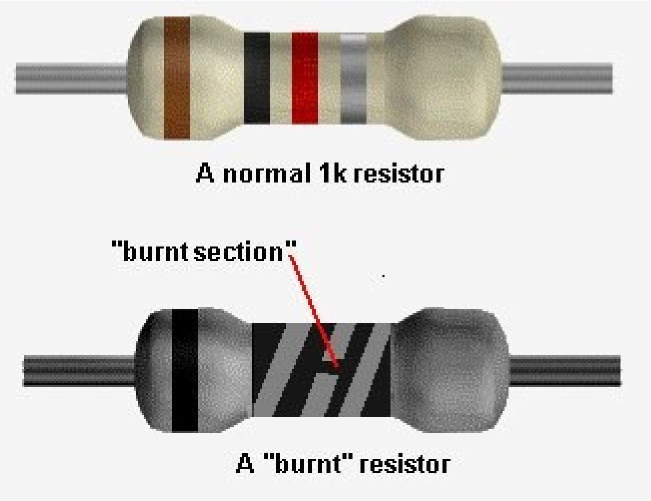
Some resistor networks have a "4S" printed on the component. The 4S indicates the package contains 4 independent resistors that are not wired together inside. The housing has eight leads as shown in the second image.
Independent resistors have an even number of pins and measuring between each pair will produce identical values. Resistance between any pair will indicate leakage and may be a fault.

TESTING A POSISTOR

A Posistor is a resistor that connects in series with the degaussing coil around the picture tube or **Monitor.** When cold, it has a very low resistance and a large current flows when the monitor or TV is switched on. This current heats up the Posistor and the resistance increases. This causes the current to decrease and any magnetism in the shadow mask is removed. The posistor can one or two elements and it is kept warm so the resistance remains high. Many Posistors have a second element inside the case that connects directly to the supply to keep the Positive Temperature Coefficient resistor high so that the current through the degaussing coil falls to almost zero. This constant heat eventually destroys the package.
The heavy current that flows when a set is turned ON also causes the posistor to crack and break and this results in poor purity on the screen - as the shadow mask gradually becomes magnetic..
Posistors have different resistance values from different manufacturers and must be replaced with an identical type. They can be checked for very low resistance when cold but any loose pieces inside the case will indicate a damaged component.

A "BURNT" RESISTOR **- normally and technically called a "burnt-out" resistor.**

The resistance of a "burnt" resistor can sometimes be determined by scraping away the outer coating - if the resistor has a spiral of resistance-material. You may be able to find a spot where the spiral has been damaged.



Clean the "spot" (burnt section of the spiral) very carefully and make sure you can get a good contact with the spiral and the tip of your probe. Measure from one lead of the resistor to the end of the damaged spiral. Then measure from the other lead to the other end of the spiral.
Add the two values and you have an approximate value for the resistor. You can add a small amount for the damaged section.
This process works very well for damaged wire-wound resistors. They can be pulled apart and each section of the resistance-wire (nichrome wire) measured and added to get the full resistance.

There is another way to determine the value of a damaged resistor.
Get a set of resistors of the same wattage as the damaged component and start with a high value. It's handy to know if the resistor is in the range: 10ohm to 100ohms or 1k to 10k etc, but this is not essential.
Start with a very high value and turn the circuit ON. You can perform voltage tests and if you know the expected output voltage, decrease the resistance until this voltage is obtained.
If you do not know the expected voltage, keep reducing the value of resistance until the circuit works

as designed.
This is the best advice in a situation where you do not know the value of a resistor.

There is a third way to determine the value and this requires measuring the voltage drop across the resistor and the current-flow. By multiplying the two you will get a wattage and this must be less than the wattage of the resistor being replaced.

TESTING POTENTIOMETERS (variable resistors)

To check the value of a variable resistor, it should be removed from circuit or at least 2 legs should be removed. A Rheostat is a variable resistor using only one end and the middle connected to a circuit.
The resistance between the two outside pins is the value marked on the component and the centre leg will change from nearly zero to the full resistance as the shaft is rotated.
"Pots" generally suffer from "crackle" when turned and this can be fixed by spraying up the shaft and into the pot via the shaft with a tube fixed to a can of "spray-lubricant" (contact cleaner).
"Pre-set pots" and "trim pots" are miniature versions of a potentiometer and they are all tested the same.

FOCUS POTS

Focus pots quite often get a spot of dirt where the wiper touches the track. Cleaning with spray fixes the bad focus but if the pot is leaking to chassis from inside the pot (due to the high voltage on the terminals) simply remove it from the chassis and leave it floating (this will restore the high voltage to the picture tube) or you can use one from an old chassis.

MAKING YOUR OWN RESISTOR, CAPACITOR, INDUCTOR or DIODE

Quite often you will not have the exact value of resistance or capacitance for a repair.
We have already covered placing resistors and capacitors in parallel and series:

Resistors in Parallel and/or Series
Capacitors in Parallel and/or Series

Here are some extras:

RESISTORS
Two 1k 0.5watt resistors in parallel produces a 470R 1watt resistor.
Two 1k 0.5watt resistors in series produces a 2k 1watt resistor.

CAPACITORS
Two 100n 100v capacitors in series produces a 50n capacitor @200v

INDUCTORS: Two inductors in series - **ADD THE VALUES**

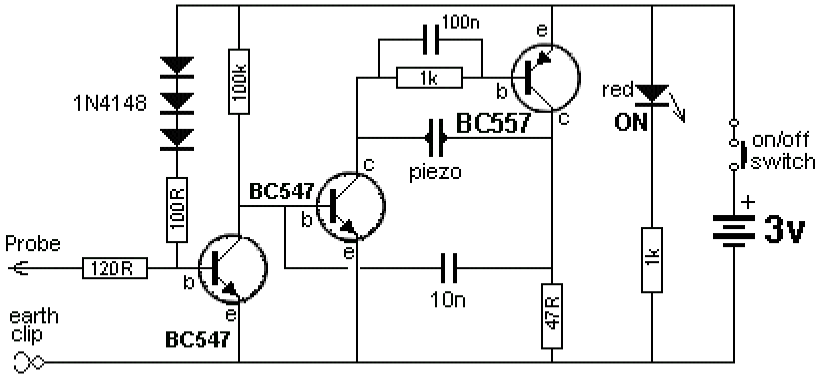
DIODES: Two 1Amp 400v diodes in series produces a 1Amp 800v diode
Two 1Amp 400v diodes in parallel produces a 2Amp 400v diode

ZENER DIODES: Zener diodes can be connected in series to get a higher voltage.
Two 12v zener diodes in series produces a 24v zener.

CONTINUITY

Some multimeters have a "buzzer" that detects when the probes are touching each other or the resistance between the probes is very LOW. This is called a CONTINUITY TESTER.
You can use the resistance scale "x1" or "x10" to detect low values of resistance.
Set the pointer to "0" (right end of the scale) by touching the probes together and adjusting the "zero ohms" control.
When taking a reading, you will have to decide if a low value of resistance is a short-circuit or an "operating value."
For instance, the cold resistance of a 12v car globe is very low (about 2 ohms) and it increases (about 6 times) to 12 ohms when hot.
The "resistance of a circuit" may be very low as the electrolytics in the circuit are uncharged. This may not indicate a true "short-circuit."
The measurement across a diode is not a resistance-value but a "voltage-drop" and that is why the needle swings nearly full-scale.
Leads and wires and cords have a small resistance and depending on the length of the lead, this small

resistance may be affecting a circuit.
Remember this:
When a circuit takes 1 amp, and the resistance of the leads is 1 ohm, the voltage drop across the leads will be 1v.
That's why a 12v battery supplying a circuit with these leads will have 11v at the circuit.
Note:
Turn off the equipment before making any continuity tests. The presence of even a small voltage (from an electrolytic) can give a false reading.
You can determine the resistance of a lead very accurately by taking the example above and applying it to your circuit.
If the battery is 12.6v and the voltage across the circuit is 10v, when the current is 2.6 amps, the resistance of the "leads" is 12.6 - 10 = 2.6 R=V/I = 2.6/2.6 = 1ohm. By making the lead shorter or using thicker wire, the resistance will be less and the voltage on the project will increase.
When taking readings in a circuit that has a number of diodes built-into IC's (Integrated Circuits) and transistors, some Continuity Testers will beep and give a false reading.
The following circuit has the advantage of providing a beep when a short-circuit is detected but does not detect the small voltage drop across a diode. This is ideal when testing logic circuits as it is quick and you can listen for the beep while concentrating on the probe. Using a multimeter is much slower.



CONTINUITY TESTER

You can build the circuit on Matrix Board and add it to your Test Equipment.
You will need lots of "Test Equipment" and they can be built from circuits in this eBook.

TESTING FUSES, LEADS AND WIRES

All these components come under the heading TESTING for CONTINUITY. Turn off all power to the equipment before testing for shorts and continuity. Use the low resistance "Ohms Scale" or CONTINUITY range on your multimeter. All fuses, leads and wires should have a low, very low or zero resistance. This proves they are working.

A BLOWN FUSE

The appearance of a fuse after it has "blown" can tell you a lot about the fault in the circuit.
If the inside of the glass tube (of the fuse) is totally blackened, the fuse has been damaged very quickly. This indicates a very high current has passed through the fuse.
Depending on the rating of the fuse, (current rating) you will be able to look for components that can pass a high current when damaged - such as high power transistors, FETs, coils, electrolytics. Before re-connecting the supply, you should test the "SUPPLY RAILS" for resistance. This is done by measuring them on a low OHMs range in one direction then reverse the leads to see if the resistance is low in the other direction.
A reading can be very low at the start because electrolytics need time to charge-up and if the reading gradually increases, the power rail does not have a short. An overload can occur when the supply voltage rises to nearly full voltage, so you sometimes have to fit a fuse and see how long it takes to "blow."
If the fuse is just slightly damaged, you will need to read the next part of this eBook, to see how and why this happens:

FAST AND SLOW BLOW FUSES

There are many different sizes, shapes and ratings of a fuse. They are all current ratings as a fuse does not have a voltage rating. Some fuses are designed for cars as they fit into the special fuse holders. A fuse can be designed for 50mA, 100mA, 250mA, 315mA, 500mA, 1Amp, 1.5amp, 2amp, 3amp, 3.15amp 5amp, 10amp, 15amp, 20amp, 25amp, 30amp, 35amp, 50amp and higher.
Some fuses are fast-blow and some are slow-blow.

A "normal" fuse consists of a length of thin wire. Or it may be a loop of wire that is thin near the middle of the fuse. This is the section that will "burn-out."
A "normal" fuse is a fast-blow fuse. For instance, a 1amp fuse will remain intact when up to 1.25 amp flows. When a circuit is turned on, it may take 2-3 amps for a very short period of time and a normal 1 amp fuse will get very hot and the wire will stretch but not "burn-out." You can see the wire move when the supply turns on.
If the current increases to 2amps, the fuse will still remain intact. It needs about 3 amp to heat up the wire to red-hot and burn out.
If the current increases to 5 amp, the wire VOLATILISES (burns-out) and deposits carbon-black on the inside of the glass tube.
A slow-blow fuse uses a slightly thicker piece of wire and the fuse is made of two pieces of wire joined in the middle with a dob of low-temperature solder. Sometimes one of the pieces of wire is a spring and when the current rises to 2.5 amp, the heat generated in the wire melts the solder and the two pieces of wire "spring apart."
A slow-blow fuse will allow a higher current-surge to pass through the fuse and the wire will not heat up and sag.
Thus the fuse is not gradually being damaged and it will remain in a perfect state for a long period of time.
A fuse does not protect electronic equipment from failing. It acts AFTER the equipment has failed.
It will then protect a power supply from delivering a high current to a circuit that has failed.
If a slow-blow fuse has melted the solder, it could be due to a slight overload, slight weakening of the fuse over a period of time or the current-rating may be too low.
You can try another fuse to see what happens.
You can replace a fast-acting fuse (normal fuse) with a slow blow if the fast-acting fuse has been replaced a few times due to deterioration when the equipment is turned on.
But you cannot replace a slow-blow fuse with a fast acting fuse as it will be damaged slightly each time the equipment is turned on and eventually fail.

TESTING COILS, INDUCTORS and YOKES

Coils inductors and yokes are just an extension of a length of wire. The wire may be wrapped around a core made of iron or ferrite.
It is labeled "L" on a circuit board.
You can test this component for continuity between the ends of the winding and also make sure there is no continuity between the winding and the core.
The winding can be less than one ohm, or greater than 100 ohms, however a coil of wire is also called an INDUCTOR and it might look like a very simple component, but it can operate in a very complex way.
The way it works is a discussion for another eBook. It is important to understand the turns are insulated but a slight fracture in the insulation can cause two turns to touch each other and this is called a "SHORTED TURN" or you can say the inductor has "SHORTED TURNS."
When this happens, the inductor allows the circuit to draw MORE CURRENT. This causes the fuse to "blow."
The quickest way to check an inductor is to replace it, but if you want to measure the inductance, you can use an INDUCTANCE METER. You can then compare the inductance with a known good component.

An inductor with a shorted turn will have a very low or zero inductance, however you may not be able to detect the fault when it is not working in a circuit as the fault may be created by a high voltage generated between two of the turns.
Faulty yokes (both horizontal and vertical windings) can cause the picture to reduce in size and/or bend or produce a single horizontal line.
A TV or monitor screen is the best piece of Test Equipment as it has identified the fault. It is pointless trying to test the windings further as you will not be able to test them under full operating conditions.

MEASURING AND TESTING INDUCTORS

Inductors are measured with an INDUCTANCE METER but the value of some inductors is very small and some Inductance Meters do not give an accurate reading.
The solution is to measure a larger inductor and note the reading. Now put the two inductors in SERIES and the values ADD UP - just like resistors in SERIES. This way you can measure very small inductors. VERY CLEVER!

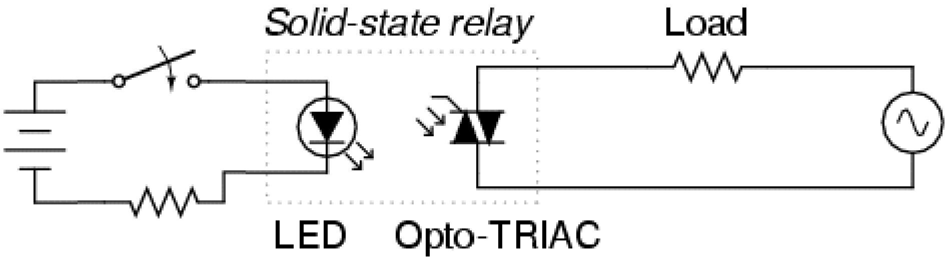
TESTING SWITCHES and RELAYS

Switches and relays have contacts that open and close mechanically and you can test them for CONTINUITY. However these components can become intermittent due to dirt or pitting of the surface of the contacts due to arcing as the switch is opened.

It is best to test these items when the operating voltage and current is present as they quite often fail due to the arcing. A switch can work 49 times then fail on each 50th operation. The same with a relay. It can fail one time in 50 due to CONTACT WEAR.
If the contacts do not touch each other with a large amount of force and with a large amount of the metal touching, the current flowing through the contacts will create HEAT and this will damage the metal and sometimes reduce the pressure holding the contact together.
This causes more arcing and eventually the switch heats up and starts to burn. Switches are the biggest causes of fire in electrical equipment and households.

A relay also has a set of contacts that can cause problems.
There are many different types of relays and basically they can be put into two groups.
1. An electromagnetic relay is a switch operated by magnetic force. This force is generated by current through a coil. The relay opens and closes a set of contacts.
The contacts allow a current to flow and this current can damage the contacts. Connect 5v or 12v to the coil (or 24v) and listen for the "click" of the points closing. Measure the resistance across the points to see if they are closing.
You really need to put a load on the points to see if they are clean and can carry a current.
The coil will work in either direction.
If not, the relay is possibly a CMOS relay or Solid State relay.

2. An electronic relay (Solid State Relay) does not have a winding. It works on the principle of an opto-coupler and uses a LED and Light Activated SCR or Opto-TRIAC to produce a low resistance on the output. The two pins that energise the relay (the two input pins) must be connected to 5v (or 12v) around the correct way as the voltage is driving a LED (with series resistor). The LED illuminates and activates a light-sensitive device.



CAPACITORS

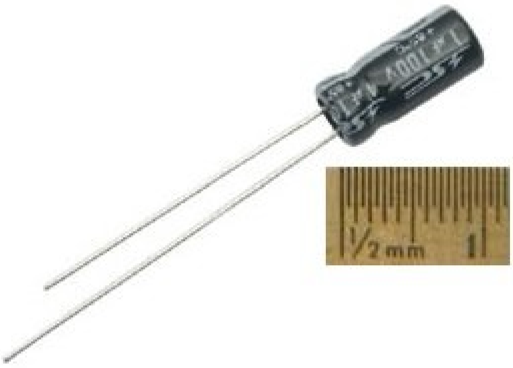
Capacitors are one of the most difficult things to test. That's because they don't give a reading on a multimeter and their value can range from 1p to 100,000u.
A faulty capacitor may be "open" when measured with a multimeter, and a good capacitor will also be "open."
You need a piece of test equipment called a CAPACITANCE METER to measure the value of a capacitor.

HOW A CAPACITOR WORKS

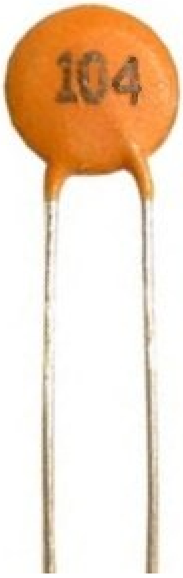
There are two ways to describe how a capacitor works. Both are correct and you have to combine them to get a full picture.
A capacitor has INFINITE resistance between one lead and the other.
This means no current flows **through** a capacitor. But it works in another way.
Suppose you have a strong magnet on one side of a door and a piece of metal on the other. By sliding the magnet up and down the door, the metal rises and falls.
The metal can be connected to a pump and you can pump water by sliding the magnet up and down.
A capacitor works in exactly the same way.
If you raise a voltage on one lead of a capacitor, the other lead will rise to the same voltage. This needs more explaining - we are keeping the discussion simple.
It works just like the magnetic field of the magnet through a door.
The next concept is this:
Capacitors are equivalent to a tiny rechargeable battery.
They store energy when the supply-voltage is present and release it when the supply drops.
These two concepts can be used in many ways and that's why capacitors perform tasks such as filtering, time-delays, passing a signal from one stage to another and create many different effects in a circuit.

CAPACITOR VALUES
The basic unit of capacitance is the FARAD. (C) This is the value used in all equations, but it is a very large value. A one FARAD capacitor would be the size of a car if made with plates and paper. Most electronic circuits use capacitors with smaller values such as 1p to 1,000u. 1p is about equal to two parallel wires 2cm long. 1p is one picofarad.

The easiest way to understand capacitor values is to start with a value of 1u. This is one microfarad and is one-millionth of a Farad. A 1 microfarad capacitor is about 1cm long and the diagram shows a 1u electrolytic.



Smaller capacitors are ceramic and they look like the following. This is a 100n ceramic:



To read the value on a capacitor you need to know a few facts.

The basic value of capacitance is the FARAD.
1 microfarad is one millionth of 1 farad.
1 microfarad is divided into smaller parts called nanofarad.
1,000 nanofarad = 1 microfarad
Nanofarad is divided into small parts called picofarad
1,000 picofarad = 1 nanofarad.

Recapping:
1p = 1 picofarad. 1,000p = 1n (1 nanofarad)
1,000n = 1u (1 microfarad)
1,000u = 1millifarad
1,000,000u = 1 FARAD.

Examples:
All ceramic capacitors are marked in "p" (puff")
A ceramic with 22 is 22p = 22 picofarad
A ceramic with 47 is 47p = 47 picofarad
A ceramic with 470 is 470p = 470 picofarad

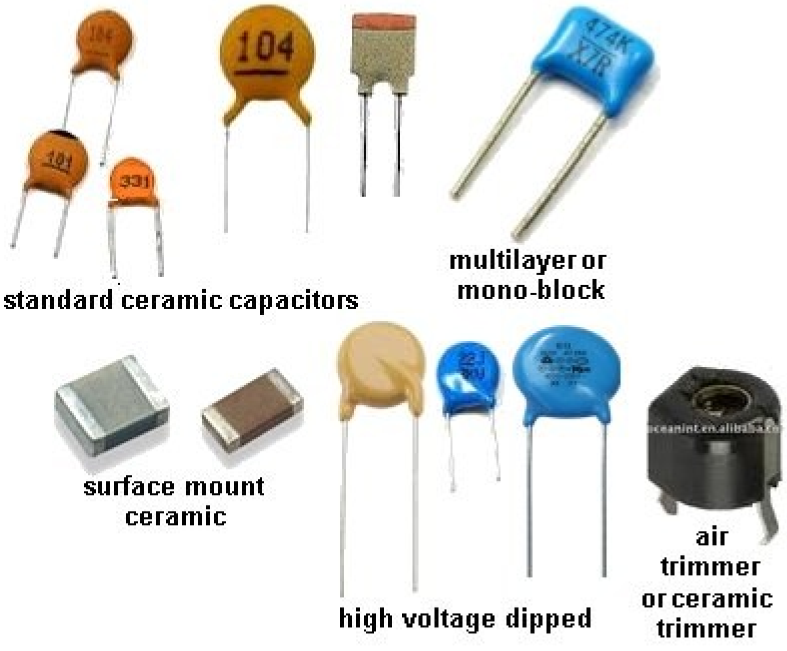
A ceramic with 471 is 470p = 470 picofarad
A ceramic with 102 is 1,000p = 1n
A ceramic with 223 is 22,000p = 22n
A ceramic with 104 is 100,000p = 100n = 0.1u

TYPES OF CAPACITOR

For testing purposes, there are two types of capacitor.
Capacitors from 1p to 100n are non-polar and can be inserted into a circuit around either way.
Capacitors from 1u to 100,000u are electrolytics and are polarised. They must be fitted so the positive lead goes to the supply voltage and the negative lead goes to ground (or earth).
There are many different sizes, shapes and types of capacitor. They are all the same. They consist of two plates with an insulating material between. The two plates can be stacked in layers or rolled together.
The important factor is the insulating material. It must be very thin to keep things small. This gives the capacitor its VOLTAGE RATING.
If a capacitor sees a voltage higher than its rating, the voltage will "jump through" the insulating material or around it.
If this happens, a carbon deposit is left behind and the capacitor becomes "leaky" or very low resistance, as carbon is conductive.

CERAMIC CAPACITORS

Nearly all small capacitors are **ceramic capacitors** as this material is cheap and the capacitor can be made in very thin layers to produced a high capacitance for the size of the component. This is especially true for surface-mount capacitors.
All capacitors are marked with a value and the basic unit is: "p" for "puff" However NO surface mount capacitors are marked and they are very difficult to test.



VALUE:	VALUE WRITTEN ON THE COMPONENT:
0.1p	0p1
0.22p	0p22
0.47p	0p47

POLYESTER, POLYCARBONATE, POLYSTYRENE, MYLAR, METALLISED POLYESTER, ("POLY"), MICA and other types of CAPACITOR

There are many types of capacitor and they are chosen for their reliability, stability, temperate-range and cost.

For testing and repair work, they are all the same. Simply replace with exactly the same type and value.

ELECTROLYTIC and TANTALUM CAPACITORS

Electrolytics and Tantalums are the same for testing purposes but their performance is slightly different in some circuits. A tantalum is smaller for the same rating as an electrolytic and has a better ability at delivering a current. They are available up to about 1,000u, at about 50v but their cost is much higher than an electrolytic.

Electrolytics are available in 1u, 2u2 3u3 4u7 10u, 22u, 47u, 100u, 220u, 330u, 470u, 1,000u, 2,200u, 3,300u, 4,700u, 10,000u and higher.
The "voltage" or "working voltage" can be: 3.3v, 10v, 16v, 25v, 63v, 100v, 200v and higher.
There is also another important factor that is rarely covered in text books. It is RIPPLE FACTOR. This is the amount of current that can enter and leave an electrolytic. This current heats up the electrolytic and that is why some electrolytics are much larger than others, even though the capacitance and voltage-ratings are the same.
If you replace an electrolytic with a "miniature" version, it will heat up and have a very short life. This is especially important in power supplies where current (energy) is constantly entering and exiting the electrolytic as its main purpose is to provide a smooth output from a set of diodes that delivers "pulsing DC." (see "Power Diodes")

NON-POLAR CAPACITORS (ELECTROLYTICS)

Electrolytics are also available in non-polar values. It sometimes has the letters "NP" on the component. Sometimes the leads are not identified.
This is an electrolytic that does not have a positive and negative lead but two leads and either lead can be connected to the positive or negative of the circuit.
These electrolytics are usually connected to the output of an amplifier (such as in a filter near the speaker) where the signal is rising and falling.
A non-polar electrolytic can be created from two ordinary electrolytics by connecting the negative leads together and the two positive leads become the new leads.
For example: two 100u 63v electrolytics will produce a 47u 63v non-polar electrolytic.
In the circuit below, the non-polar capacitor is replaced with two electrolytics.

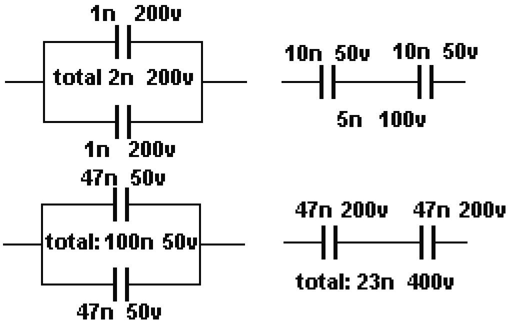
PARALLEL and SERIES CAPACITORS

Capacitors can be connected in PARALLEL and/or SERIES for a number of reasons.
1. If you do not have the exact value, two or more connected in parallel or series can produce the value you need.

2. Capacitors connected in series will produce one with a higher voltage rating.
3. Capacitors connected in parallel will produce a larger-value capacitance.

Here are examples of two equal capacitors connected in series or parallel and the results they produce:



VOLTAGE RATING OF CAPACITOR

Capacitors have a voltage rating, stated as WV for working voltage, or WVDC. This specifies the maximum voltage that can be applied across the capacitor without puncturing the dielectric. Voltage ratings for "poly," mica and ceramic capacitors are typically 50v to 500 VDC. Ceramic capacitors with ratings of 1kv to 5kv are also available. Electrolytic capacitors are commonly available in 6v, 10v 16v, 25v, 50v, 100v, 150v, and 450v ratings.

CAUTION

If a capacitor has a voltage rating of 63v, do not put it in a 100v circuit as the insulation (called the dielectric) will be punctured and the capacitor will "short-circuit." It's ok to replace a 0.22uF 50WV capacitor with 0.22uF 250WVDC.

SAFETY

A capacitor can store a charge for a period of time after the equipment is turned off. High voltage electrolytic caps can pose a safety hazard. These capacitors are in power supplies and some have a resistor across them, called a bleed resistor, to discharge the cap after power is switched off.
If a bleed resistor is not present the cap can retain a charge after the equipment is unplugged.

How to discharge a capacitor

Do not use a screwdriver to short between the terminals as this will damage the capacitor internally and the screwdriver.
Use a 1k 3watt or 5watt resistor on jumper leads and keep them connected for a few seconds to fully discharge the electro.
Test it with a voltmeter to make sure all the energy has been removed.

Before testing any capacitors, especially electrolytics, you should look to see if any are damaged, overheated or leaking. Swelling at the top of an electrolytic indicates heating and pressure inside the case and will result in drying out of the electrolyte. Any hot or warm electrolytic indicates leakage and ceramic capacitors with portions missing indicates something has gone wrong.

TESTING A CAPACITOR

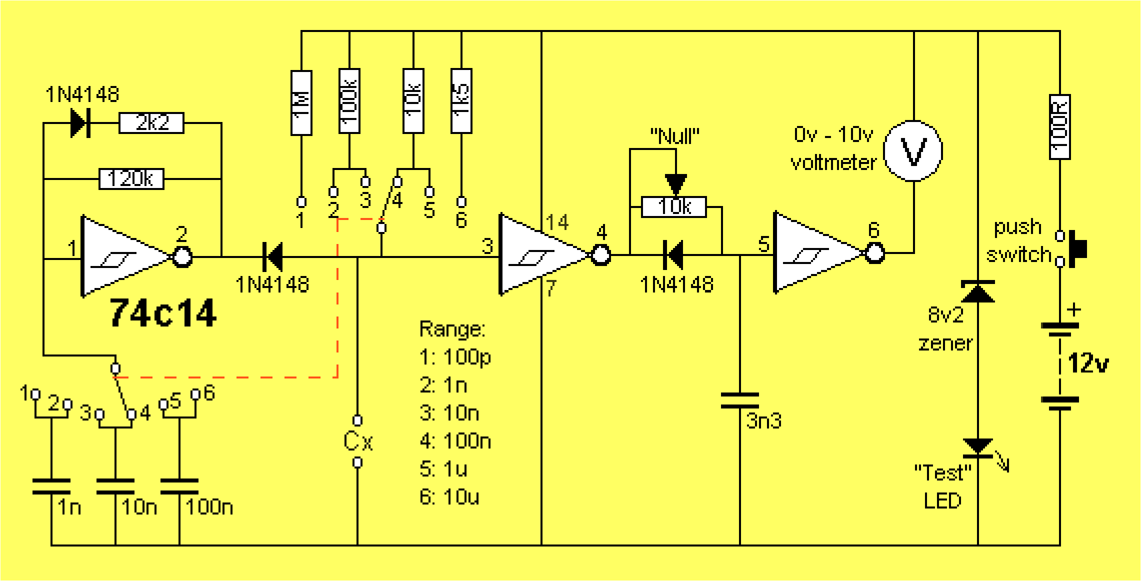
There are two things you can test with a multimeter:
1. A short-circuit within the capacitor
2. Capacitor values above 1u.

You can test capacitors in-circuit for short-circuits. Use the x1 ohms range.
To test a capacitor for leakage, you need to remove it or at least one lead must be removed. Use the x10k range on an analogue or digital multimeter.
For values above 1u you can determine if the capacitor is charging by using an analogue meter. The needle will initially move across the scale to indicate the cap is charging, then go to "no deflection." Any permanent deflection of the needle will indicate leakage.
You can reverse the probes to see if the needle moves in the opposite direction. This indicates it has been charged. Values below 1u will not respond to charging and the needle will not deflect.
This does not work with a digital meter as the resistance range does not output any current and the electrolytic does not charge.

Rather than spending money on a capacitance meter, it is cheaper to replace any suspect capacitor or electrolytic.
Capacitors can produce very unusual faults and no piece of test equipment is going to detect the problem.
In most cases, it is a simple matter to solder another capacitor across the suspect component and view or listen to the result.
This saves all the worry of removing the component and testing it with equipment that cannot possibly give you an accurate reading when the full voltage and current is not present.
It is complete madness to even think of testing critical components such as capacitors, with TEST EQUIPMENT. You are fooling yourself. If the Test Equipment says the component is ok, you will look somewhere else and waste a lot of time.

FINDING THE VALUE OF A CAPACITOR

If you want to find the value of a surface-mount capacitor or one where the markings have been removed, you will need a CAPACITANCE METER. Here is a simple circuit that can be added to your meter to read capacitor values from 10p to 10u.
The full article can be found HERE.



ADD-ON CAPACITANCE METER

REPLACING A CAPACITOR

Always replace a capacitor with the exact same type.
A capacitor may be slightly important in a circuit or it might be extremely critical.
A manufacturer may have taken years to select the right type of capacitor due to previous failures.
A capacitor just doesn't have a "value of capacitance."
It may also has an effect called "tightening of the rails."
In other words, a capacitor has the ability to react quickly and either absorb or deliver energy to prevent spikes or fluctuations on the rail.
This is due to the way it is constructed. Some capacitors are simply plates of metal film while others are wound in a coil. Some capacitors are large while others are small.
They all react differently when the voltage fluctuates.
Not only this, but some capacitors are very stable and all these features go into the decision for the type of capacitor to use.
You can completely destroy the operation of a circuit by selecting the wrong type of capacitor.
No capacitor is perfect and when it gets charged or discharged, it appears to have a small value of resistance in series with the value of capacitance. This is known as "ESR" and stands for EQUIVALENT SERIES RESISTANCE. This effectively makes the capacitor slightly slower to charge and discharge.
We cannot go into the theory on selecting a capacitor as it would be larger than this eBook so the only solution is to replace a capacitor with an identical type.
However if you get more than one repair with identical faults, you should ask other technicians if the original capacitor comes from a faulty batch.
The author has fixed TV's and fax machines where the capacitors have been inferior and alternate types have solved the problem.

Some capacitor are suitable for high frequencies, others for low frequencies.

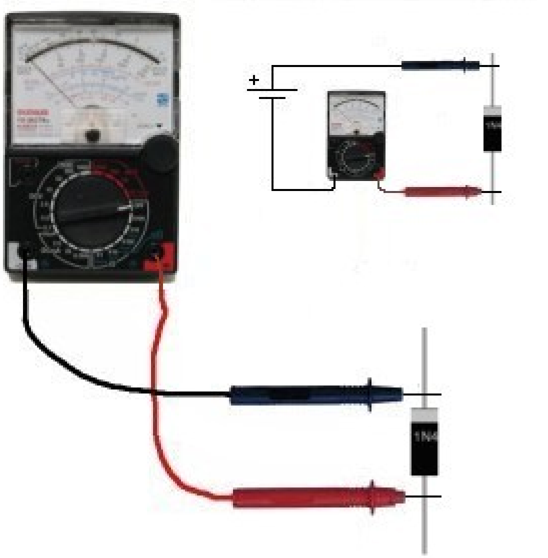
TESTING DIODES

Diodes can have 4 different faults.
1. Open circuit in both directions.
2. Low resistance in both directions.
3. Leaky.
4. Breakdown under load.

TESTING A DIODE ON AN ANALOGUE METER

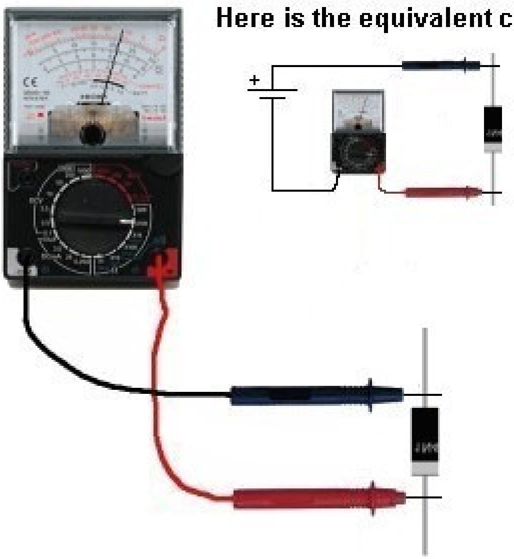
Testing a diode with an **Analogue Multimeter** can be done on any of the resistance ranges. [The high resistance range is best - it sometimes has a high voltage battery for this range but this does not affect our testing]
There are two things you must remember.
1. When the diode is measured in one direction, the needle will **not move at all**. The technical term for this is the diode is **reverse biased**. It will not allow any current to flow. Thus the needle will not move.
When the diode is connected around the other way, the needle will swing to the right (move up scale) to about 80% of the scale. This position represents the voltage drop across the junction of the diode and is NOT a resistance value. If you change the resistance range, the needle will move to a slightly different position due to the resistances inside the meter. The technical term for this is the diode is **forward biased**. This indicates the diode is not faulty.
The needle will swing to a slightly different position for a "normal diode" compared to a Schottky diode. This is due to the different junction voltage drops.
However we are only testing the diode at very low voltage and it may break-down when fitted to a circuit due to a higher voltage being present or due to a high current flowing.

2. The leads of an **Analogue Multimeter** have the positive of the battery connected to the black probe and the readings of a "good diode" are shown in the following two diagrams:



The diode is REVERSE BIASED in the diagram above and diodes not conduct.

Here is the equivalent circuit:

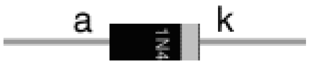


The diode is FORWARD BIASED in the diagram above and it conducts

TESTING A DIODE ON A DIGITAL METER

Testing a diode with a Digital Meter must be done on the "DIODE" setting as a digital meter does not deliver a current through the probes on some of the resistance settings and will not produce an accurate reading.

signal diode



power diode

diode symbol

The best thing to do with a "suspect" diode is to replace it. This is because a diode has a number of characteristics that cannot be tested with simple equipment. Some diodes have a fast recovery for use in high frequency circuits. They conduct very quickly and turn off very quickly so the waveform is processed accurately and efficiently.
If the diode is replaced with an ordinary diode, it will heat up as does not have the high-speed characteristic.
Other diodes have a low drop across them and if an ordinary is used, it will heat up.
Most diodes fail by going: SHORT-CIRCUIT. This can be detected by a low resistance (x1 or x10 Ohms range) in both directions.
A diode can also go OPEN CIRCUIT. To locate this fault, place an identical diode across the diode being tested.
A leaky diode can be detected by a low reading in one direction and a slight reading the other direction.
However this type of fault can only be detected when the circuit is working. The output of the circuit will be low and sometimes the diode heats up (more than normal).
A diode can go open under full load conditions and perform intermittently.
Diodes come in pairs in surface-mount packages and 4 diodes can be found in a bridge.
They are also available in pairs that look like a 3-leaded transistor.
The line on the end of the body of a diode indicates the cathode and you cannot say "this is the positive lead." The correct way to describe the leads is to say the "cathode lead." The other lead is the anode. The cathode is defined as the electrode (or lead) through which an electric current flows out of a device.

POWER DIODES

To understand how a power diode works, we need to describe a few things. This has NEVER been described before, so read carefully.

The 240v AC (called the "mains") consists of two wires, one is called the ACTIVE and the other is NEUTRAL. Suppose you touch both wires. You will get a shock. The neutral is connected to an earth wire (or rod driven into the ground or connected to a water pipe) at the point where the electricity enters the premises and you do not get a shock from the NEUTRAL.

But the voltage on the active is rising to +345v then goes to -345v at the rate of 50 times per second (for a complete cycle).

345v is the peak voltage of 240v. You never get a 240v shock. (It is a 345v shock.)

In other words, if you touch the two wires at a particular instant, you would get a POSITIVE 345v shock and at another instant you would get a negative 345v shock. This is shown in the diagram below.

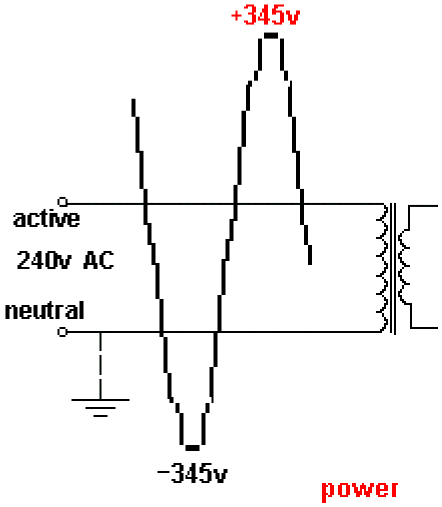
We now transfer this concept to the output of a transformer. The diagram shows an AC waveform on the output of the secondary.

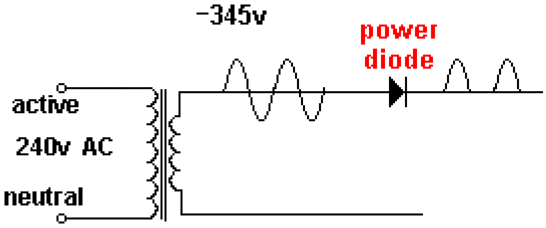
This voltage is rising 15v higher than the bottom lead then it is 15v LOWER than the bottom lead. The bottom lead is called "zero volts." You have to say one lead or wire is not "rising and falling" as you need a "reference" or starting-point" or "zero point" for voltage measurements.

The diode only conducts when the voltage is "above zero" (actually when it is 0.7v above zero) and does not conduct (at all) when the voltage goes below zero.

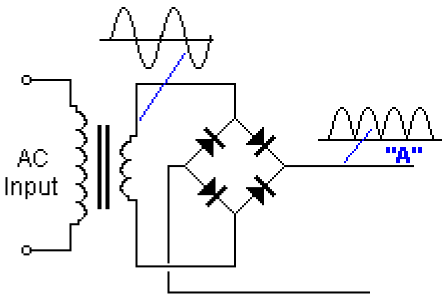
This is shown on the output of the Power Diode. Only the positive peaks or the positive parts of the waveform appear on the output and this is called "pulsing DC." This is called "half-wave" and is not used in a power supply. We have used it to describe how the diode works. The electrolytics charge during the peaks and deliver energy when the diode is not delivering current. This is how the output becomes a steady DC voltage.

Power supplies use FULL WAVE rectification and the other half of the AC waveform is delivered to the output (and fills in the "gaps") and appears as shown in "A."





Half-wave rectifier



Full-wave rectifier

DAMPER DIODES

A damper diode is a diode that detects a high voltage and SQUELCHES IT (reduces it - removes it).
The signal that it squelches is a voltage that is in the opposite direction to the "supply voltage" and is produced by the collapsing of a magnetic field. Whenever a magnetic filed collapses, it produces a voltage in the winding that is opposite to the supply voltage and can be much higher. This is the principle of a flyback circuit or EHT circuit. The high voltage comes from the transformer.
The diode is placed so that the signal passes through it and less than 0.5v appears across it.
A damper diode can be placed across the coil of a relay, incorporated into a transistor or FET or placed across a winding of a flyback transformer to protect the driving transistor or FET.
It can also be called a "Reverse-Voltage Protection Diode," "Spike Suppression Diode," or "Voltage Clamp Diode."
The main characteristic of a Damper Diode is HIGH SPEED so it can detect the spike and absorb the energy.
It does not have to be a high-voltage diode as the high voltage in the circuit is being absorbed by the diode.

SILICON, GERMANIUM AND SCHOTTKY DIODES

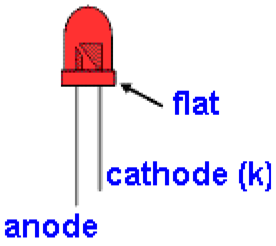
When testing a diode with an analogue meter, you will get a low reading in one direction and a high (or NO READING) in the other direction. When reading in the LOW direction, the needle will swing nearly full scale and the reading is not a resistance-value but a reflection of the characteristic voltage drop across the junction of the diode. As we mentioned before, a resistance reading is really a voltage reading and the meter is measuring the voltage of the battery minus the voltage-drop across the diode.
Since Silicon, Germanium and Schottky Diodes have slightly different characteristic voltage drops across the junction, you will get a slightly different reading on the scale. This does not represent one diode being better than the other or capable of handling a higher current or any other feature.
The quickest, easiest and cheapest way to find, fix and solve a problem caused by a faulty diode is to replace it.
There is no piece of test equipment capable of testing a diode fully, and the circuit you are working on

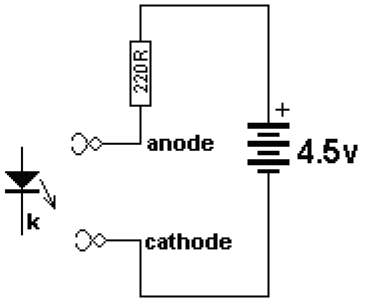
is actually the best piece of test equipment as it is identifying the fault UNDER LOAD.

Only very simple tests can be done with a multimeter and it is best to check a diode with an ANALOGUE MULTIMETER as it outputs a higher current though the diode and produces a more-reliable result.
A Digital meter can produce false readings as it does not apply enough current to activate the junction.
Fortunately almost every digital multimeter has a **diode test mode.** Using this, a silicon diode should read a voltage drop between 0.5v to 0.8v in the forward direction and open in the reverse direction.
For a germanium diode, the reading will be lower, around 0.2v - 0.4v in the forward direction. A bad diode will read zero volts in both directions.

LIGHT EMITTING DIODES (LEDs)

Light Emitting Diodes (LEDs) are diodes that produce light when current flows from anode to cathode. The LED does not emit light when it is revered-biased. It is used as a low current indicator in many types of consumer and industrial equipment, such as monitors, TV’s, printers, hi-fi systems, machinery and control panels.
The light produced by a LED can be visible, such as red, green, yellow or white. It can also be invisible and these LEDs are called Infrared LEDs. They are used in remote controls and to see if they are working, you need to point a digital camera at the LED and view the picture on the camera screen.
An LED needs about 2v - 3.6v across its leads to make it emit light, but this voltage must be exact for the type and colour of the LED. The simplest way to deliver the exact voltage is to have a supply that is higher than needed and include a voltage-dropping resistor. The value of the resistor must be selected so the current is between 2mA and 25mA.
The cathode of the LED is identified by a flat on the side of the LED. The life expectancy of a LED is about 100,000 hours. LEDs rarely fail but they are very sensitive to heat and they must be soldered and de-soldered quickly. They are one of the most heat-sensitive components.
Light emitting diodes cannot be tested with most multimeters because the characteristic voltage across them is higher than the voltage of the battery in the meter.
However a simple tester can be made by joining 3 cells together with a 220R resistor and 2 alligator clips:





LED TESTER

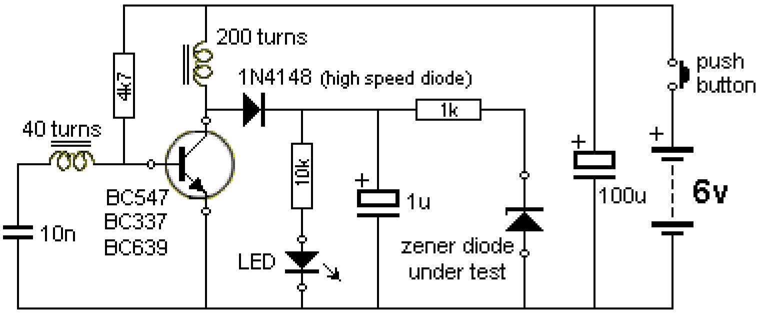
Connect the clips to a LED and it will illuminate in only one direction.
The colour of the LED will determine the voltage across it. You can measure this voltage if you want to match two or more LEDs for identical operation.
Red LEDs are generally 1.7v to 1.9v. - depending on the quality such as "high-bright"
Green LEDs are 1.9v to 2.3v.
Orange LEDs are about 2.3v and
White LEDs and IR LEDs are about 3.3v to 3.6v.
The illumination produced by a LED is determined by the quality of the crystal. It is the crystal that produces the colour and you need to replace a LED with the same quality to achieve the same illumination.
Never connect a LED across a battery (such as 6v or 9v), as it will be instantly damaged. You must have a resistor in series with the LED to limit the current.

ZENER DIODES

All diodes are Zener diodes. For instance a 1N4148 is a 120v zener diode as this is its reverse breakdown voltage.
And a zener diode can be used as an ordinary diode in a circuit with a voltage that is below the zener value.
For instance, 20v zener diodes can be used in a 12v power supply as the voltage never reaches 20v, and the zener characteristic is never reached.

Most diodes have a reverse breakdown voltage above 100v, while most zeners are below 70v. A 24v zener can be created by using two 12v zeners in series and a normal diode has a characteristic voltage of 0.7v. This can be used to increase the voltage of a zener diode by 0.7v. See the diagram above. It uses 3 ordinary diodes to increase the output voltage of a 3-terminal regulator by 2.1v.
To tests a zener diode you need a power supply about 10v higher than the zener of the diode. Connect the zener across the supply with a 1k to 4k7 resistor and measure the voltage across the diode. If it measures less than 1v, reverse the zener.
If the reading is high or low in both directions, the zener is damaged.

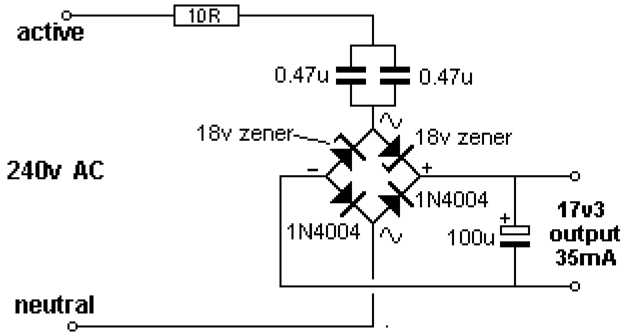
Here is a zener diode tester. The circuit will test up to 56v zeners.



ZENER DIODE TESTER

TRANSFORMERLESS POWER SUPPLY

Here's a circuit that uses zener diodes in a power supply to show how they work. This clever design uses 4 diodes in a bridge to produce a fixed voltage power supply capable of supplying 35mA.
If we put 2 zener diodes in a bridge with two ordinary power diodes, the bridge will break-down at the voltage of the zener. This is what we have done. If we use 18v zeners, the output will be 17v4.



SUPPLY USING ZENER DIODES

When the incoming voltage is positive at the top, the left zener provides 18v limit (and the other zener produces a drop of 0.6v). This allows the right zener to pass current just like a normal diode. The output is 17v4. The same with the other half-cycle.
You cannot use this type of bridge in a normal power supply as the zener diode will "short" when the input voltage reaches the zener value. The concept only works in the circuit above.

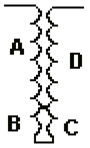
VOLTAGE REGULATORS

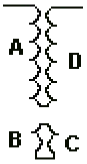
A Voltage Regulator takes a high input voltage and delivers a fixed output voltage.
Providing the input voltage is 4v above the output voltage, the regulator will deliver a fixed output voltage with almost no ripple.
Voltage regulators are also called "3-TERMINAL REGULATORS" or "REGULATOR IC's" - although this name is not generally used.
In most cases, a voltage regulator gets quite hot and for this reason it has a high failure-rate.
If a regulator is not getting hot (or warm) it has either failed or the circuit is not operating.
A regulator can only decrease the voltage. It cannot increase the current. This means the current being supplied to a circuit must also be available from the circuit supplying the regulator.
All regulators have different pin-outs, so you need to find the input pin and output pin and make sure

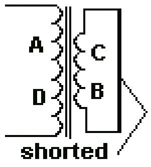
the voltage-difference is at least 4v. Some regulators will work with a difference as low as 1v, so you need to read the specifications for the type you are servicing.
Some regulators are called "negative voltage regulators" and the input voltage will be negative and the output will be negative.
You need to test a voltage regulator with the power "ON".
Make sure you do not allow the probes to short any of the pins together as this will destroy the regulator or the circuit being supplied.
With the power turned off or the regulator removed from the circuit, you can test it with a multimeter set to resistance to see if it is ok. If any resistance readings are very low or zero ohms, the regulator is damaged.

TRANSFORMERS

All transformers and coils are tested the same way. This includes chokes, coils, inductors, yokes, power transformers, EHT transformers (flyback transformers), switch mode transformers, isolation transformers, IF transformers, baluns, and any device that has turns of wire around a former. All these devices can go faulty.
The coating on the wire is called insulation or "enamel" and this can crack or become overheated or damaged due to vibration or movement. When two turns touch each other, a very interesting thing happens. **The winding becomes two separate windings.**







We will take the case of a single winding such as a coil. This is shown in the first diagram above and the winding is wound across a former and back again, making two layers. The bottom and top layers touch at the point shown in the diagram and the current that originally passed though A, B, C, D now passes though A & D.

Winding B C becomes a separate winding as shown in the second diagram.
In other words the coil becomes a TRANSFORMER with a SHORT CIRCUIT on the secondary winding as shown in the third diagram.
When the output wires of a transformer are shorted together, it delivers a very high current because you have created a SHORT-CIRCUIT. This short-circuit causes the transformer to get very hot.
That's exactly what happens when any coil or transformer gets a "shorted turn."
The shorted turns can be a single turn or many turns.
It is not possible to measure a fault like this with a multimeter as you don't know the exact resistance of a working coil or winding and the resistance of a faulty winding may be only 0.001 ohms less.
However when a transformer or coil is measured with an inductance meter, an oscillating voltage (or spike) is delivered into the core as magnetic flux, then the magnetic flux collapses and passes the energy into the winding to produce a waveform. The inductance meter reads this and produces a value of inductance in Henry (milliHenry or microHenry.)
This is done with the transformer removed from the circuit and this can be a very difficult thing to do, as most transformers have a number of connections.
If the coil or transformer has a shorted turn, the energy from the magnetic flux will pass into the turns that are shorted and produce a current. Almost no voltage will be detected from winding.
The reading from the inductance meter will be low or very low and you have to work out if it is correct.

However there is one major problem with measuring a faulty transformer or coil.
It may only become faulty when power is applied.
The voltage between the turns may be sparking or jumping a gap and creating a problem. A tester is not going to find this fault.
Secondly, an inductance meter may produce a reading but you do not know if the reading is correct.
An improved tester is a RING TESTER.
The circuit for a ring tester can be found here:

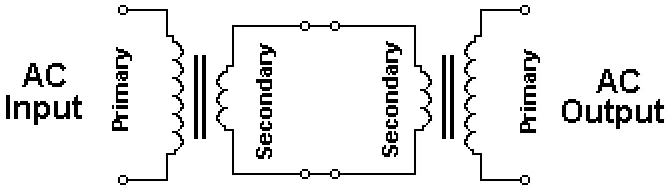
http://www.flippers.com/pdfs/k7205.pdf

It sends a pulse to the coil and counts the number of returning pulses or "rings." A faulty coil (or winding) may return one pulse but nearly all the energy will be passed to the shorted turns and you will be able to see this on the scale. You will only get one or two return pulses, whereas a good winding will return more pulses.

One way to detect a faulty power transformer is to connect it to the supply and feel the temperature-rise (when nothing is connected to the secondary).
It should NOT get hot.
Detecting shorted turns is not easy to diagnose as you really need another identical component to compare the results.
Most transformers get very hot when a shorted turn has developed. It may deliver a voltage but the heat generated and a smell from the transformer will indicate a fault.

ISOLATION TRANSFORMER

An isolation transformer is a piece of Test Equipment that provides "Mains Voltage" but the voltage is "floating." You will still get a shock if you touch the two output leads, but it has a special use when testing unknown equipment.
Many electrical appliances are fully insulated and only have two leads connected to the mains.
When you take these appliances apart, you do not know which end of say a heating element is connected to the "live" (active) side of the mains and which end connects to the neutral.
I am not suggesting you carry out the following tests, but they are described to show how an isolation transformer works.
If you touch a soldering iron on the "live" (active) end of the heating element it will cause a short-circuit.
However when the appliance is connected to the main via an **isolation transformer**, you can touch an earthed soldering iron on either end of the heater as both leads from the isolation transformer are "floating."
Note: As soon as you earth one lead of the output an isolation transformer, the other lead becomes "active."
You can make your own **Isolation Transformer** by connecting two identical transformers "back-to-back."
The following diagram shows how this is done:



You can use any transformers providing the primary and secondary voltages are the same. The current capability of the secondary winding does not matter. However if you want a supply that has almost the same voltage as your "Mains," you need two transformers with the same voltages.
This handy isolation transformer will provide you with "Mains Voltage" but with a limited current.
In other words it will have a limited capability to supply "wattage." If you are using two 15VA transformers, you will only be able to test an appliance rated at 15 watts.
This has some advantages and some disadvantages.
If you are working on a project, and a short-circuit occurs, the damage will be limited to 15 watts.
If you are using two transformers with different VA ratings, the lower rating will be the capability of the combination.
If the secondaries are not equal, you will get a higher or lower "Mains Voltage."
If you get two old TV's or Monitors with a rating on the compliance plate of 45 watts, or 90 watts, you can assume the transformers are capable of delivering this wattage and making an isolation transformer will enable you to test similar items with the safety of being isolated from the mains.
Colin Mitchell designs a lot of "LED lighting lamps" that are connected directly to the mains. He always works with an isolating transformer, just to be safe. Working on exposed "mains" devices is extremely nerve-wracking and you have to very careful.

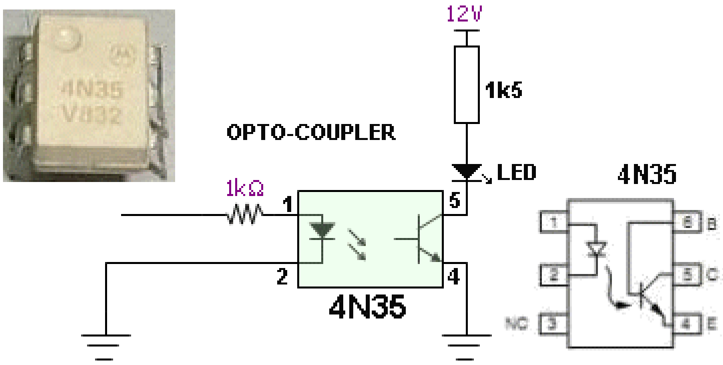
DETERMINING THE SPECS OF A TRANSFORMER

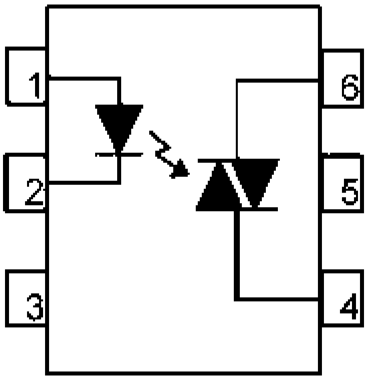
Suppose you have a "mains transformer" with unknown output voltages and unknown current capability.
You must be sure it is a mains transformer designed for operation on 50Hz or 60Hz. Switch-Mode transformers operate at frequencies 40kHz and higher and are not covered in this discussion.
To be on the safe-side, connect the unknown transformer to the output of your isolating transformer.
Since the transformer will take almost no current when not loaded, the output voltages it produces will be fairly accurate. Measure the input AC voltage and output AC voltage.

If the transformer has loaded your isolating transformer it will be faulty.
Mains transformers are approx 15 VA for 500gm, 30VA for 1kgm 50VA for 2kgm and and 100VA for 2.5kgm.
VA stands for Volts-Amps and is similar to saying watts. Watts is used for DC circuits, while VA refers to AC circuits.
Once you have the weight of the transformer and the output voltage, you can work out the current capability of the secondary.
For transformers up to 30vA, the output voltage on no-load is 30% higher than the final "loaded voltage."
This is due to the poor regulation of these small devices.
If the transformer is 15VA and the output voltage will be 15v AC, the current will be 1 amp AC.
You can check the "quality" of the transformer, (the regulation) by fully loading the output and measuring the final voltage. If the transformer has a number of secondaries, the VA rating must be divided between all the windings.

OPTO ISOLATORS and OPTO COUPLERS

Opto Isolators and Opto Couplers are the same thing. A common opto-coupler is 4N35. It is used to allow two circuits to exchange signals yet remain electrically isolated. The signal is applied to the LED, which shines on a silicon NPN photo-transistor in the IC.
The light is proportional to the signal, so the signal is transferred to the photo transistor to turn it on a proportional amount. Opto-couplers can have Light Activated SCR's, photodiodes, TRIAC's and other semiconductor devices as an output. The 4N35 opto-coupler schematic is shown below:





An opto-Coupler using a TRIAC

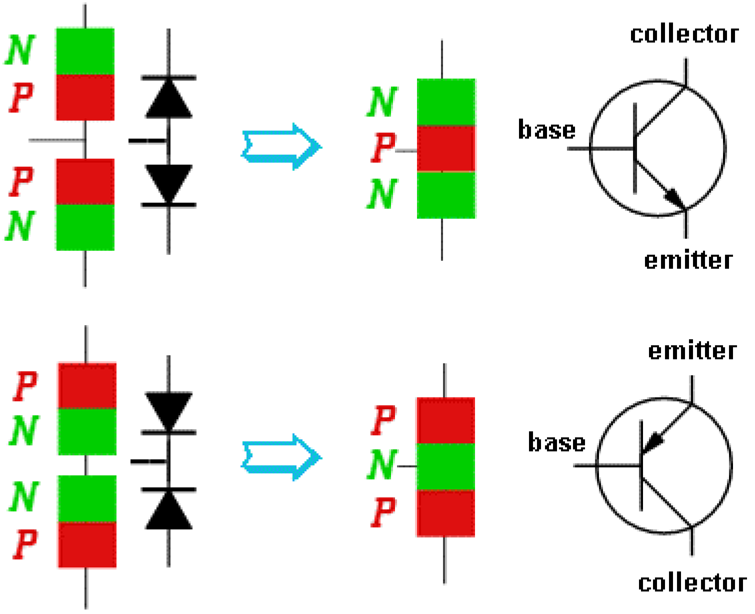
TESTING AN OPTO COUPLER

Most multimeters cannot test the LED on the input of an opto-coupler because the ohms range does not have a voltage high enough to activate the LED with at least 2mA.
You need to set-up the test-circuit shown above with a 1k resistor on the input and 1k5 on the output.
When the 1k is connected to 12v, the output LED will illuminate.
The opto-coupler should be removed from circuit to perform this test.

TRANSISTORS

Transistors are solid-state devices and although they operate completely differently to a diode, they appear as two back-to-back diodes when tested.
There are basically 2 types of transistor NPN and PNP.

A transistor is sometimes referred to as BJT (Bi-polar Junction Transistor) to distinguish it from other types of transistor such as Field Effect transistor, Programmable Unijunction Transistor and others.
In the following diagram, two diodes are connected together and although the construction of a transistor is more complex, we see the transistor as two diodes when testing it.



A TRANSISTOR APPEARS AS TWO DIODES WHEN TESTING IT

All transistors have three leads. Base (b), Collector (c), and Emitter (e).
For an NPN transistor, the arrow on the emitter points away from the base.
It is fortunate that the arrow on both symbols points in the direction of the flow of current (Conventional Current) and this makes it easy to describe testing methods using our simplified set of instructions. The symbols have been drawn exactly as they appear on a circuit diagram.

All transistors **are the same** but we talk about digital and analogue transistors. There is no difference between the two.
The difference is the circuit. And the only other slight difference between transistors is the fact that some have inbuilt diodes and resistors to simplify the rest of the circuit.
All transistors work the same way. The only difference is the amount of amplification they provide, the current and voltage they can withstand and the speed at which they work. For simple testing purposes, they are all the same.

NPN transistors are the most common and for an NPN transistor, the following applies.
(the opposite applies for PNP)
To test a transistor, there is **one thing** you have to know:
When the base voltage is higher than the emitter, current flows though the collector-emitter leads.
As the voltage is increased on the base, nothing happens until the voltage reaches 0.55v. At this point a very small current flows through the collector-emitter leads. As the voltage is increased, the current-flow increases. At about 0.75v, the current-flow is a MAXIMUM. (can be as high as 0.9v). That's how it works. A transistor also needs **current** to flow into the base to perform this amplifying function and this is the one feature that separates an ordinary transistor from a FET.

If the voltage on the base is 0v, then instantly goes to 0.75v, the transistor initially passes NO current, then FULL current. The transistor is said to be working in its two states: OFF then ON (sometimes called: "cut-off" and "saturation"). These are called digital states and the transistor is said to be a **DIGITAL TRANSISTOR** or a **SWITCHING TRANSISTOR** , working in **DIGITAL MODE.**

If the base is delivered 0.5v, then slowly rises to 0.75v and slowly to 0.65v, then 0.7v, then 0.56v etc, the transistor is said to be working in ANALOGUE MODE and the transistor is an **ANALOGUE TRANSISTOR**.
Since a transistor is capable of amplifying a signal, it is said to be an active device. Components such as resistors, capacitors, inductors and diodes are not able to amplify and are therefore known as passive components.

In the following tests, use your finger to provide the **TURN ON** voltage for the base (this is 0.55v to

0.7v) and as you press harder, more current flows into the base and thus more current flows through the collector-emitter terminals. As more current flows, the needle of the multimeter moves UP-SCALE.

TESTING A TRANSISTOR ON A DIGITAL METER

Testing a transistor with a **Digital Meter** must be done on the "DIODE" setting as a digital meter does not deliver a current through the probes on some of the resistance settings and will not produce an accurate reading.
The "DIODE" setting must be used for diodes and transistors. It should also be called a "TRANSISTOR" setting.

TESTING AN unknown TRANSISTOR

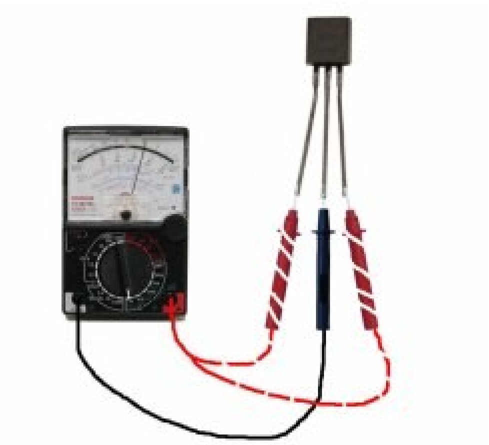
The first thing you may want to do is test an unknown transistor for COLLECTOR, BASE AND EMITTER.
You also want to perform a test to find out if it is NPN or PNP.
That's what this test will provide.
You need a cheap multimeter called an ANALOGUE METER - a multimeter with a scale and pointer (needle).
It will measure resistance values (normally used to test resistors) - (you can also test other components) and Voltage and Current. We use the resistance settings. It may have ranges such as "x10" "x100" "x1k" "x10"
Look at the resistance scale on the meter. It will be the top scale.
The scale starts at zero on the right and the high values are on the left. This is opposite to all the other scales.
When the two probes are touched together, the needle swings FULL SCALE and reads "ZERO." Adjust the pot on the side of the meter to make the pointer read exactly zero.

How to read: "x10" "x100" "x1k" "x10"

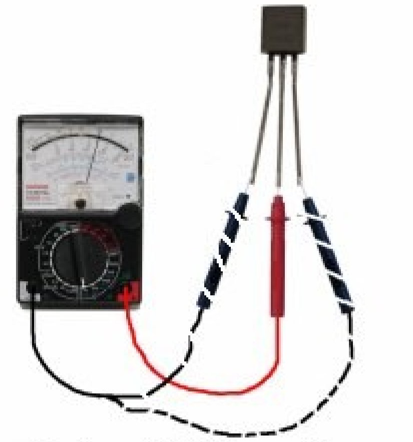
Up-scale from the zero mark is "1"
When the needle swings to this position on the "x10" setting, the value is 10 ohms.
When the needle swings to "1" on the "x100" setting, the value is 100 ohms.
When the needle swings to "1" on the "x1k" setting, the value is 1,000 ohms = 1k.
When the needle swings to "1" on the "x10k" setting, the value is 10,000 ohms = 10k.
Use this to work out all the other values on the scale.
Resistance values get very close-together (and very inaccurate) at the high end of the scale. [This is just a point to note and does not affect testing a transistor.]

Step 1 - FINDING THE BASE and determining NPN or PNP

Get an unknown transistor and test it with a multimeter set to "x10"
Try the 6 combinations and when you have the black probe on a pin and the red probe touches the other pins and the meter swings nearly full scale, you have an NPN transistor. The black probe is BASE
If the red probe touches a pin and the black probe produces a swing on the other two pins, you have a PNP transistor. The red probe is BASE
If the needle swings FULL SCALE or if it swings for more than 2 readings, the transistor is **FAULTY**.



This is an NPN transistor
The black probe is the BASE

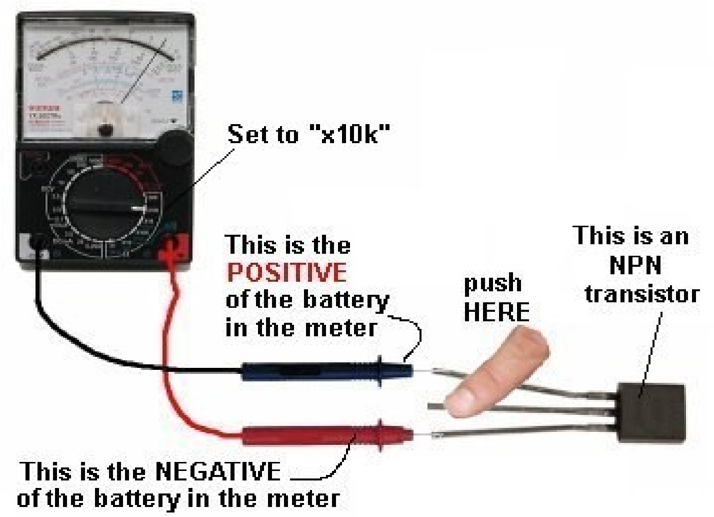


This is a PNP transistor
The red probe is the BASE

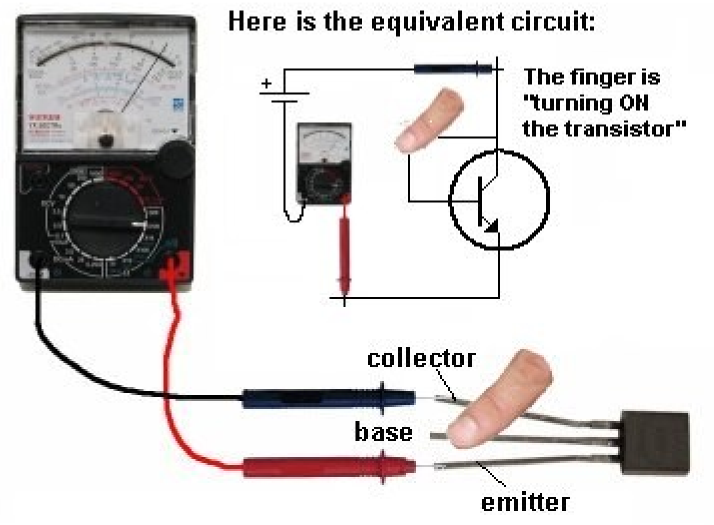
Step 2 - FINDING THE COLLECTOR and EMITTER

Set the meter to "x10k."

For an NPN transistor, place the leads on the transistor and when you press hard on the two leads shown in the diagram below, the needle will swing almost full scale.



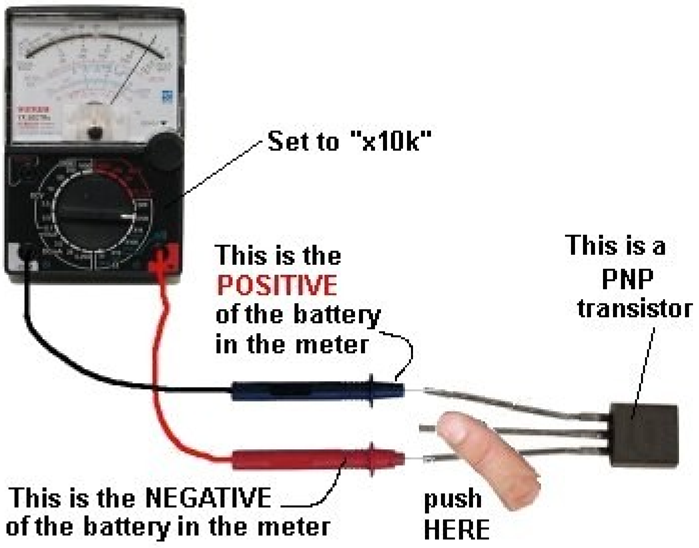
Set to "x10k"
This is the POSITIVE of the battery in the meter
push HERE
This is an NPN transistor
This is the NEGATIVE of the battery in the meter



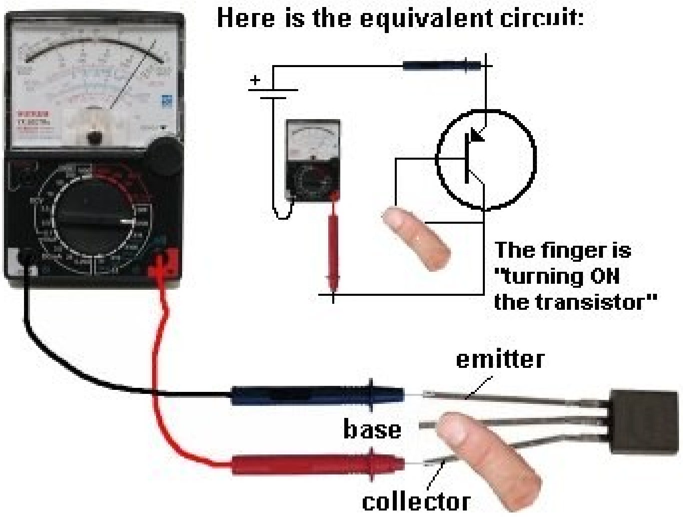
Here is the equivalent circuit:
+
The finger is "turning ON the transistor"
collector
base
emitter

You have found the Collector Base and Emitter

For a PNP transistor, set the meter to "x10k" place the leads on the transistor and when you press hard on the two leads shown in the diagram below, the needle will swing almost full scale.



Set to "x10k"
This is the POSITIVE of the battery in the meter
This is a PNP transistor
This is the NEGATIVE of the battery in the meter
push HERE



Here is the equivalent circuit:
+
The finger is
"turning ON
the transistor"
emitter
base
collector

You have found the Collector Base and Emitter

SIMPLEST TRANSISTOR TESTER

The simplest transistor tester uses a 9v battery, 1k resistor and a LED (any colour). Keep trying a transistor in all different combinations until you get one of the circuits below. When you push on the two leads, the LED will get brighter.

The transistor will be NPN or PNP and the leads will be identified:

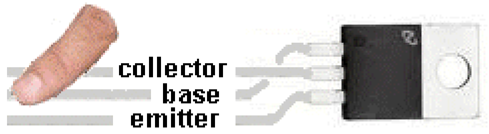
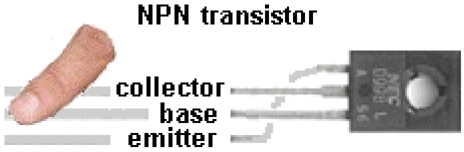
The leads of some transistors will need to be bent so the pins are in the same positions as shown in the diagrams. This helps you see how the transistor is being turned on. This works with NPN, PNP transistors and Darlington transistors.



NPN transistor



NPN transistor

HEATSINKING

Heat generated by current flowing between the collector and emitter leads of a transistor causes its temperature to rise. This heat must be conducted away from the transistor otherwise the rise may be high enough to damage the P-N junctions inside the device. Power transistors produce a lot of heat, and are therefore usually mounted on a piece of aluminium with fins, called a **HEATSINK**.
This draws heat away, allowing it to handle more current. Low-power signal transistors do not normally require heat sinking. Some transistors have a metal body or fin to connect to a larger heatsink. If the transistor is connected to a heatsink with a mica sheet (mica washer), it can be damaged or cracked and create a short-circuit. (See Testing Mica Washers). Or a small piece of metal may be puncturing the mica. Sometimes white compound called **Heatsink Compound** is used to conduct heat through the mica. This is very important as mica is a very poor conductor of heat and the compound is needed to provide maximum thermal conduction.

TRANSISTOR FAILURE

Transistor can fail in a number of ways. They have forward and reverse voltage ratings and once these are exceeded, the transistor will ZENER or conduct and may fail. In some cases a high voltage will "puncture" the transistor and it will fail instantly. In fact it will fail much faster via a voltage-spike than a current overload.

It may fail with a "short" between any leads, with a collector-emitter short being the most common. However failures will also create shorts between all three leads.
A shorted transistor will allow a large current to flow, and cause other components to heat up.
Transistors can also develop an open circuit between base and collector, base and emitter or collector and emitter.
The first step in identifying a faulty transistor is to check for signs of overheating. It may appear to be burnt, melted or exploded. When the equipment is switched off, you can touch the transistor to see if it feels unusually hot. The amount of heat you feel should be proportional to the size of the transistor's heat sink. If the transistor has no heat sink, yet is very hot, you can suspect a problem.
DO NOT TOUCH A TRANSISTOR IF IT IS PART OF A CIRCUIT THAT CARRIES 240VAC. Always switch off the equipment before touching any components.

TRANSISTOR REPLACEMENT

If you can't get an exact replacement, refer to a transistor substitution guide to identify a near equivalent.

The important parameters are:
- Voltage
- Current
- Wattage
- Maximum frequency of operation

The replacement part should have parameters equal to or higher than the original.

Points to remember:
- Polarity of the transistor i.e. PNP or NPN.
- At least the same voltage, current and wattage rating.
- Low frequency or high frequency type.
- Check the pinout of the replacement part
- Use a desoldering pump to remove the transistor to prevent damage to the printed circuit board.
- Fit the heat sink.

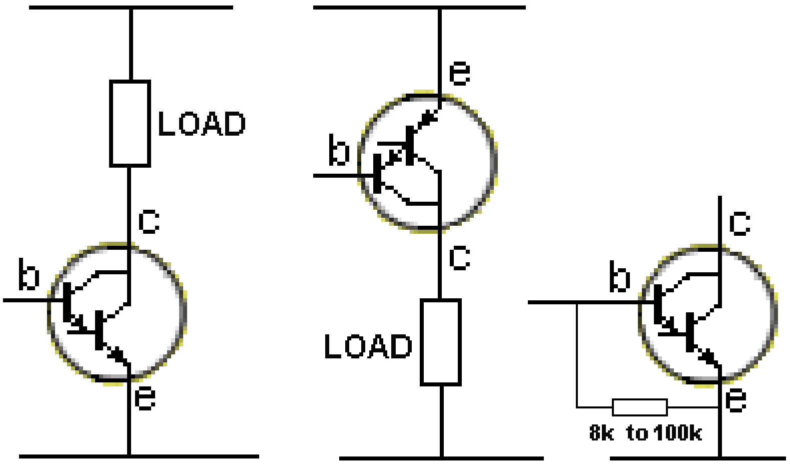
- Check the mica washer and use heat-sink compound
- Tighten the nut/bolt - not too tight or too loose.
- Horizontal output transistors with an integrated diode should be replaced with the same type.

DIGITAL TRANSISTORS

There is no such thing as a DIGITAL TRANSISTOR, however some transistors are available with built-in resistors between base and emitter (to save space on the board) and these transistors are often used in digital circuits. The transistor will amplify analogue signals but when the signal is 0v then immediately goes to a voltage above 0.7v, the transistor is in a DIGITAL CIRCUIT and the transistor is called a DIGITAL TRANSISTOR.   It is tested like an ordinary transistor but the low value resistor between base and emitter will produce a low reading in both directions.

DARLINGTON TRANSISTORS

A DARLINGTON TRANSISTOR is two transistors in a single package with three leads. They are internally connected in cascade so the gain of the pair is very high. This allows a very small input signal to produce a large signal at the output. They have three leads (Base, Collector and Emitter and can be PNP or NPN) and are equivalent to the leads of a standard individual transistor, but with a very high gain. The second advantage of a Darlington Transistor is its high input impedance. It puts very little load on the previous circuit.
Some Darlington transistors have a built-in diode and/or built-in resistor and this will produce a low reading in both directions between the base and emitter leads.



NPN Darlington   PNP Darlington

Darlington transistors are tested the same as an ordinary transistor and a multimeter will produce about the same deflection, even though you will be measuring across two junctions, (and a base-emitter resistor is present).

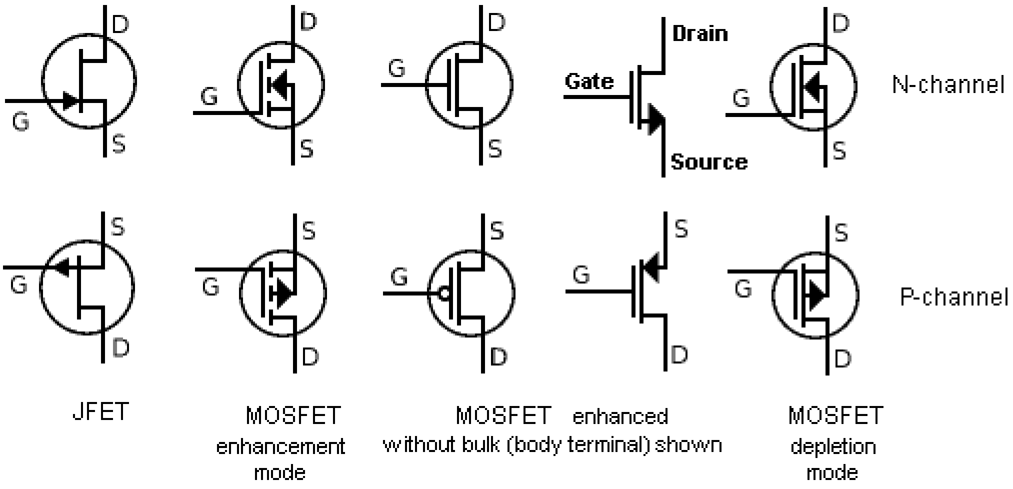
HORIZONTAL OUTPUT TRANSISTORS, SWITCH-MODE TRANSISTORS, FLYBACK TRANSISTORS, POWER TRANSISTORS, VERTICAL TRANSISTORS . . . .

These are all names given to a transistor when it is used in a particular circuit. ALL these transistors are the same for testing purposes.
We are not testing for gain, maximum voltage, speed of operation or any special feature. We are just testing to see if the transistor is completely faulty and SHORTED.
A transistor can have lots of other faults and the circuit **using the transistor** is the best piece of TEST EQUIPMENT as it is detecting the fault.

TESTING MOSFETs and FETs

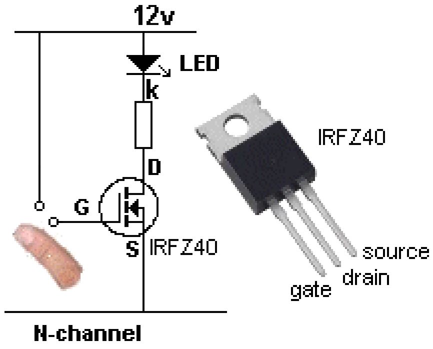
MOSFETs and **JFETs** are all part of the **FET** family.
MOSFET stands for **Metal Oxide Semiconductor Field Effect Transistor.**
FETs operate exactly the same as a "normal" transistor except they have different names for the input and output leads and the voltage between the gate and the source has to between 2v to 5v for the device to turn on fully. A FET requires almost NO CURRENT into the Gate for it to turn on and when it

does, the voltage between drain and source is very low (only a few mV). This allows them to pass very high currents without getting hot. There is a point where they start to turn on and the input voltage must rise higher than this so the FET turns on FULLY and does not get hot.
Field Effect Transistors are difficult to test with a multimeter, but "fortunately" when a power **MOSFET** blows, it is completely damaged. All the leads will show a short circuit. 99% of bad **MOSFETs** will have GS, GD and DS shorted.
The following symbols show some of the different types of MOSFETs:

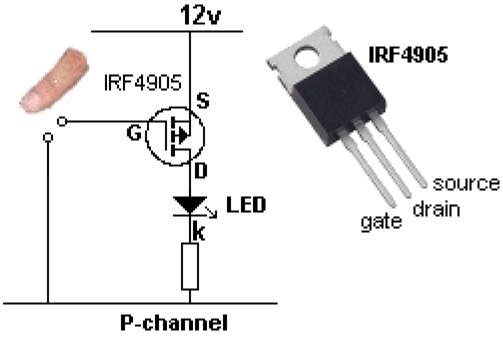


D
G
S
Drain
Gate
Source
N-channel
P-channel
JFET
MOSFET
enhancement mode
MOSFET enhanced
without bulk (body terminal) shown
MOSFET
depletion mode

Most **MOSFET** transistors cannot be tested with a multimeter. This due to the fact that the Gate needs 2v - 5v to turn on the device and this voltage is not present on the probes of either meter set to any of the ohms ranges.
You need to build the following Test Circuit:



12v
LED
k
D
G
S
IRFZ40
IRFZ40
source
drain
gate
N-channel



12v
IRF4905
S
G
D
LED
k
IRF4905
source
drain
gate
P-channel

Touching the Gate will increase the voltage on the Gate and the MOSFET will turn on and illuminate the LED. Removing your finger will turn the LED off.

SILICON CONTROLLED RECTIFIERs (SCR)

The **Silicon Controlled Rectifier** (SCR) is a semiconductor device that is a member of a family of control devices known as **Thyristors**. It is a 3-leaded device and when a small current enters the Gate, the **thyristor** turns on. AND STAYS ON. It only conducts current between Anode and Cathode in one direction and it is mainly only used in DC circuits. When it is used with AC, it will only conduct for a maximum of half the cycle.

B

To understand how an SCR "latches" when the gate is provided with a small current, we can replace it with two transistors as shown in diagram B above. When the ON button is pressed, the BC547 transistor turns on. This turns ON the BC557 and it takes over from the action of the switch.
To turn the circuit off, the OFF button removes the voltage from the base of the BC547.

Testing an SCR

An **SCR** can be tested with some multimeters but a minimum current Anode-to-Cathode is needed to keep the device turned on. Some multimeters do not provide this amount of current and the **SCR Tester** circuit above is the best way to test these devices.
Shorted SCRs can usually be detected with an ohmmeter check (SCRs usually fail shorted rather than open).
Measure the anode-to-cathode resistance in both the forward and reverse direction; a good SCR should measure near infinity in both directions.
Small and medium-size SCRs can also be gated ON with an ohmmeter (on a digital meter use the Diode Check Function). Forward bias the SCR with the ohmmeter by connecting the black (-) lead to the anode and the red (+) lead to the cathode (because the + of the battery is connected to the negative lead, in most analogue multimeters). Momentarily touch the gate lead to the anode while the probes are still touching both leads; this will provide a small positive turn-on voltage to the gate and the cathode-to-anode resistance reading will drop to a low value. Even after removing the gate voltage, the SCR will stay conducting. Disconnecting the meter leads from the anode or cathode will

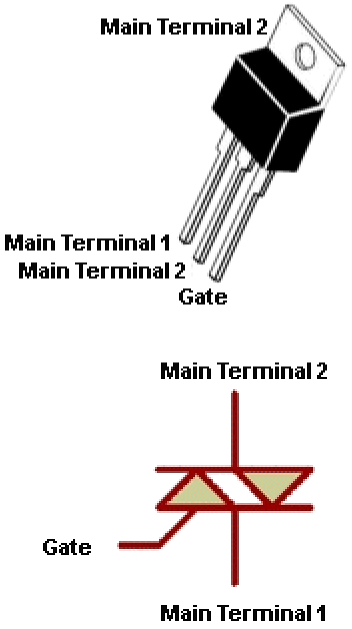
cause the SCR to revert to its non-conducting state.
When making the above test, the meter impedance acts as the SCR load. On larger SCRs, it may not latch ON because the test current is not above the SCR holding current.

Using the SCR Tester

Connect an SCR and press Switch2. The lamp should not illuminate. If it illuminates, the SCR is around the wrong way or it is faulty.
Keep Switch 2 PRESSED. Press Sw1 very briefly. The lamp or motor will turn ON and remain ON.
Release Sw 2 and press it again. The Lamp or motor will be OFF.

TRIACs

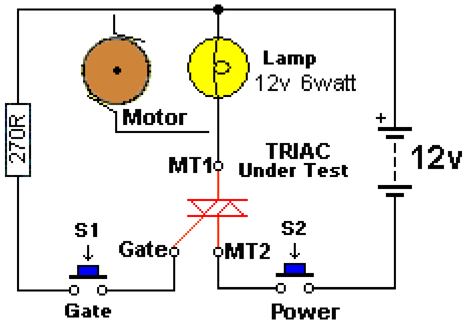
A triac is a bidirectional, three-terminal dual, back-to-back thyristor (SCR) switch. This device will conduct current in both directions when a small current is constantly applied to the Gate.
If the gate is given a small, brief, current during any instant of a cycle, it will remain triggered during the completion of the cycle until the current though the Main Terminals drops to zero.
This means it will conduct both the positive and negative half-cycles of an AC waveform. If it is tuned on (with a brief pulse) half-way up the positive waveform, it will remain on until the wave rises and finally reaches zero. If it is then turned on (with a brief pulse) part-way on the negative wave, the result will be pulses of energy and the end result will be about 50% of the full-energy delivered at a rate of 100 times per second for a 50HZ supply.
TRIACs are particularly suited for AC power control applications such as motor speed control, light dimmers, temperature control and many others.



TRIAC (2 SCR's)
TRIode for Alternating Current

Using the TRIAC Tester

Connect a TRIAC and press Switch2. The lamp should not illuminate. If it illuminates, the TRIAC is faulty.
Keep Switch 2 PRESSED. Press Sw1 very briefly. The lamp or motor will turn ON and remain ON. If the lamp does not turn on, reverse the TRIAC as the current into the gate must produce a slight voltage between **Gate** and **Main Terminal 1**.
Release Sw 2 and press it again. The Lamp or motor will be OFF.



TRIAC TESTER

MICA WASHERS AND INSULATORS

Plastic insulating sheets (washers) between a transistor and heatsink are most often made from mica but some are plastic and these get damaged over a period of time, turn dark and become cracked. The plastic eventually becomes carbonized and conducts current and can affect the operation of the appliance. You can see the difference between a mica sheet (washer) and plastic by looking where it extends from under the transistor. Replace all plastic insulators as they eventually fail.

SPARK GAPS

Some TV's and monitors with a CRT (picture tube), have spark gaps either on the socket at the end of the tube or on the chassis.
These can consist of two wires inside a plastic holder or a glass tube or special resistive device.
The purpose of a spark gap is to take any flash-over (from inside the tube), to earth. This prevents damage to the rest of the circuit.
However if the tube constantly flashes over, a carbon track builds up between the wires and effectively reduces the screen voltage. This can cause brightness and/or focus problems. Removing the spark-gap will restore the voltage.
These are not available as a spare component and it's best to get one from a discarded chassis.

CO-AX CABLES

Co-Ax cables can produce very high losses and it seems impossible that a few metres of cable will reduce the signal. The author has had a 3 metre cable reduce the signal to "snow" so be aware that this can occur. Faults can also come from a splitter and/or balun as well as dirty plugs and sockets. This can result in very loud bangs in the sound on digital reception.

TESTING EARTH LEAKAGE DETECTORS or Residual Current Devices or Ground Fault Circuit Interrupters or GFCI

An Earth Leakage Detector or Sensor is a circuit designed to continuously monitor the imbalance in the current in a pair of load carrying conductors.
These two conductors are normally the Active and Neutral. Should the imbalance current reach 30mA the sensor will "trip" and remove the voltage (and current) from the line being monitored.
Some detectors will trip at 15mA.
You cannot alter the sensitivity of the device however there are a number of faults in these devices that can be fixed.
In some devices the contact pressure for the 10Amp or 15 Amp contacts is very weak and they arc and produce an open circuit. The result is this: When you press the rest button, power is not restored to the output.
Clean the contacts with a small file and bend the metal strips to the contacts so they make a very strong contact.
The other fault is the trip mechanism.
The magnetism from the coil does not allow the pin to move and "trip" the contacts. It may be due to a small metal filing or the pin not moving freely enough.
All good Earth Leakage Detectors have a TEST BUTTON. This connects a resistor between the active line and earth so that 15mA or 30mA flows.
The detector should trip immediately. Make sure the trigger mechanism trips when the test button is pressed.
None of the electronics in the detector can be replaced however you can test the mechanical operation and the pressure on the contacts when the unit is removed from the power. Do not work on the device

when it is connected to the mains.

TESTING CELLS AND BATTERIES

There is an enormous number of batteries and cells on the market and a number of "battery testers." Instead of buying a battery tester that may give you a false reading, here is a method of testing cells that is guaranteed to work.
There are two types of cell: a **rechargeable** cell and a non rechargeable cell.

The easiest way to test a **rechargeable** cell is to put a group of them in an appliance and use them until the appliance "runs down" or fails to work. If you consider the cells did not last very long, remove them and check the voltage of each cell. The cell or cells with the lowest voltage will be faulty. You can replace them with new cells or good cells you have in reserve.
There is no other simple way to test a rechargeable cell.
You cannot test the "current of a cell" by using an ammeter. A rechargeable cell can deliver 10 amps or more, even when nearly discharged and you cannot determine a good cell for a faulty cell.

Dry cells are classified as "non-rechargeable" cells.
DRY CELLS and MANGANESE CELLS are the same thing. These produce 1.5v per cell (manganese means the Manganese Dioxide depolariser inside the cell. All "dry cells" use manganese dioxide).
ALKALINE CELLS produce between 2 - 10 times more energy than a "dry cell" and produce 1.5v per cell.
Alkaline cells can fail for no reason at any stage in their life and are not recommended for emergency situations.
The output voltage of some Alkaline cells can fall to 0.7v or 0.9v for not apparent reason.
There are lots of other cells including "button cells," hearing-aid cells, air cells, and they produce from 1.2v to 3v per cell.

Note:
Lithium cells are also called "button cells" and they produce 3v per cell.
Lithium cells are non-rechargeable (they are generally called "button cells") but some Lithium cells can be recharged. These are Lithium-ion cells and generally have a voltage of 3.6v. Some Lithium-ion cells look exactly like 3v Lithium cells, so you have to read the data on the cell before charging.

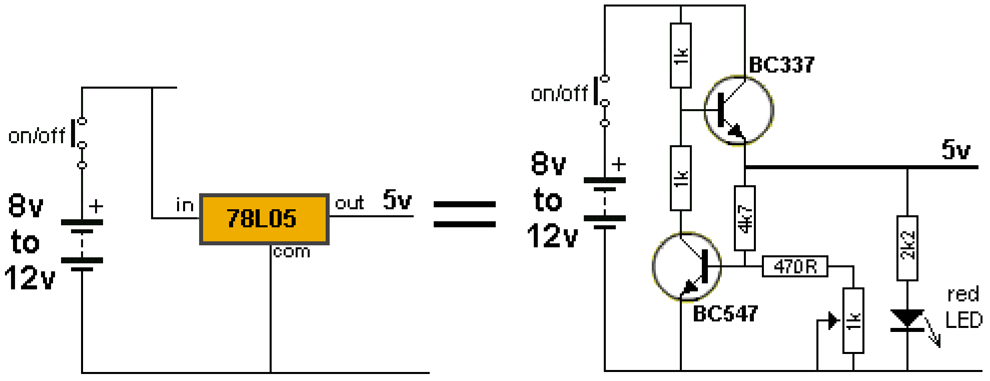
You cannot test the voltage of a cell and come to any conclusion as to the age of the cell or how much energy remains. The voltage of a cell is characteristic to the chemicals used and the actual voltage does not tell you its condition.
Some "dry cells" deliver 1.5v up to the end of their life whereas others drop to about 1.1v very quickly.

Once you know the name of the cell that drops to 1.1v, avoid them as the operation of the equipment "drops off" very quickly.

However if you have a number of different cells and need to know which ones to keep, here's the solution:

1. Check the voltage and use those with a voltage above 1.1v
2. Next, select 500mA or 10A range on a meter and place the probes on a cell. For a AAA or AA cell, the current should be over 500mA and the needle will swing full scale very quickly.
Keep the testing short as you are short-circuiting the cell but it is the only way to determine the internal impedance of the cell and this has a lot to do with its stage-of-charge.
This will give you a cell with a good terminal voltage and a good current capability.

This also applies to button cells, but the maximum current they will deliver will be less.
If you want to get the last of the energy out of a group of cells they can be used in the following circuits:



1mV drop @100mA @10v supply

10mV drop @100mA @10v supply

TESTING PIEZO DIAPHRAGMS and PIEZO BUZZERS

There are two types of piezo devices that produce a sound.
They are called **PIEZO DIAPHRAGMS** and **PIEZO BUZZERS**.
A **piezo diaphragm** consists of two metal plates with a ceramic material between. The ceramic expands and contracts when an alternating voltage is placed on the two plates and this causes the main plate to "dish" and "bow."
This creates a high-pitched sound. There are no other components inside the case and it requires an AC voltage of the appropriate frequency to produce a sound.
A **piezo buzzer** has a transistor and coil enclosed and when supplied with a DC voltage, the buzzer produces a sound.
Both devices can look exactly the same and the only way to tell them apart is by connecting a 9v battery. One device may have "+' and "-" on the case to indicate it is a piezo buzzer, but supplying 9v will make the buzzer produce a sound while the piezo diaphragm will only produce a "click."

PIEZO DIAPHRAGM
PIEZO BUZZER

A piezo diaphragm will produce a click
when connected to 9v DC.
A piezo buzzer will produce a tone when
connected to a DC voltage.

TESTING A CIRCUIT

Whenever you test a circuit, the TEST EQUIPMENT puts "a load" or "a change" on it.
It does not matter if the test equipment is a multimeter, Logic Probe, CRO, Tone Injector or simply a LED and resistor.
There are two things you need to know.
1. The IMPEDANCE of the circuit at the location you are testing, and
2. The amount of load you are adding to the circuit via the test equipment.

There is also one other hidden factor. The test equipment may be injecting "hum" due to its leads or the effect of your body at absorbing hum from the surroundings or the test equipment may be connected to the mains.
These will affect the reading on the test equipment and also any output of the circuit.
Sometimes the test equipment will prevent the circuit from working and sometimes it will just change the operating conditions slightly. You have to be aware of this.
The last section of this eBook covers High and Low Impedance and understanding impedance is something you need to know.
The point to note here is the fact that the equipment (and the reading) can be upset by hum and resistance/capacitance effects of test equipment. This is particularly critical in high impedance and high

frequency circuits.

TESTING INTEGRATED CIRCUITS (IC's)

Integrated Circuits can be tested with a LOGIC PROBE. A Logic Probe will tell you if a line is HIGH, LOW or PULSING.
Most logic circuits operate on 5v and a Logic Probe is connected to the 5v supply so the readings are accurate for the voltages being tested.
A Logic Probe can also be connected to a 12v CMOS circuit.
You can make your own Logic Probe and learn how to use it from the following link:

http://www.talkingelectronics.com/projects/LogicProbeMkIIB/LogicProbeMk-IIB.html

LOGIC PROBE with PULSE

This is a very simple transistor circuit to provide HIGH-LOW-PULSE indication for digital circuits. It can be built for less than $5.00 on a piece of matrix board or on a small strip of copper clad board if you are using surface mount components. The probe will detect a HIGH at 3v and thus the project can be used for 3v, 5v and CMOS circuits.

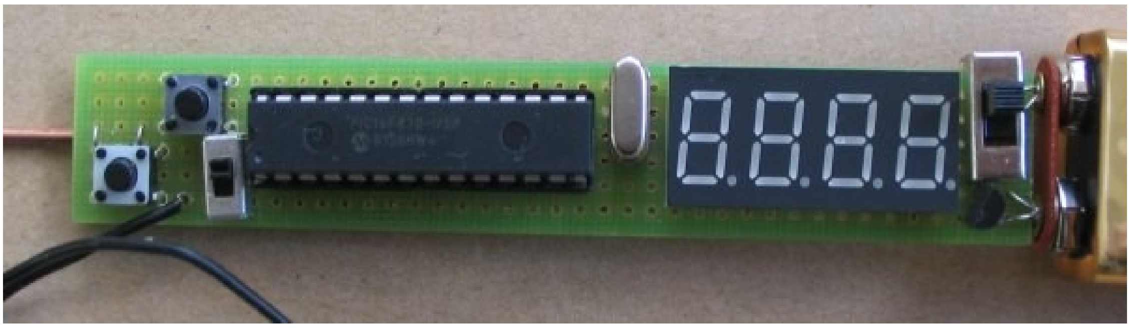
SUPER PROBE MkII Circuit



SUPER PROBE MkII

To test an IC, you need a circuit diagram with waveforms. These diagrams will show the signals and are very handy if a CRO (cathode ray Oscilloscope) is used to diagnose the problem. The CRO will reproduce the waveform and prove the circuit is functioning correctly.
A Logic Probe will just show activity and if an output is not producing a "pulse" or "activity," you should check the power to the IC and test the input line.
It is beyond the scope of this eBook to explain how to diagnose waveforms, however it is important to know if signals are entering and exiting an IC and a Logic Probe is designed for this.

SIGNAL INJECTOR

This circuit is rich in harmonics and is ideal for testing amplifier circuits. To find a fault in an amplifier, connect the earth clip to the 0v rail and move through each stage, starting at the speaker. An increase in volume should be heard at each preceding stage. This Injector will also go through the IF stages of radios and FM sound sections in TV's.

TESTING AUDIO AMPLIFIERS and AUDIO IC's

The **Super Probe MII** described above has a "noise" function and a tone function that allows you to inject a signal into an audio stage, amplifier (made from discrete components) or an audio chip, and detect the output on a speaker.
Audio stages are very difficult to work-with if you don't have a TONE GENERATOR or SIGNAL INJECTOR.
The signals are very small and not detected by a multimeter.
You can start anywhere in an amplifier and when a tone is heard, you can keep probing until the signal is not present or louder. From this you can work out which way the signal is travelling.
A Signal Injector is very handy for finding shorts and broken wires in switches, plugs, sockets and especially leads to headphones.
You can determine the gain of a stage (amplification) by probing before and after a chip or transistor and listen for the relative increase in volume from the speaker.
You can also use your finger to produce "hum" or "buzz" if a **Signal Injector** is not available.
Nearly all audio problems are plugs, sockets and cracks in the PC board, but finding them takes a lot of time and skill.

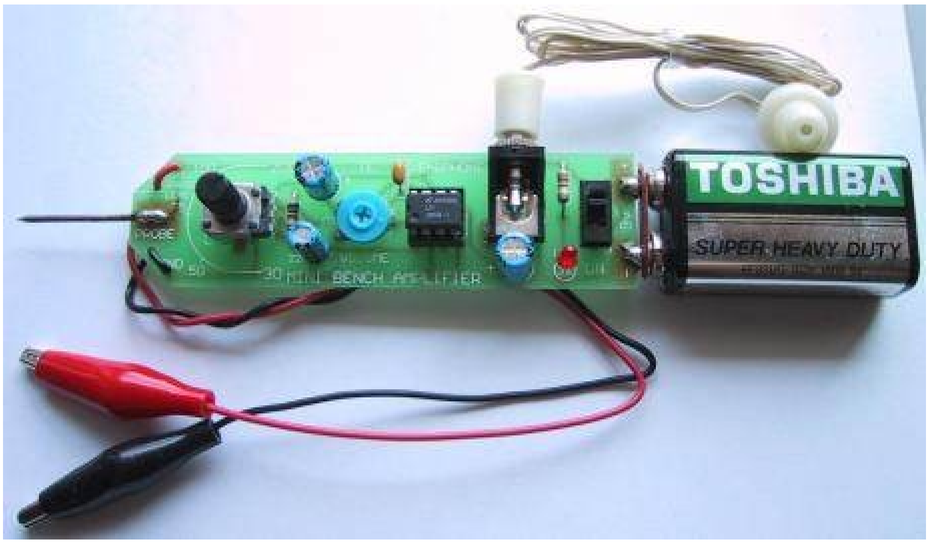
TESTING IC's - also called "CHIPS"

An Integrated Circuit is also called a "chip." It might have 8 pins or as many as 40.
Some chips are ANALOGUE. This means the input signal is rising and falling slowly and the output produces a larger version of the input.
Other chips are classified as DIGITAL and the input starts at 0v and rises to rail voltage very quickly. The output does exactly the same - it rises and falls very quickly.
You might think the chip performs no function, because the input and output voltage has the same value, but you will find the chip may have more than one output and the others only go high after a number of clock-pulses on the input, or the chip may be outputting when a combination of inputs is recognised or the output may go HIGH after a number of clock pulses.

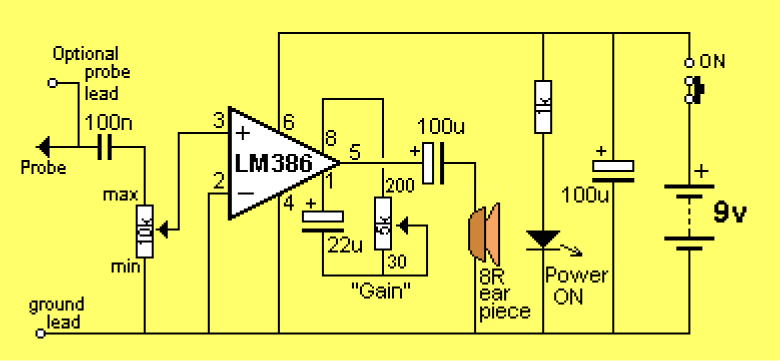
ANALOGUE CHIPS (also see above)

Analogue chips are AUDIO chips or AMPLIFIER chips.
To test these chips you will need three pieces of test equipment:
1. A multimeter - this can be digital or analogue.
2. A Signal Injector
3. A Mini Bench Amplifier.

The Mini Bench Amplifier is available as a kit.



MINI BENCH AMPLIFIER



MINI BENCH AMPLIFIER CIRCUIT

Start by locating the power pin with a multimeter.
If the chip is receiving a voltage, you can use the Mini Bench Amplifier to detect an output.
Connect the Ground Lead of the Mini Bench Amplifier to 0v and touch the Probe tip on each of the pins.

You will hear faint audio on the Input pin and very loud audio on the Output pin.
If no input is detected, you can use a Signal Injector to produce a tone.
Connect the clip of the Signal Injector to 0v and the probe to the input pin of the amplifier chip. At the same time, connect the Mini Bench Amplifier to the output pin and you will hear a very loud tone.
These pieces of test equipment can also be used to diagnose an amplifier circuit constructed with individual components.
Amplifier circuits using discrete components are very hard to trouble-shoot and these pieces of test equipment make it very easy.

DIGITAL CHIPS

It is always best to have data on the chip you are testing, but if this is not available, you will need three pieces of equipment:
1. A multimeter - this can be digital or analogue.
2. A Logic Probe,
3. A logic Pulser.
Firstly test the chip to see if power is being delivered. This might be anything from 3v3 to 15v.
Place the negative lead of the multimeter on the earth rail of the project - this might be the chassis, or the track around the edge of the board or some point that is obviously 0v.
Try all the pins of the chip and if you get a reading, the chip will have "supply."
Identify pin 1 of the chip by looking for the "cut-out" at the end of the chip and you may find a small dimple below the cut-out (or notch). This is pin 1 and the "power pin" can be directly above or any of the other pins.
Next you need to now if a signal is entering the chip.
For this you will need a LOGIC PROBE.
A Logic Probe is connected to the same voltage as the chip, so it will detect a HIGH and illuminate a red LED.
Connect the Logic Probe and touch the tip of the probe on each pin.
You will not know if a signal is an input or output, however if you get two or more active pins, you can assume one is input and the other is output. If none of the pins are active, you can assume the signal is not reaching this IC.
If only one pin is active, you can assume the chip is called a CLOCK (or Clock Generator). This type of chip produces pulses. If more than two pins are active, you can assume the chip is performing its function and unless you can monitor all the pins at the same time, you don't know what is happening.
This is about all you can do without any data on the chip.

If you have data on the chip, you can identify the input(s) and output(s).
A Logic Probe on each of these pins will identify activity.
A Logic Probe has 3 LEDs. Red LED indicates a HIGH, Green indicates a LOW and Orange indicates a PULSE (activity).
Some Logic Probes include a piezo and you can hear what is happening, so you don't take your eyes off the probe-tip.
It is important not to let the probe tip slip between the pins and create a short-circuit.

LOGIC PULSER

If you have a board or a single chip and want to create activity (clock pulses), you can use a Logic Pulser. This piece of test equipment will produce a stream of pulses that can be injected into the clock-line (clock input) of a chip.

You can then use a Logic Probe at the same time on the outputs to observe the operation of the chip.

You can also use the Mini Bench Amplifier to detect "noise" or activity on the inputs and outputs of digital chips.
This only applies if the frequency is in the audio range such as scanning a keyboard or switches or a display.

This is how to approach servicing/testing in a general way. There are thousands of digital chips and if you want to test a specific chip for its exact performance, you will need to set-up a "test-bed."

REMOTE CONTROLS

There are two types of remote control - Infrared and RF. Infrared is used for short-range, line-of-sight for TV's DVD's etc.
A few faults can be fixed, but anything complex needs a new remote control.
Check the batteries and battery-contacts. See if the IR LED is illuminating by focusing it into a digital camera and looking on the screen for illumination.
The only other things are a sticky button, a worn-out button or a crack in the PC board. Water damage is generally too much work to repair.
RF remote controls for cars, garage doors etc need a second working unit to check the power output.
Here is a simple circuit that can be connected to an analog multimeter to detect the signal strength at a very close range:

MINI BUG DETECTOR

Any further investigation requires a circuit diagram so you can work out what is actually being sent from the transmitter.
Most of the time it is a faulty switch, battery or contacts. Make sure the setting is correct on the "dip switches" and use a working unit to compare all your testing.

TESTING VOLTAGES ON (in) A CIRCUIT

There are basically two different types of circuit.
1. **ANALOGUE CIRCUIT**
An analogue circuit can also be called an AUDIO CIRCUIT and the voltages at different points in a circuit can be measured with a multimeter but the changes (the waveforms) will be quite small or changing at a rapid rate and cannot be detected by a multimeter.

You need a CRO to "see" the signals or a **Signal Injector** to inject a waveform into the circuit and hear the result on the circuit's speaker.

2. **DIGITAL CIRCUIT**
A digital circuit can also be called a "Computer Circuit" or "Logic Circuit" and some of the voltages can be measured with a multimeter (such as supply voltages) but the "signal lines" will be be changing from HIGH to LOW to HIGH very quickly and these signals are detected with a **Logic Probe**.

Here are some circuits with details of how to test the voltages.
Most circuits do not show voltages at various different points and we will explain what to expect on each "stage."

A "STAGE"

A stage is a set of components with an input and output. A "stage" can also be called a "Building Block."
Sometimes it has a capacitor on the input and one on the output.
This means the stage is completely isolated as far as DC is concerned.
The stage has a supply (a DC supply) and it is producing its own voltages on various points on the "stage." It can only process (amplify) "AC." (signals).
Sometimes the stage can be given a name, such as small-signal amplifier, push-pull amplifier or output.
If the stage has a link or resistor connected to a previous stage, the previous stage will have a "DC effect" on the stage. In other words it will be biasing or controlling the voltages on the stage. The stage may be called a "timer" or "delay" or "DC amplifier."

It is important to break every circuit into sections. This makes testing easy. If you have a capacitor at the input and output, you know all the problems lie within the two capacitors.
In a digital circuit (no capacitors) you need to work on each IC (integrated Circuit) and test the input for activity and all the outputs.

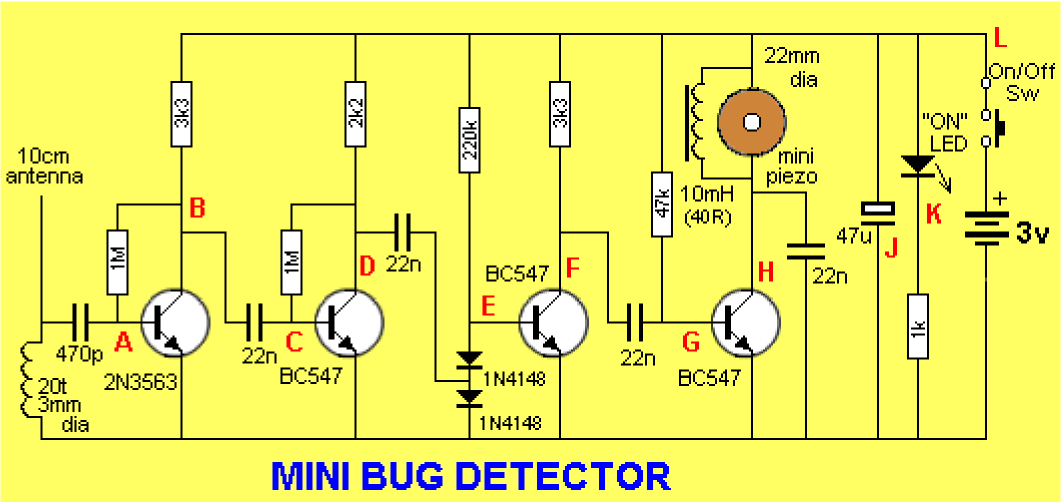
Once you have determined if the circuit is Analogue or Digital, or a combination of both, you have to look at the rail voltage and work out the size or amplitude of the voltage or waveform.
This is done before making a test, so your predictions are confirmed.
You will need a **multimeter** (either Digital or Analogue) a **Logic Probe** and a **Signal Injector** (**Tone Generator**). An analogue meter has the advantage that it will detect slight fluctuations of voltage at a test-point and its readings are faster than a digital meter. A digital meter will produce an accurate voltage-reading - so you should have both available.

HIGH IMPEDANCE AND LOW IMPEDANCE

Every point in a circuit has a characteristic called "IMPEDANCE." This has never been discussed before in any text book. That's why it will be new to you.
In other words, every point will be "sensitive to outside noise."
An audio amplifier is a good example. If you put your finger on the active input, it will produce hum or buzz in the speaker. This is because it is a HIGH IMPEDANCE line or high impedance section of the circuit.
The same applies to every part in a circuit and when you place Test Equipment on a line for testing purposes, the equipment will "upset" the line. It may be very slight but it can also alter the voltage on the point CONSIDERABLY.
We have already mentioned (above) how a cheap multimeter can produce a false reading when measuring across a 1M resistor. That's why you need high impedance test Equipment so you do not "load" the point you are testing and create an inaccurate reading.
The word **Impedance** really means resistance, but when you have surrounding components such as diodes, capacitors, transistors, coils, Integrated Circuits, supply-voltages and resistors, the combined effect is very difficult to work out as a "resistance" and that's why we call it "Impedance."
The term "**High and Low Impedance**" is a relative term and does not have any absolute values but we can mention a few points to help you decide.
In general, the base of a transistor, FET input of an IC are classified as HIGH IMPEDANCE.
The output of these devices are LOW IMPEDANCE.
Power rails are LOW IMPEDANCE.
An oscillator circuit and timing circuit are HIGH IMPEDANCE.
A LOAD is low impedance.
And it gets tricky: An input can be designed to accept a low-impedance device (called a transducer or pick-up) and when the device is connected, the circuit becomes LOW impedance, but the input circuitry is actually high impedance.
The impedance of a diode or LED is HIGH before the device sees a voltage higher than the junction

voltage and then it becomes LOW Impedance.
Impedance is one of the most complex topics however it all comes down to testing a circuit without loading it.
That's why test equipment should have an input impedance higher than 1M.

The first circuit we will investigate is the **Mini Bug Detector**, shown above and below. Points on the circuit have been labelled A, B, C etc:



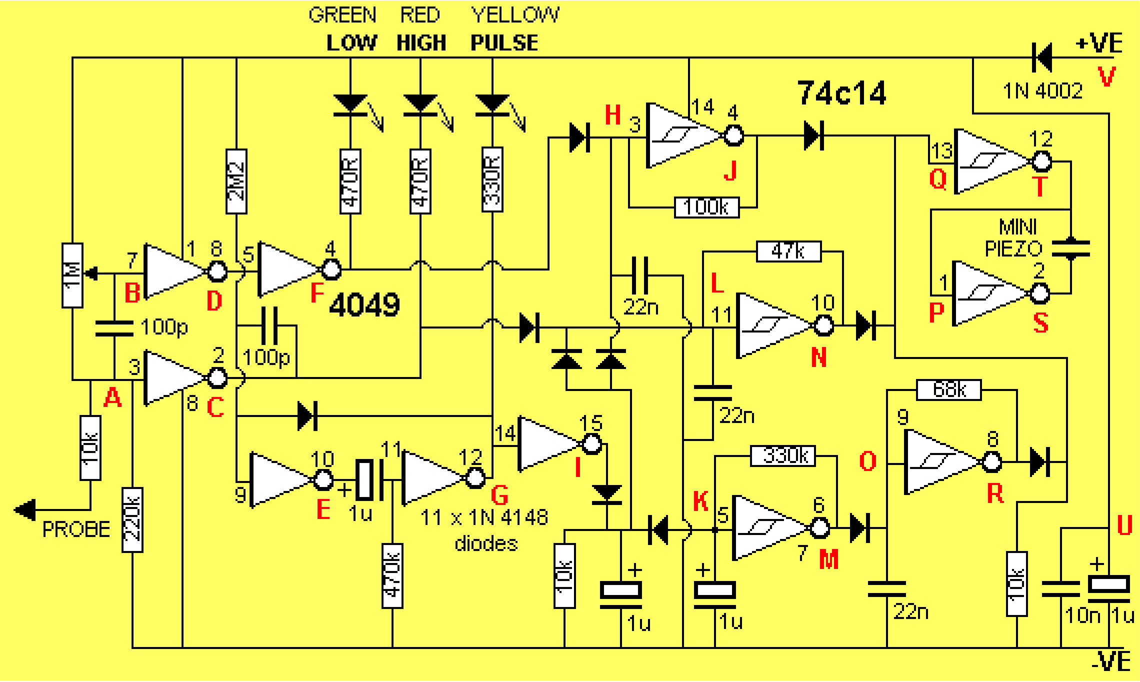
Point A - The first transistor is "self-biased" and will have 0.6v on the base. The antenna is connected to a 20 turn coil and you might think the coil will "short" the signals to earth.
But the coil and 470p capacitor form a circuit that oscillates at a high frequency when the antenna wire picks up stray signals. The coil and capacitor actually amplify the signals (see Talking Electronics website: Spy Circuits to see how a TANK CIRCUIT works) and these signals enter the base of the first transistor.
This is classified as a HIGH Impedance section because the signals are small and delicate and any loading via test equipment will kill them. The first transistor amplifies the signals about 70 times and they appear at **Point B**.

The signal passes though a 22n to **Point C** and the transistor amplifies the signal about 70 times to **point D**. **Point C** is classified as high impedance as any voltage measurement at this point will upset the biasing of the stage as a few millivolts change in base-voltage will alter the voltage on the collector considerably. **Point D** is classified as low impedance as any voltage-testing will not alter the voltage appreciably.
The output of the second stage passes through a capacitor to the join of two diodes. These two diodes are not turned on because the voltage at **Point E** can never rise above 0.7v as this is the voltage produced by the base-emitter of the third transistor.
The purpose of the two diodes is to remove background noise. Background noise is low amplitude waveforms and even though the transistor is turned on via the 220k, low amplitude signals will not be received. The third transistor works like this: It cannot be turned ON any more because any waveform from the 22n will be "clipped" by the bottom diode and it will never rise above 0.6v.
So, the only signal to affect the transistor is a negative signal - to turn it OFF.
Firstly we have to understand the voltage on the 22n. When the second transistor is sitting at mid-rail voltage, the 22n gets charged via the 2k2 and lower diode. When the transistor gets tuned ON, the collector voltage falls and the left side of the 22n drops. The right side of the 22n also drops and when it drops 0.6v, the top diode starts to conduct and when the voltage on the 22n drops more than 0.6v the third transistor starts to turn OFF. This effect is amplified by the transistor at least 100 times and appears at **Point F.** All the voltages around the two diodes are classified as HIGH Impedance as any piece of test equipment will upset the voltage and change the output.
There are some losses in amplitude of the signal as it passes through the 22n coupling capacitors but the end result is a very high strength signal at **point G.** The 4th transistor drives a 10mH choke and the mini piezo is effectively a 20n capacitor that detects the "ringing" of the inductor to produce a very loud output.
The 22n capacitor on the collector eliminates some of the background noise. The choke and piezo form an oscillatory circuit that can produce voltages above 15v, even though the supply is 3v.
The 47n capacitor at **Point J** is to keep the supply rails "tight" (to create a LOW Impedance) to allow weak cells to operate the circuit.
The "Power-ON" LED tells you to turn the device off when not being used and **Point L** is the power

supply - a low impedance line due to the 47u electrolytic.

Testing the Mini Bug Detector
To test the Mini Bug Detector, you will need a Signal Injector.
Place the Injector on **Point G** and you will hear a tone. Then go to **E**, **C** and **A**. The tone will increase in volume. If it does not increase, you have pin-pointed the faulty stage.

The next circuit is a combination of digital and analogue signals. It is a **Logic Probe**:



The voltage on a circuit (to be tested) is detected by the probe at **Point A** of the circuit above and the "tip" is classified as "reasonably high impedance" as it has a 220k resistor between the tip and 0v rail. The 1M reduces the impedance by about 20% but the inputs of the two inverters have no effect on the "tip" impedance as they are extremely high input-impedance devices.
The 1M trim pot is designed to put put a voltage on **point B** that is slightly higher than mid-rail so the green LED is turned off.
Point A will see a voltage below mid-rail and **point C** will be HIGH. **Point C** and **F** are low-impedance outputs.
When the tip of the probe is connected to a LOW voltage, Point B sees a LOW and Point F goes LOW to illuminate the green LED. At the same time it removes the "jamming voltage" produced by the diode between pin 4 of the 4049 and pin 3 of the 74C14 and the oscillator between **points H and J** produces a low-tone via the 100k resistor and 22n to indicate a LOW.
When the probe tip sees a HIGH, a lot more things happen.
Point C goes LOW and turns on the red LED. At the same time the 100p is in an uncharged state and the right lead goes LOW. This takes the left lead LOW as the left lead connects to a HIGH Impedance line and pin 9 goes LOW. This makes **point E** HIGH
and since the 1u is in an uncharged state, pin 11 goes HIGH. This makes **point G** LOW and the diode between pins 9 and 12 keeps pin 9 LOW and takes over from the pulse from the 100p. The yellow LED is illuminated. The 1u starts to charge via the 470k and when it is approx half-charged, pin 11 sees a HIGH and **point G** goes low. This creates the length of pulse for the yellow LED.
At the same time, **Point L** goes LOW because the "jamming diode" from pin 2 of the 4049 goes low and allows the inverter between point L and N to produce a tone for the piezo.
In addition, **Point I** goes HIGH and quickly charges a 1u electrolytic. This removes the effect of the jamming diode on pin 5 of the 74C14 and a low frequency oscillator made up of 68k and 1u between pins 5&6 turns on and off an oscillator between **points O** and **R** to get a beep. The mini piezo is driven n bridge mode via the two gates between **points QT** and **PS**.
Point U is a 1u electrolytic to reduce the impedance of the power rail and **Point V** is a protection diode to prevent damage if the probe is connected to the supply around the wrong way.

Testing the Logic Probe
You can test the Logic Probe with the simple Logic Probe with Pulse project described above. It will let you know if each point in the circuit is HIGH or LOW. You will also find out the difficulty in testing the points that are HIGH Impedance, as the Probe will upset the voltage levels and the reading may be

inaccurate.

More circuits will be added here in the future.

SOLDERING

Here are three 30-minute videos on soldering.
1. **TOOLS**
2. **Soldering components**
3. Soldering **SURFACE MOUNT** components

TESTING A MOTOR

Strictly speaking, a motor is not an electronic component, but since a website gave a useless description on testing motors, I have decided to supply the correct information.
The only REAL way to test a motor is to have two identical motors and check the torque by connecting them to a low voltage and trying to stop the shaft with your fingers. This will give you two results. Firstly it will let you know the torque of the motor.
This is the twisting effect of the shaft. There is no way to determine the torque by knowing the voltage or current.
The unknown factor is the strength of the field magnets (permanent magnets) and this determines the torque.
Secondly, feeling the shaft will let you know if the torque is even for a complete revolution.
By having two identical motors, you can see if one has a lower torque.
Almost nothing can go wrong with a motor except for the brushes. If the brushes wear out, additional resistance will be produced at the interface between the brush and commutator and this can be detected by allowing the shaft to rotate slowly and feeling the resistance as it revolves. A 3-pole motor will have three places where the strength is greatest and each should have the same feeling. A 5-pole motor will have five places of strength.
If the strength is weak or not uniform, the motor is faulty.
You cannot test a motor with a multimeter as the resistance of the armature winding is very low and if the motor is allowed to spin, the back voltage produced by the spinning, increases the reading on the meter and is false.
Micro motors have a coreless armature. This means the 3 windings for the armature are wound on a machine then bent slightly into shape and glued. A circular magnet with 3 poles is in the centre and the armature rotates around this.
This type of motor is reasonably efficient because the armature is the greatest distance from the point of rotation, and the motor reaches full RPM very quickly.
I have not heard of the armature-winding flying apart but if you hear any scraping noise, it may be the winding.
3-pole, 5-pole and micro motors can be found in printers, eject mechanisms of CD players, toys, RC helicopters, cars etc and rarely fail. This discussion has been presented to clarify the testing procedure and expose the absurd claims of another site.

TESTING COMPONENTS "IN-CIRCUIT"

You can test components while they are IN CIRCUIT, but the surrounding components will have an effect on the results.
You can get all sorts of "In-Circuit" testers. They are expensive and offer little more accuracy than a multimeter.
In-Circuit testing with a multimeter can give you the same results as a tester.
All you have to do is turn the project ON and use a multimeter (set to voltage) to determine the voltage at various points. It is best to have a circuit of the equipment so you can what to expect at each point.
Only major departures from the expected can be located in this way.
Obviously the first thing to look for is burnt-out components. Then feel components such as transistors for overheating.
The look for electrolytics that may be dry. Sometimes these have changed colour or are slightly swollen.
If they are near hot components, they will be dry.
For the cost of a few dollars I change ALL THE ELECTROLYTICS in some pieces of equipment, as a dry electrolytic is very difficult to detect.
Testing a transistor "in-circuit" is firstly done with the supply ON. That's because it is quicker.
Measure the voltage between ground and collector.
In most cases you should get a voltage of about half-rail. If it is zero, or close to rail voltage, you may

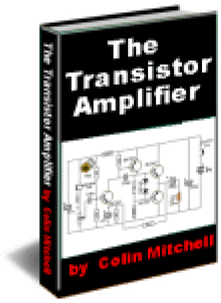
have a problem.
Turn off the supply and use the multimeter on low-ohms to measure all six resistances between the leads.
A low resistance in both directions on two leads will indicate a fault.
Resistors almost NEVER go "HIGH." For instance, a 22k will never go to 50k. However a low-value resistor will "burn-out" and you will read the value of the surrounding components.
Don't forget, some low-value resistors are designed to burn-out (called fusible resistors) and anytime you find a damaged low-value resistor, you will need to look for the associated semiconductor.
You can replace the resistor quickly and turn the circuit ON to see it burn out again.
Alternatively you can trace though the circuit and find the shorted semiconductor.
It's always nice to "see the fault" then "fix the fault."
Sometimes a transistor will only break-down when a voltage is present, or it may be influenced by other components.
When the piece of equipment is turned OFF, you can test for resistance values. The main thing you are looking for is "dry joints" and continuity. Dry joints occur around the termination of transformers and any components that get hot. Rather than wasting time checking for dry joints, it is better to simply go over the connections with a hot iron and fresh solder.
You may need to check the continuity of a track (trace) and it may go from one side of the PC board to the other.
Use a multimeter set to low-ohms and make sure the needle reads "zero-ohms."
It is very dangerous to do any testing on a project using a multimeter set to "amps" or "milliamps."
You cannot test "current flowing through a component" by placing the probes across a component. You will simply over-load the rest of the circuit and create a problem.
To find out if current is flowing though a circuit or a low-value resistor, turn the project ON and measure the voltage either across the component or the voltage on one end then the other.
A voltage-drop indicates current is flowing.
That's about it for testing "in-circuit." Use the rest of this eBook to help you with diagnosis.
Don't think an IN-CIRCUIT COMPONENT TESTER is going to find a fault any faster than a multimeter. They all use a multimeter principle.

THE END

This is not the full story to learning about servicing. It is just the beginning.
We have only covered the simplest tests and shown how 90% of faults can be found by checking voltages, waveforms and looking for obvious things such as burnt out components, cracks in PC boards.
The author has fixed over 35,000 TV's, radios, stereos, VCRs and all those things that were on the market 30 years ago.
Things have not changed. It's just that some repairs cost nearly as much as buying a new product and half the customers opt for dumping a faulty item and buying the latest "flat screen" version. That's why you have to get things through the workshop as fast and as cheaply as possible, to make a living.

If you want any more devices added to this list, email **Colin Mitchell**.

To help with understanding how a transistor circuit works, we have produced an eBook: **The Transistor Amplifier.** It covers a whole range of circuits using a transistor.



Not copyright by Colin Mitchell
You can use any of this material. Please pass this eBook to your friends and let them know that everything on the web is FREE. I have looked at all the "Pay Sites" and found the information they "sell" is available on the web at NO COST.
Nearly all text books are also downloadable for free on "Download.com" etc and when you see a used copy of a $74.00 textbook on Amazon for $12.00 you realise many users have already discarded their copy. A good textbook never gets thrown out.

See the enormous amount of information on Talking Electronics website.

Preface

This book is all about how to make electronics devices, from a constructional perspective. It is aimed at relative newcomers to electronics construction — that is, not the knowledgeable and trained electronics engineer, but those of us who want to find out about how to actually make up the circuits and projects that have already been designed.

It matters not whether the circuits you want to construct have been designed by others — perhaps they are presented in a magazine or a book as projects to build — or by yourself. It matters not whether you actually understand how that circuit works, or whether you haven't the foggiest idea of even its first principles — and maybe you don't even care! It matters not whether the intricate workings of a resistor; transistor; transformer; capacitor; or the latest wonder component is like Greek to double Dutch ears. There are other books that you can read which can give you all that understanding — and I'm bound to suggest my own book *Starting Electronics* as the ideal companion reference to this one, if that's the sort of understanding you are also looking for.

What *does* matter, on the other hand, is that *this* book (at least, that's my intention) shows everyone how to take an existing circuit and transform it into a complete and working device. This book starts from only the most limited knowledge of electronics processes, assuming very little — hopefully nothing at all, and introduces you to *all* the required concepts; the tools; the components; and the processes involved in turning a circuit into a finished electronic device. In fact, my intention in writing it is not only to make the journey from circuit to device as easy as possible to traverse, but to make it fun at the same time. I hope I've succeeded.

Running to keep up…

In electronics, as with most fast-moving technologies, there's always the risk that a book such as this one can become out-of-date very quickly. The way electronics moves these days, it's not unfair to say that a book like this is only up-to-date for as long as the ink is wet. So, at this point, I'd like to introduce readers to a central website:

http://keithbrindley.members.beeb.net

where I will try to keep relevant information about the methods and processes covered here up-to-date. The website also features relevant links to manufacturers, component stockists, and other links as I see fit. Projects (in Chapter 8) all feature printed circuit board copper foil track patterns, and there are links on the website to allow you to download these in electronic formats too. Indeed, I'd go as far as suggesting that if you intend constructing any of the projects here you should look on the website to see if there are any alterations or other suggestions regarding the projects before you start. Any corrections or alterations to the copper foil track patterns (or anything else to do with the projects) will be featured on the website as soon as I can get them there.

As you make it…

Electronics in general is a fascinating area. However, getting 'into it' in the first place is sometimes daunting. It is my aim that *Starting Electronics Construction* gives as many people as possible the means whereby they can do just that. In the meanwhile, if I can offer anyone a suggestion if they intend to try, it is this: make it fun!

That way, you'll learn so much more than you ever could from stuffy textbooks. I hope that by reading this book and getting into practical electronics construction that you do have fun.

Keith Brindley

1

Introduction

This book is a guide to anyone who wants to build an electronic device. It assumes very little prior knowledge, and so introduces you to the various practices that you need to follow — whether you want to build something for pleasure, or for education, or even for profit. Also, this book takes the stance that it matters little what the particular electronic product is you wish to build — the most important fact is that the practices you follow are similar (if not identical) whatever the electronic device happens to be.

Electronics is in part a theoretical entity, and you could go to textbooks or to magazines, schools, colleges or universities, or elsewhere to find and learn that theory. However, it is also in a very large part a practical entity; a fact that — particularly in recent years — seems almost to have been overlooked. The many students of electronics at universities who have little or no prior experience with the handling of components or the building of circuits attest to this.

So, although what you read on the pages of this book is theory, it is theory about the practical aspects of building electronic devices. As such, included in this book are (hopefully most of, possibly all) the practical things you need to know about and be able to do before you can make an electronic device.

What this book is *not*, on the other hand, is a book about how electronics circuits *work* (for that, see this book's sister book: *Starting Electronics*, which is written also by me). What you have in front of you now is a book only about how to *construct* electronic devices. I hope you enjoy it, and gain some knowledge about how to do just that.

What do you need to know about making an electronic device?

This section is intended as a summary of the whole book. It would be easy to miss this out altogether, but my feeling in writing it is that you need to see the *big picture* before you go on to look at things in more detail.

And the big picture in terms of building electronics devices is simply a quick overview of what an electronic device is, and also what parts of it should we understand in order that we can build it.

So, what is an electronic device?

We can summarize an electronic device (an example of which is given in Figure 1.1) as below.

An electronic device invariably has three main features:

NUMBER 1 Electronic components. An electronic device is anything that incorporates electronic components of any description.

NUMBER 2 A printed circuit board. The electronic components which make up an electronic device are mounted upon a *printed circuit board* — (often called just a *PCB*), which is a means of holding all the components securely while at the same time making the necessary electrical connections between them all.

NUMBER 3 A housing. The printed circuit board, together with all the electronic components that it holds, will be housed in a box, or a module, or a case. In this way the electronic components are protected from damage.

So, what's next?

Given that any electronic device you might choose to build has these three main features, it follows that you need to know as much as you can

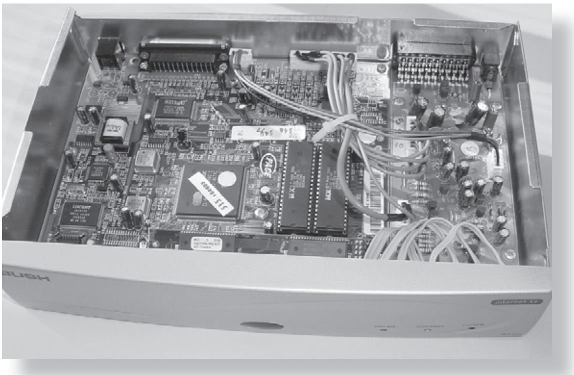

Figure 1.1 An example of an electronic device – note the electronic components, the printed circuit board, and the housing

about the features. And we'll look at them now, in brief, before devoting the rest of the book to that purpose.

Electronic components

There are many categories of electronic components, and each category is divided often into several sub-categories, and from there into a multitude of sub-sub-categories. You don't need to know about them *all* by any means, but you do need to know about the most common categories, and their most common sub-categories. You need to know how to handle these components so that you don't damage them, and so you need to know what damage *can* be done to them.

Some components are easily damaged just by holding them a little too roughly; some components are damaged by heat; and certainly many components are damaged if you insert them into a circuit incorrectly (the wrong way round, say, or too forcefully, thereby breaking their connection pins).

You also need to know about which tools you need to handle them and how to use these tools correctly.

Printed circuit boards

Making the printed circuit board onto which the electronic components of a device are mounted is not a trivial job. Indeed, the work involved in designing it, making it, then attaching the components to it represents a major proportion of the overall task. However, making a printed circuit board is not a job which should be rushed, for a poorly made printed circuit board is a recipe for disaster.

The printed circuit board is used for two main purposes: to support the electronics component; and to connect between the electronic components so that the circuit they are to be connected into can be formed. As a result, a printed circuit board that cannot support the components adequately, or makes incorrect connections, will prevent the electronic device from functioning correctly. So, you need to know about all aspects of printed circuit boards: how to design them; how to make them; and how to mount the components. You need to know what tools to use to do these tasks, and how to use the tools correctly.

I simply cannot stress enough how important the printed circuit board is. If the circuit itself is the brain of an electronic device — that monitors, controls and sends the signals that make the device work — then the printed circuit board is the heart that keeps the whole device going in the first place.

Housings

Once the printed circuit board is complete, with all electronic components in place, you have to consider how to house it. Housings are used to protect the components inside, as well as their printed circuit board. Housings also usually give a little extra space to allow batteries to be held, when needed, as well as providing mounting space for some components and controls not mounted on the board. They also protect users from potentially harmful voltages that may be present in the circuit — mains voltages, say. Labelling on a housing's facing panels can indicate what various control adjustments may be made by the user. As such, a housing is the interface — technically, visually, and aesthetically — with the outside world.

In short, if the circuit is the brain, and the printed circuit board is the heart, then the housing is the body, the skeleton, and the skin of an electronic device.

Housings done right can make a product a winner; done wrong the product is a duffer.

What have we learned?

To summarize this chapter we only need to remember one thing — an electronic device comprises three main parts. These main parts — the electronic components, the printed circuit board, and the housing — are highly dependent on each other. Designers and makers of *good* electronic devices understand this dependence, and use the main parts to the best advantage of their devices.

2

Tools

As with any practical technology, having the right tools for the task is important. Indeed, some of the tools are not just important — they are critical! You simply cannot do electronics construction without them. So, first off in this chapter is a hit parade of the tools you need, followed by another of the tools you should seriously consider (although you *could* do without them at a push!).

Tools you absolutely, positively, indisputably, and without a doubt need:

SOLDERING IRON — to solder components into place. The connecting lead of each component must be soldered into place on the printed circuit board. A specialized soldering iron must be used — one that is neither too big nor too powerful to harm either the component or the circuit board

MINIATURE SIDE-CUTTERS — to cut wire or component leads. While constructing an electronic device, there will be many wires to cut to size. Each component mounted on the printed circuit board needs its leads trimming close to the board after soldering

MINIATURE LONG-NOSED PLIERS — to form leads. Component leads are formed to the correct shape for mounting on a printed circuit board with small, long-nosed pliers. Larger components and many controls are attached with nuts and bolts, so a larger pair of long-nosed pliers is also needed

CONTINUED…

…CONTINUED

WIRE-STRIPPERS — to strip insulation from wires. Insulation must be removed from wires prior to soldering, and gripping the wire in your teeth before pulling the insulation off isn't the best method. A good pair of wire-strippers solves the problem and keeps your dental bills as low as possible

SOLDER REMOVAL TOOLS — to err… remove solder. At some point or other, you will need to remove solder from a soldered joint, usually to take out a component you have accidentally put in the wrong place, or to replace a faulty component. Some type of solder-removal tool is required, allowing you to extract the component's leads

DRILLS AND BITS — to err… drill holes. Every component lead goes through a hole in the printed circuit board. Each hole must be drilled. Components not mounted on the printed circuit board are usually mounted on the housing, usually with nuts and bolts, and holes for these must be drilled in the housing

SAFETY GOGGLES — to protect your eyes. Some of the processes involved in electronics construction may create potential hazards. You need to protect yourself! Goggles should be used when undertaking any process likely to create flying debris, such as drilling or using chemicals.

Tools you don't exactly *need* — but which make some jobs easier:

PLIERS — ordinary hand pliers

FILES — a small set of needle files, and a selection of larger files

PUNCHES — for making some larger holes in housings

VICE — to hold housings while working

A STAND — to hold printed circuit boards.

The Tools

We'll now take a closer look at the most important of those tools listed, and note any particular attributes they should have.

Soldering irons

Soldering in electronics does not have any particular requirements, other than the soldering iron should not be too powerful. On the face of it, this might sound odd to a newcomer given that the process of soldering requires solder to be melted thus forming a soldered joint, but it's quite logical when you consider exactly *what* you are soldering — electronic components. The problem is that electronic components can be damaged by too much heat — and the more powerful the soldering iron, the greater its capacity to deliver heat.

Soldering iron power is measured in watts, and a reasonable wattage for soldering electronic components is somewhere between 12 and 25 watts. Prices vary between models, but you should expect to pay between about £10 and £20 for a basic soldering iron, although more expensive soldering irons (with extra features) exist.

A typical soldering iron is shown in Figure 2.1, where you can see its main parts — a handle to hold it, a bit (the part that heats the joint and the solder), and a heating element (the part that heats the bit). Also shown in Figure 2.1 is a mains lead, although not all soldering irons require mains electricity to function, as we'll see soon.

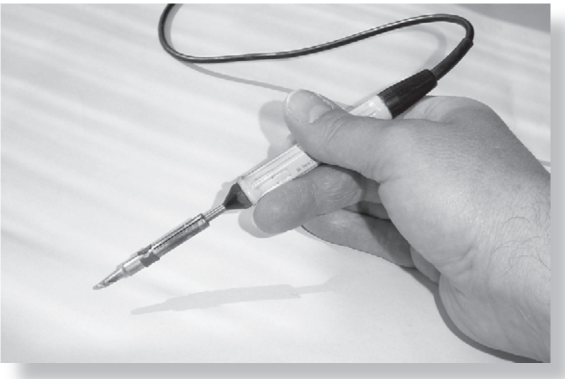

Figure 2.1 A typical soldering iron – the main parts of which are (from left to right): the bit; the heating element; the handle. This particular soldering iron is mains-powered, so you can also see the mains lead exiting the handle at the right.

Soldering iron types

There are several variants of soldering irons, in terms of heating methods, listed below.

Mains-powered irons — the most common. The advantage of these is that they work wherever a main outlet is available. The disadvantage is that they do have a mains lead, which some people find a little fiddly in use. Basic soldering irons of this type have no temperature control, and merely get as hot as they can. Soldering irons with thermostatic controls are available, and even complete soldering iron/base station combinations are common (see later). Your budget defines what you buy.

Rechargeable irons — with base station. Rechargeable irons have internal batteries that are used to heat the element and bit. They have a base station that is mains-powered, into which the soldering iron fits when not in use. Connections in the base station and soldering iron mate, and so the batteries are recharged whenever the iron is in the base station (and the base station is powered, of course).

The main advantage of rechargeable soldering irons is their lack of mains lead in use. The main disadvantage is that the batteries can't power the element for longer than just a few minutes at a time. By replacing the soldering iron into the base station after each joint is soldered though (so that its batteries recharge partially), this can be extended somewhat. Figure 2.2 shows a rechargeable soldering iron with its base station.

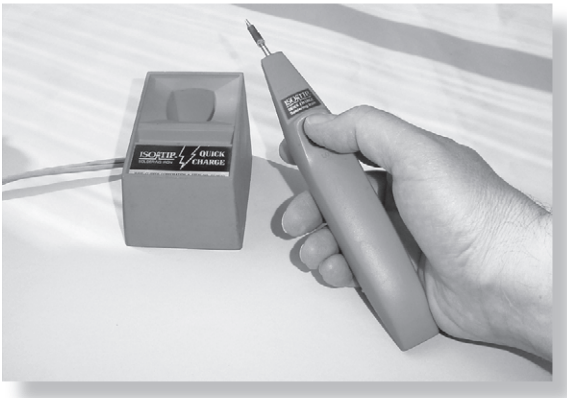

FIGURE 2.2 **Rechargeable soldering iron in use. To conserve batteries, the element only heats up when the button on the handle is pressed – heating rapidly to soldering temperature within seconds. In the background is the base station which recharges the soldering iron's batteries.**

Gas-powered irons — the ultimate in portability. Fitted with small refillable charges of butane gas which last up to around 30 minutes of constant use, these soldering irons require no electrical power. Figure 2.3 shows a gas soldering iron in use.

Priced between around £20 to £40 or so, these soldering irons are useful for certain awkward soldering jobs where electrical power is not available. They tend to be quite powerful, particularly the more expensive models, though with care can be used to good effect in electronics soldering.

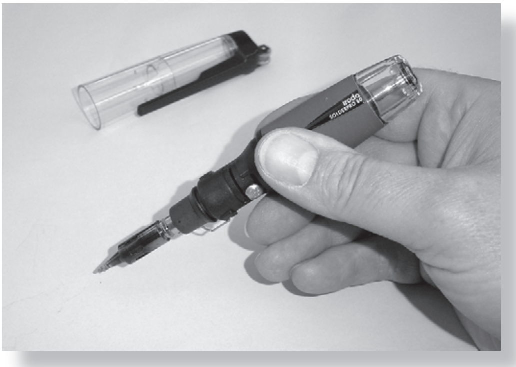

FIGURE 2.3 A gas-powered soldering iron. Small and portable, these can be recharged from lighter fuel butane gas containers.

Low-voltage irons — for battery-powered applications. Occasionally, when working on a car, say, there are applications where a low-voltage soldering iron might be useful. Some 12 V-powered soldering irons are available (an example is shown in Figure 2.4), usually having battery clips attached to the power lead.

Soldering iron stations

While we're on the subject of soldering iron types, it's worth taking a look at soldering iron stations. These are complete units, comprising a soldering iron, a stand to hold the iron when not in use, and a controlling circuit of some description. A typical soldering iron station is shown in Figure 2.5. The controlling circuit typically controls the power to the soldering iron element, so that the bit stays at a constant, definable temperature. While such stations are expensive, ranging from around £30 to over £100, they are excellent tools if you do a considerable amount of soldering.

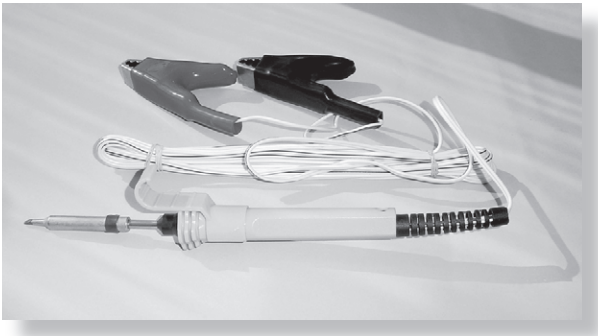

FIGURE 2.4 A 12 V-powered soldering iron. The battery clips on the lead attach to a car's battery for (relatively) portable power.

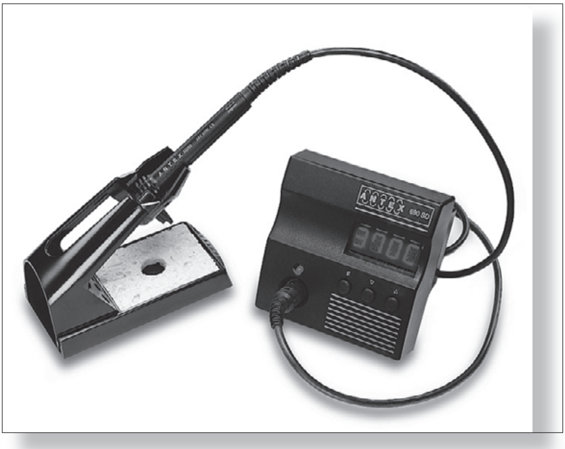

FIGURE 2.5 A soldering iron station, showing the iron itself in a stand, and the control knob to set bit temperature (Antex Electronics).

Soldering iron bits

Alongside the iron itself, you need to think about the bit. The bit is the part of the iron that comes into contact with the parts to be joined, so is a fairly critical part of the process.

A typical range of bit shapes is shown in Figure 2.6. Usually, for soldering electronic component joints an angled bit of about 2.4 mm diameter is ideal.

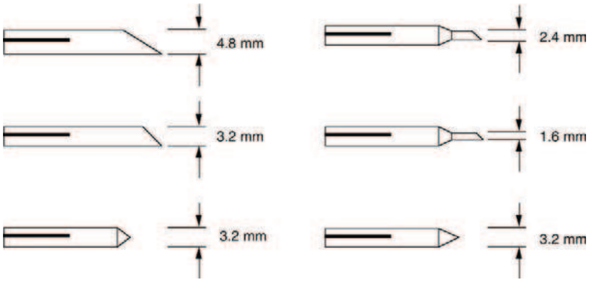

Figure 2.6 Typical sizes of soldering iron bits.

How the bit fits onto the soldering iron element is of concern, for two reasons:

- it determines how much of the heat generated by the iron's element passes to the bit's tip — and hence to the joint to be soldered
- it determines how easy it is to remove the bit — important if you are to solder different types of joints (for example, a bit with a smaller diameter would be used for finer joints), or for when you need to replace an old and worn bit.

In general, bits that slide over a soldering iron's element are most efficient, allowing much of the heat generated by the element to pass to the bit's tip. Figure 2.7 shows such a bit, fitted to its element. Also, this bit type is the easiest to remove.

Bits that fit inside an element, or screw onto it, are probably best avoided, if only because the very nature of the soldering process means that metal bits often corrode — even slightly — due to heat, and this may mean that the bit becomes hard to remove. Excessive pulling or twisting of the bit to remove it may then damage the element.

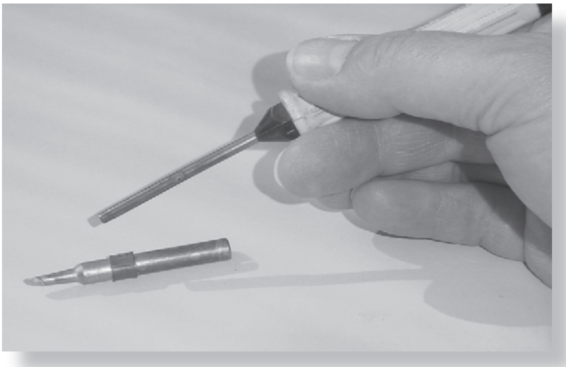

Figure 2.7 A soldering iron whose bit slides over the element. The bit is easily removed and/or replaced, and provides an efficient heat transfer between the element and the bit's tip.

Some soldering irons use a bit type that also comprises the element. The bit/element combination attaches to the soldering iron by two prongs that slide into the soldering iron body. Element and bit tip being unified in this way, there is a highly efficient heat transfer between element and tip, and this design has the great advantage that changing the bit effectively replaces the element in one operation. One of the best examples is the rechargeable soldering iron bit tip shown in Figure 2.8.

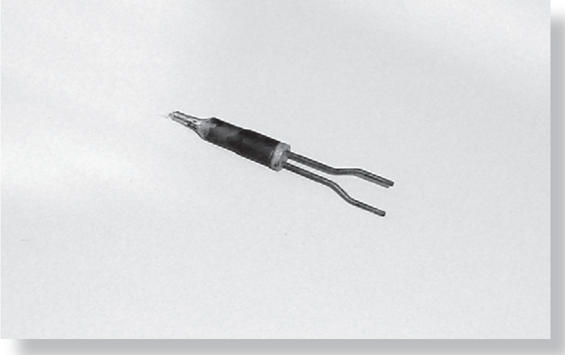

Figure 2.8 The unified element/bit of the rechargeable soldering iron shown in Figure 2.2 fits to the soldering iron's body by pushing in the two prongs.

Soldering iron accessories

Soldering iron stand

There's a few accessories for soldering irons that are worth buying. First — and most important — of these is a soldering iron stand (a typical stand is shown in Figure 2.9), which holds an iron while it's not in use. Soldering irons, of course, by their very nature are hot, so having a stand to put one in when not actually using it adds up to quite a safety feature. The stand in Figure 2.9 is around a fiver — so shouldn't break the bank.

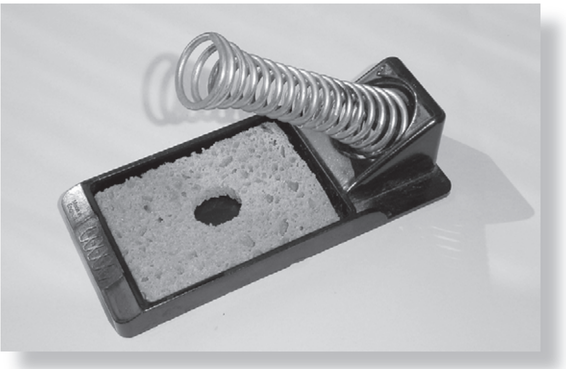

FIGURE 2.9 A soldering iron stand. This particular stand features a sponge.

Sponge

Talking of a soldering iron stand with a sponge, a sponge is actually a very handy accessory to have. Even if you have to resort to — as I have done on occasion — using a simple kitchen sponge, dampened with water, stood on a tea-plate, then so be it!

The £5 soldering iron stand of Figure 2.9, featuring an integrated sponge is a great way to combine the two accessories — not essential, just neat.

You use a dampened sponge to wipe your hot soldering iron bit tip on, immediately prior to tinning it (see page 117) and using it to solder joints. As you'll see later, a clean soldering iron bit tip is one of the prerequisites of good soldering.

Put another way: if your soldering iron bit tip is not clean, don't expect to make good soldered joints, and *do* expect your circuit not to work!

Tip tinning and cleaning block

Another way to keep your soldering iron bit's tip clean is to use a tip tinning and cleaning block. It's a thin disc-shaped block in a metal container that can be carried in a pocket, or mounted on a suitable surface close to the soldering iron. In use, you simply wipe the hot soldering iron bit's tip over the block's surface, simultaneously cleaning and tinning the tip, as shown in Figure 2.10. It's convenient, it's handy, it's cheap (around £4), and it saves having a wet sponge on your worktop.

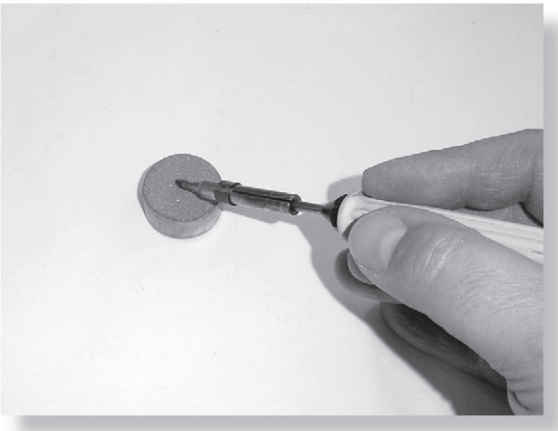

FIGURE 2.10 Using a tip tinning and cleaning block to err... clean and tin a hot soldering iron bit tip.

Abrasive fibreglass pencil

While we're on the subject of cleanliness (which we'll return to often throughout the book), the other components that go to make up a soldered joint have to be clean — just as much as the soldering iron bit tip. Fortunately, there are products that can help here too. The copper surfaces of the track on a printed circuit board should be clean and, as they oxidize when left for more than just a few hours (and copper oxide can prevent a good joint from being made), they should be cleaned more-or-less immediately prior to soldering the joints.

A good tool for this job is a fibreglass abrasive pencil. It's a propelling-pencil type of design, with an internal fibreglass stick instead of pencil lead — see Figure 2.11. In use, you rub the end of the fibreglass stick on the copper track a few times, removing any dirt, grease, or pre-finishes, leaving clean, shiny copper, ready for soldering.

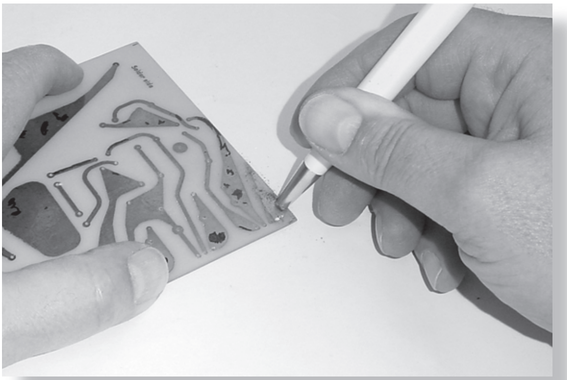

FIGURE 2.11 An abrasive fibreglass pencil in use – note the residue, which is of fibreglass origins.

After cleaning the copper surface, care should be taken when removing the residual dust created in the process — it *is* fibreglass-based after all, so may irritate skin, eyes, or internal organs.

Abrasive scrubbing block

An alternative to the fibreglass pencil is an abrasive scrubbing block, which performs the same function — scrub the copper track prior to soldering with the block, in an action reminiscent of using an eraser to rub out pencil marks. Figure 2.12 shows such a scrubbing block.

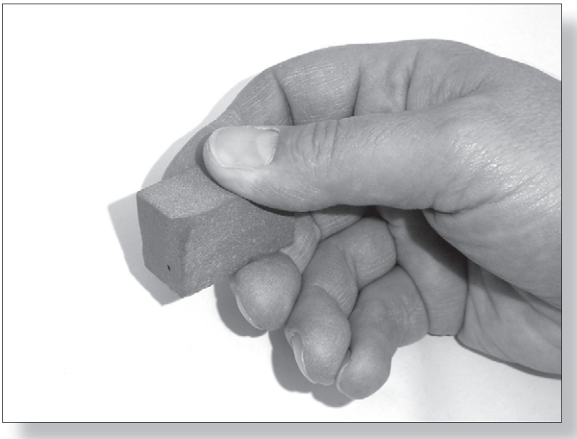

FIGURE 2.12 An abrasive scrubbing block.

Component leads — which form a third critical part of a soldered joint on a printed circuit board need to be clean every bit as much as the copper track and the soldering iron bit's tip. Most components are supplied with tinned leads (ie, they are coated with molten solder then cooled), fortunately, which means that a simple reheating to soldering temperature re-melts the solder which helps the process of soldering the joint. Even so, excess dirt — particularly grease — on a lead may still prevent a good joint being made, so if you suspect that to be the case you should clean the lead prior to soldering. It's much easier to do this before soldering, than trying to correct the effects of it afterwards.

Chemical solvent cleaners

Chemical cleaners such as isopropyl alcohol may be useful for cleaning printed circuit board tracks or component leads prior to soldering, as they dissolve grease, dirt, and some pre-finishes which may be present. They can be purchased in liquid form, although aerosol or pen applicators are often much more convenient.

Heat shunt

The final soldering accessory you might want to consider in your armoury is a heat shunt. Soldering — by its very nature — requires heat, but too much heat can damage some electronic components. Some people therefore like to use a heat shunt between the soldered joint and the component body to help ensure the heat at the joint is shunted away from the component itself.

The simplest form of heat shunt is a pair of locking tweezers which are clamped onto the component lead. As the joint is heated, heat is shunted into the tweezers rather than passing down the component lead into the component body.

Figure 2.13 shows such a pair of tweezers.

Take Note:

Having said all that, I am duty-bound to say that I have never owned a heat shunt, I have never even used a heat shunt, and I don't think I will ever use a heat shunt. All but a very few electronic components are fairly heat-resilient after all, and as long as the soldered joint is performed rapidly and without leaving the soldering iron in place on the joint too long, then excessive heat should not be a problem.

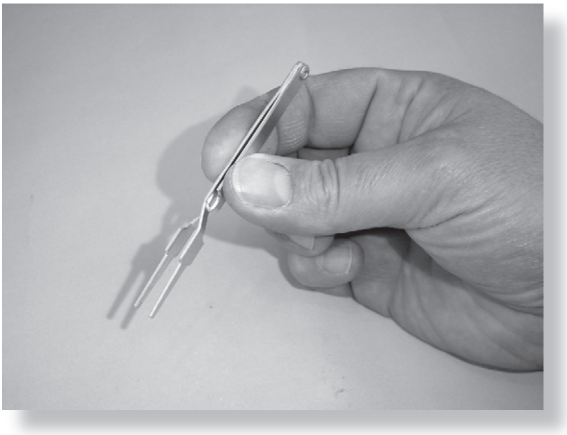

Figure 2.13 A heat shunt.

Side-cutters

After your soldering iron, the single most important tool in your toolbox is a decent-to-good quality pair of miniature side-cutters. As side-cutters *are* so important, it's best not to skimp on this tool — buy the best you can afford (decent quality side-cutters are available at around £10, while *good* quality side-cutters are priced between about £20 and £80…).

Before you baulk at the price, remember that the side-cutters you buy will be used every time you solder a printed circuit board, to trim the component leads after soldering joints. They'll be used every time you cut wires to length, for insertion into a printed circuit. They'll be used every time you trim your toenails. They should *not* be used for cutting thick wires or metal (or pruning the roses, or cutting toenails, if you hadn't already realized I wasn't being serious).

And finally, just to labour the point, a decent pair of side-cutters will last a lifetime in electronics, but a cheap pair will probably last till you need them.

Figure 2.14 shows a pair of side-cutters that have lasted a lifetime (mine). They were expensive (costing around £50 in 1976), and at the time I was young and foolish and thought it was a little over-the-top, but now that I've matured and I'm 21 again (err… yes, well…) I certainly realize their worth. In all seriousness though, the money you spend on this tool is worth it in the long run.

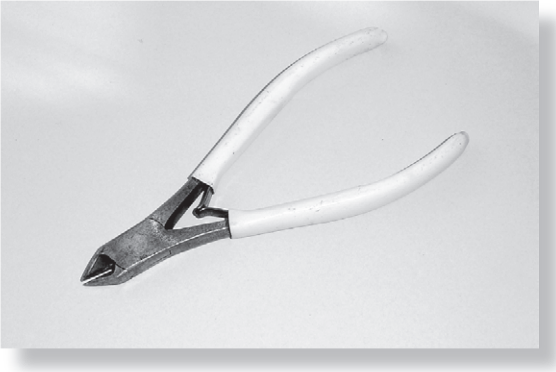

Figure 2.14 A good quality pair of miniature side-cutters. After your soldering iron, it's the tool you'll use the most in electronics.

Long-nosed pliers

Like side-cutters, a miniature pair of long-nosed pliers is an essential tool for the builder of electronics circuits. Like side-cutters also, it's pretty important to have a decent-to-good quality pair. And, if you haven't already guessed it, like side-cutters too, they may be expensive — decent quality long-nosed pliers will cost around £10, while a good quality pair will be priced between around £20 and £80). Again, get the best you can afford — they will be worth it. Figure 2.15 shows my long-nosed pliers (which I bought along with my side-cutters in 1976, for around £50). They're still working perfectly, which is more than I can say for myself.

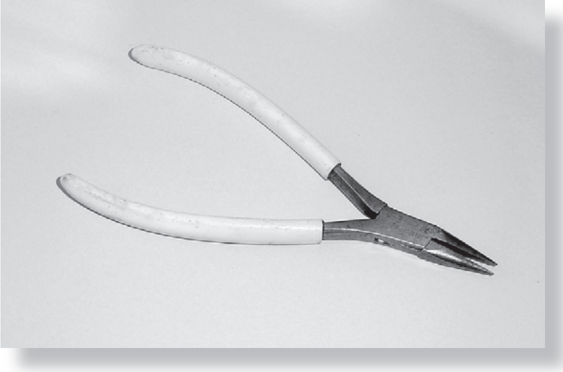

Figure 2.15 Miniature long-nosed pliers are extremely useful tools to keep in your electronics toolbox.

Long-nosed pliers are very useful for forming component leads prior to mounting the component in the printed circuit board. They should not be used for anything heavier than this — and should definitely *not* be used for tightening nuts onto large bolts, or working on the car. They are precision instruments which require a little forethought in handling.

Wire-strippers

Printed circuit boards are not usually complete entities, and they need to be connected to the outside world. The easiest and most popular way to do that is with interconnecting wires, which are normally insulation-covered to prevent short circuit with their neighbours. Each wire has to be soldered to the printed circuit board, so it's necessary to remove a piece of insulation at the wire end, leaving a short length of uninsulated wire that can be soldered. It's perfectly possible to strip a short piece of insulation away by putting the end of the wire into your mouth between your teeth, biting on the wire while pulling it back out of your mouth. Indeed, I used to do this very thing before I wore a hole in my front teeth and suffered many expensive dental bills. Now I use a pair of wire-strippers, and I wholeheartedly recommend you do the same.

Wire-strippers work in exactly the same way that front teeth do, in that you insert the wire into the wire-strippers jaws (and yes, they are called jaws) whereupon you squeeze the wire-strippers' handles together so that the wire-strippers' teeth catch the wire between them. Further squeezing of the handles forces the teeth into the insulation and simultaneously pulls the jaws back, stripping the insulation from the wire. Figure 2.16 shows a pair of wire-strippers in action.

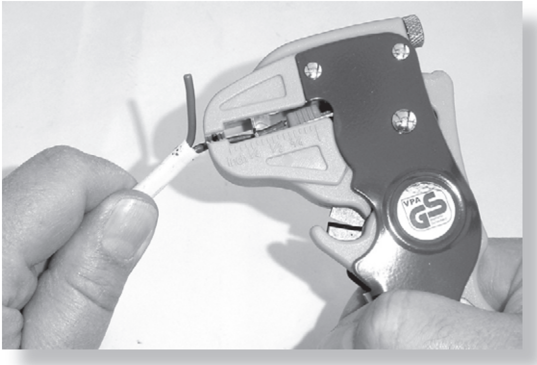

FIGURE 2.16 Using a pair of wire-strippers to strip the insulation from the end of a wire, prior to soldering to a printed circuit board.

Such wire-strippers aren't too expensive (around a tenner), although you can get much more expensive ones. As with the case of wire-cutters and long-nosed pliers, get the best you can afford. The best wire-strippers have replaceable jaws (unlike me) so can be always maintained with a good set of teeth. The cheaper ones are just throw-away tools (I've heard *that* said about me before, as well…).

Solder removal tools

If you solder electronic components into printed circuit boards, then sooner or later you will need to desolder them to remove them from printed circuit boards. It goes without saying that you will at some stage put a component in the wrong place and need to take it out, or you will find that you have a faulty component and need to replace it.

There are two tools that can help you do this and your selection of which you buy is merely a matter of choice. The cheapest is desoldering braid — lengths of copper braided wires that attract molten solder away from a soldered joint, simply because solder flows to cover the copper wire surfaces in the braid. Figure 2.17 shows desoldering braid in use — the braid is placed over the joint and a hot soldering iron bit presses on top. As the heat from the iron bit melts the solder it is attracted onto the braid away from the joint. Once the component lead becomes sufficiently free of solder to be removed, the braid and the soldering iron bit are removed, and the lead can be extracted from the joint hole.

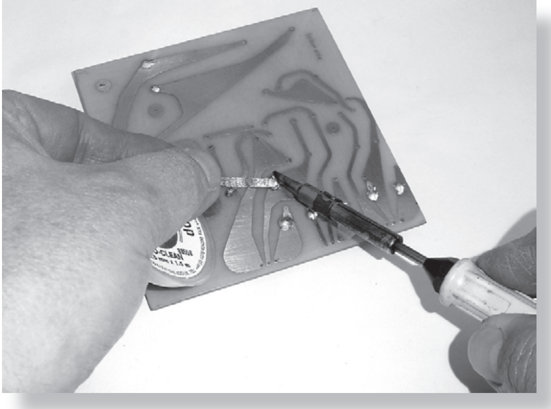

FIGURE 2.17 Desoldering braid in action. The braid is heated by the iron's bit, which in turn heats the solder on the joint to melting point, whereupon the solder is attracted to the copper wires in the braid.

Once the braid end has been used to desolder a joint, it becomes loaded with solder so must be cut off, leaving fresh braid for the next desoldering operation. As such, a length of desoldering braid only has a limited life (depending on how many joints you desolder). Desoldering braid costs £2 or £3 for a metre or so, although you can buy it in longer length reels if you need.

The alternative tool for desoldering purposes is a desoldering pump, commonly called a *solder sucker*. This works something like a bicycle pump in reverse — you operate the pump (which is spring-loaded) to push out air, then apply the pump to molten solder on a joint and release the plunger to literally suck the molten solder away from the joint into the pump where it rapidly hardens. The next operation of the pump forces out the hardened solder and primes the pump ready for the next desoldering operation. Figure 2.18 shows a desoldering pump in position over a joint as the joint is heated to become molten by a soldering iron bit tip. The pump has been primed (ie, its plunger has been pushed down the pump body), and as the solder becomes molten, the button catch on the desoldering pump body is pushed, thereby releasing the spring-loaded plunger which returns to the top of the pump body.

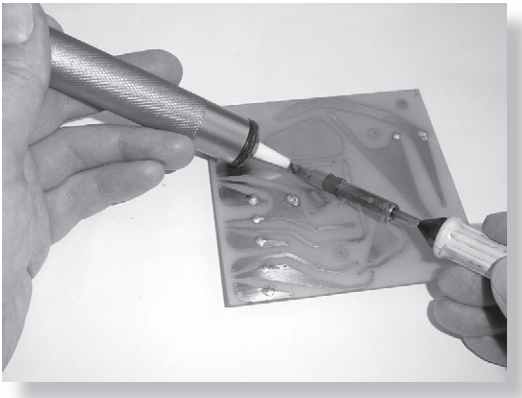

FIGURE 2.18 A desoldering pump in use. As the plunger returns to the top of the pump body, suction it creates sucks the molten solder on the joint inside the pump.

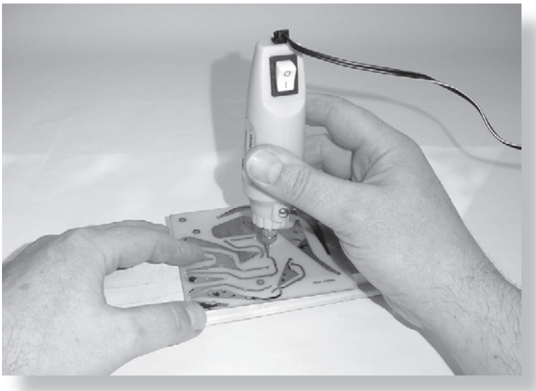
While a little more expensive than desoldering braid, desoldering pumps last considerably longer. Indeed, really the only part of the pump that may be worn by the desoldering process is the pump nozzle, due to the repetitive application of the heat of soldering, which nevertheless will have an operating life of many thousands of operations. Most desoldering pumps have a replaceable nozzle, so even if the nozzle *is* worn, the pump is not necessarily written off. Desoldering pumps are available from as little as £5 to £20.

Drills and bits

Each and every component mounted on a printed circuit board in the conventional way (note I say *conventional way* here: there *are* other methods which don't normally affect the individual electronic circuit builder, most notably the surface mounted component method — see page 36) has its component leads going through holes in the printed circuit board. Thus, the printed circuit board has to be drilled with holes for those very same component leads. The hole size is around 1 mm (give or take a very small percentage — depending on the actual component's leads), which means that your average power drill that you use to drill masonry or steel is not exactly the best tool to use. Power drills are good where the thing being drilled is hard, and the holes don't have to be too accurately positioned.

Printed circuit board, on the other hand, is made from a thin and fairly soft substrate, and the copper track is but a few micrometres thick, while the copper pads you'll be drilling through are not that much bigger than the holes required themselves. So, a drill for the task of drilling printed circuit board has few power requirements, but accuracy is of prime importance.

Small, hand-held, low-voltage drills (complete with mains transformer) are available from most do-it-yourself stores, and these are ideal for hand drilling of printed circuit boards. Figure 2.19 shows such a drill, being used to drill holes in a printed circuit board, prior to mounting and soldering of components.



FYI

Make sure you keep a couple of 1 mm and 1.5 mm drills in your toolbox at all times – it's useful when one drill breaks (which they invariably do at the wrong time) to have another one ready to use. Oh, and make sure all your drills are sharp.

Figure 2.19 Using a hand-held low-voltage drill to drill holes in a printed circuit board.

Later in the book we'll see that larger power drills do actually have a place in the electronics circuit builder's toolbox, for drilling of large holes in housings for example. But you *do* need to have a low-voltage, hand-held drill for the finer tasks like that in Figure 2.19. They are not that expensive — starting at around £10 and going up to about £30. Even the cheapest will do the job effectively. Usually they are sold in kits, complete with a range of drill bits, together with small grinding wheels, polishing wheels and engraving tools. If you buy a kit, complete with a range of drills, then you will probably have all the drill sizes you need. If you buy the drill alone, make sure you also buy drills of 1 mm and 1.5 mm sizes — they are the most common ones you'll need.

Printed circuit board stand

When working on a printed circuit board by hand, it's not always easy to mount and solder components without the board moving along the worksurface as you work. If you have a hot soldering iron in one hand, and solder in the other hand, the last thing you want is your printed circuit board sliding along the bench and falling to the floor. Face it: you could do with a third hand! An alternative is to use a printed circuit board stand, into which your printed circuit board is clamped. The board can be repositioned easily, and even turned over to suit.

A typical stand is shown in Figure 2.20, which is a miniature vice with a lever-operated sucker arrangement on the bottom. The sucker allows the vice to be clamped to a work surface, while the vice holds a printed circuit board safely, leaving your hands free to insert and solder components.

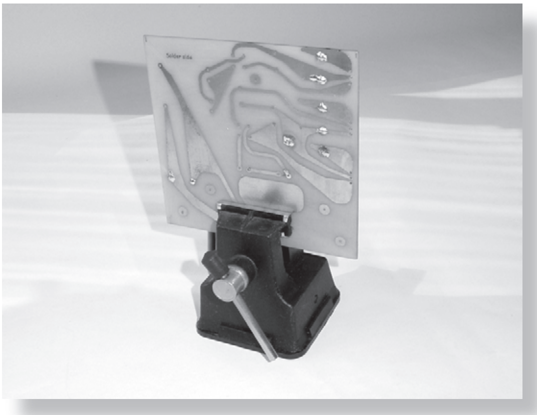


Figure 2.20 A printed circuit board stand.

Many other types of stand are available, ranging from a simple box that holds a printed circuit board, to a multi-armed arrangement complete with magnifying glass and clips to hold other components.

IC insertion tool

As you construct electronic circuits on printed circuit boards, you will come across integrated circuits (ICs — see page 53). Integrated circuits are components that contain many miniaturized components within. They are quite small, but usually have many relatively fragile connection pins (most commonly in two rows — the *dual-in-line* arrangement).

Inserting such integrated circuits into a printed circuit board is a little tricky, as the rows of connection pins are angled somewhat away from the vertical plane, so need to be sprung in as they enter their corresponding holes in the printed circuit board. It's perfectly possible to do this by hand with care, but an IC insertion tool (such as that shown in use in Figure 2.21) is well worth the cost (often less than £1) and makes the task a bit of a doddle.

In use, the integrated circuit is pushed into the tool (which keeps the connection pins at the correct angle and distance), then the tool is pushed down onto the printed circuit board to engage the integrated circuit into its correct position.

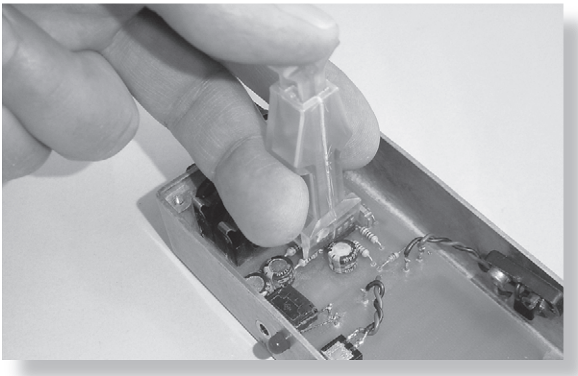

FIGURE 2.21 An integrated circuit insertion tool in operation.

IC extraction tool

Getting an integrated circuit back out of a printed circuit board is an equally tricky task. However, there are equally cheap extraction tools — one is shown in use in Figure 2.22. Just hook the tool at each end of the integrated circuit, and pull. Of course, if an integrated circuit is soldered directly into a printed circuit board, you'll need to desolder it first (see earlier). However, the integrated circuit shown in Figure 2.22 has been inserted into a holder. Integrated circuit holders provide a push-fit method of inserting integrated circuits (see Chapter 3).

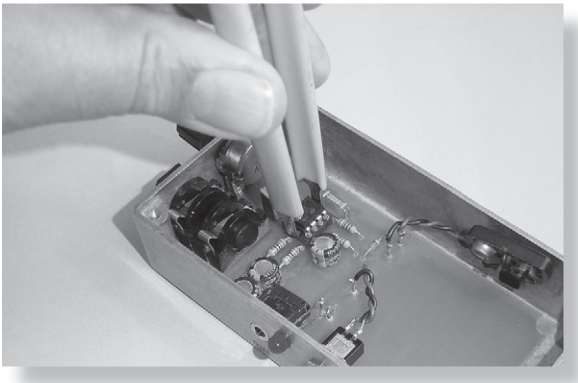

FIGURE 2.22 Using an extraction tool to pull out an integrated circuit – note the use of an integrated circuit holder, which means the integrated circuit itself is not soldered into the printed circuit board.

Terminal pin pusher

When connections are needed on a printed circuit board, it's common to use push-fit terminal pins (see Chapter 3) in the printed circuit board. It's then easy to solder a connecting lead to the pin (see Chapter 5) as required. However, while it's possible to push these pins into place in a printed circuit board using pliers, say, a good tool to buy is a terminal pin pusher — shown in use in Figure 2.23.

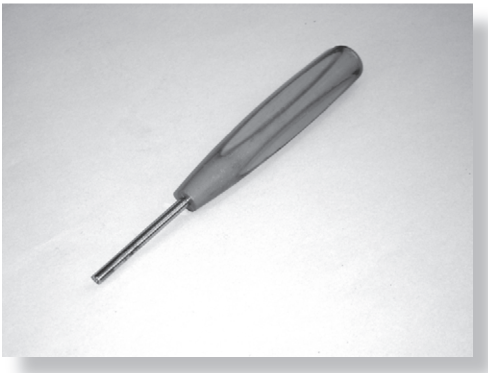

FIGURE 2.23 Terminal pin pusher – just put the pin loosely in place in the printed circuit board, then push home firmly with the pusher.

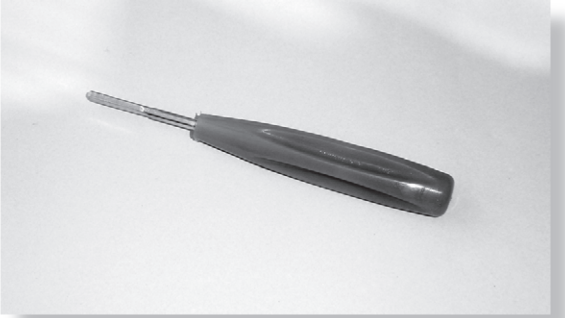
Spot-face cutter

When using stripboard to build a circuit on, it's inevitable that some of the strips need to be broken — particularly when siting a dual-in-line integrated circuit, which has two rows of parallel pins. In this case, if strips aren't broken between the rows of pins, short circuit between the pins will occur.

Breaking the strip can be done with a sharp craft knife, but this is messy, and a potentially dangerous method. Best to buy a spot-face cutter, which is a tool with a rotating cutting edges. Figure 2.24 shows a common type. Chapter 4 shows how to use one.



FYI

While stripboard is fine for prototype work, I would not condone it for use in a final project. Always use printed circuit board to produce best end results.

FIGURE 2.24 A spot-face cutter, used to break strips in stripboard.

3

Components

There are many types of components used in electronic devices — the main types are listed below. You need to know what each of them are, what their circuit symbols are, how they function, how to identify them, and what their units of measurement and values are.

Component types

- **RESISTORS**
- **CAPACITORS**
- **SEMICONDUCTORS**
- **SWITCHES**
- **INDUCTORS**
- **CONNECTORS**

There are other types of components, but those listed here and described in this chapter are the most important.

Resistors

The resistor is one of the most (if not *the* most) common yet important components used in electronics. Its primary function is to resist the flow of electricity in a defined manner.

To do this it has a resistance, specified in the unit of ohms (named after the physicist Ohm, who did considerable early work into the qualities of resistance) and given the abbreviation Ω. So, a resistor's value is given as a number followed by the ohms symbol eg, 100 Ω. Occasionally, the abbreviation Ω is changed to the abbreviation R — simply because the abbreviation Ω is not always easily produced in word processing applications on some personal computers. Nevertheless, you should know that the R stands for Ω.

Values of resistors range from a fraction of an ohm, through to many millions of ohms. Where thousands of ohms are specified, it is usual to use the unit of kilohms (a kilohm is 1000 ohms), so that say, 2 kΩ is used to specify 2000 ohms), or 470 kΩ specifies 470,000 ohms. Likewise millions of ohms are known as megohms, so that say, 2.2 MΩ is used to specify 2,200,000 ohms, and so on. With kilohms and megohms it has become usual to drop the superfluous Ω, thus values would be written 2.7 k, 470 k, 2.7 M and so on.

On some circuits (and even in some texts or lists), in an effort to decrease the digits and hence size of labels and complexity of the circuit, the ohmic unit is used to indicate the decimal point position — so 8.2 Ω would be written 8R2, 2.7 k would be written 2k7, and 3.3 M would be written 3M3.

Common symbols for a resistor in circuits are shown in Figure 3.1. The correct British standard is the rectangular box shape of Figure 3.1(a), though the zigzagged shape of Figure 3.1(b) is often used, so you must be aware of and be confident with both.

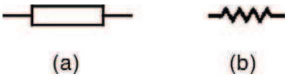


FIGURE 3.1 Resistor symbols commonly found in electronic circuits (a) correct British standard (b) zig-zag shape also used.

Apart from a resistor's value — which is by far the most important criterion — there are other important differences which define how well a given resistor works in a given circuit:

- **TOLERANCE — resistors are rarely the exact value specified.** Usually resistors are within a small percentage of the specified value — this small percentage is called their tolerance. So, a resistor of value 1000 Ω, which has a tolerance of ±5%, will have a value between 950 Ω and 1050 Ω

- **POWER RATING — as electricity flow causes heat.** If too much heat is generated in a resistor, the resistor may be damaged. Therefore resistors have a power rating (specified in units of watts, and given the abbreviation W) which must not be exceeded. A typical power rating for resistors used in common electronic devices is 0.25 W — in all but the most power hungry of circuits this will usually suffice. In fact, lower power resistors (eg, 0.125 W) will probably do — and are of course smaller

- **STABILITY — the ability of a resistor to keep its value over time.** Despite other changes (such as heat, humidity) that can occur around it, it should be able to maintain its resistance value as closely as possible.

Resistor types

There's a few important types of resistor, classified by how they are created.

Carbon resistors

There are actually two main types of carbon resistors, but they look similar if not identical — see Figures 3.2 and 3.3.

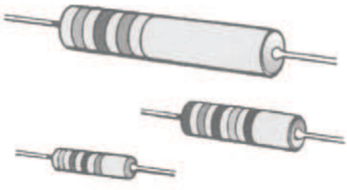

FIGURE 3.2 Carbon resistors – illustration.

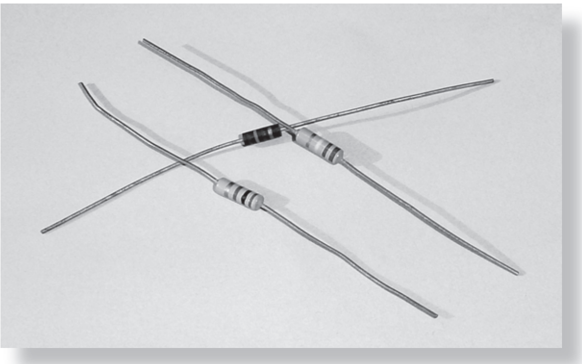

FIGURE 3.3 Photograph of carbon resistors.

Carbon composition resistors are made from a mixture of carbon and clay. Carbon conducts electricity but clay does not, so by mixing the two, resistors are formed. Stability and tolerance of resistors made this way are not particularly good, but they are cheap to make so are very common.

Carbon film resistors are made by moulding a layer of carbon material onto an insulating rod then etching a spiral track through the carbon till the resistance increases. Tolerance and stability are good.

Metal film resistors

These are made in much the same way as carbon film resistors, but tolerance and stability are much better so they are used in circuits which require great accuracy. They are however, more expensive. Figure 3.4 shows illustrations of some metal film resistors, while Figure 3.5 shows a photograph.

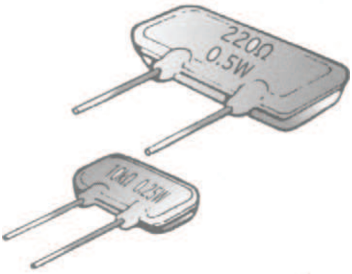

FIGURE 3.4 Metal film resistors – illustration.

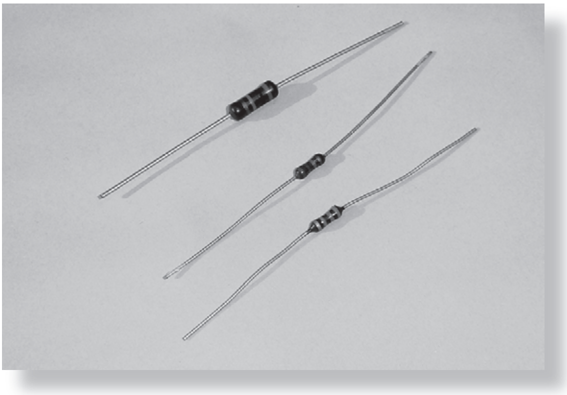

FIGURE 3.5 Photograph of metal film resistors.

Wirewound resistors
Wire is wound around and along a ceramic former to make these resistors. The thickness of wire and the size of the former define the resistance of the resistor. While being quite expensive, resistors made this way have the advantage of high power rating. Figures 3.6 and 3.7 show illustrations and a photograph of wirewound resistors.

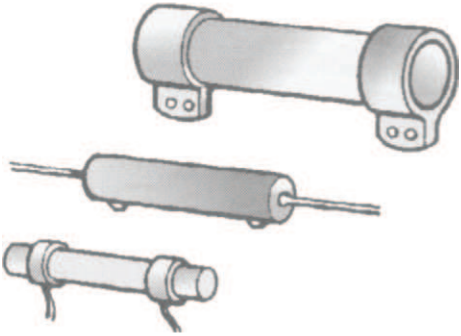

FIGURE 3.6 Wirewound resistors – illustration.

Variable resistors — potentiometers
Often in an electronic circuit there is a requirement for a control knob of some sort (volume, tone, voltage and so on). Variable resistors (usually called *potentiometers*, or just *pots*) can be used for this purpose. They feature a resistive track usually made from a carbon composition mixture in a circular format, with a rotating wiper arm whose position can be

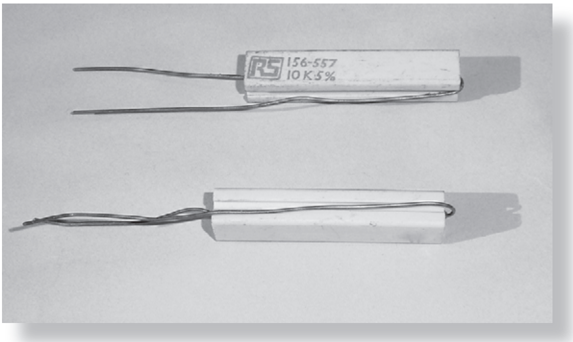

FIGURE 3.7 Photograph of wirewound resistors.

adjusted. There are two main types — standard potentiometers, featuring a central shaft that can be attached to a circuit's front panel for user-control, and *preset potentiometers* which are mounted on a printed circuit board and are adjusted with a screwdriver-type tool. Their various symbols are shown in Figure 3.8.

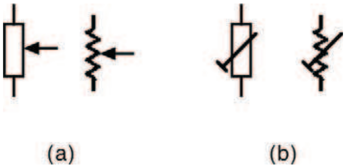

FIGURE 3.8 Symbols of (a) standard and (b) preset potentiometers.

Potentiometers can be of one of two main groups, *logarithmic* (or *log*) and *linear* (or *lin*) — which refers to whether the resistance along the track varies in a linear manner (ie, the resistance varies directly according to the position of the wiper arm) or in a logarithmic manner (ie, the resistance varies logarithmically according to the wiper arm position).

Mostly, linear potentiometers are used. However, in audio circuits in particular — where volume is being adjusted, say — then logarithmic potentiometers are used.

FYI

Volume is a logarithmic variant, in so far as a doubling in volume means a 3dB louder sound. So a sound of say 60dB is double the volume of a sound of 57dB. Similarly, a sound of 63dB is double the volume of the 60dB sound. To represent and control this with a potentiometer, the potentiometer must have a logarithmically scaled track. Logarithmic and linear scaled potentiometers can be used and will work in circuits requiring the use of the other type, but the characteristic of the potentiometer control as you turn it will not be correct.

Dual-gang potentiometers are common, particularly in audio circuits where both channels of a stereo amplifier, say, need to be adjusted simultaneously. These are quite literally made of two potentiometers coupled together with a single control that rotates both wipers together.

Most potentiometers are rotary, but sometimes you will see potentiometers that operate in a line. Such *slider potentiometers* work in exactly the same way — with a resistive track and a wiper arm.

Standard potentiometers are relatively large, and the shaft allows for a control knob to be fitted for user control. Switch mechanisms can also be incorporated into the back of the potentiometer body, which means that the control can be used as an on/off switch, say, at the same time as it being a volume control for example. Preset potentiometers are much smaller and get their name because they are typically set before the completed electronic device is first used, then rarely touched or adjusted again. All potentiometers — whether standard or preset — have three terminals: one for each end of the internal resistor, and one for the wiper arm. It's not always necessary to use all three terminals in a circuit though, and often one of the terminals is left unconnected.

Figure 3.9 shows illustrations of various potentiometers, while Figure 3.10 shows a photograph.

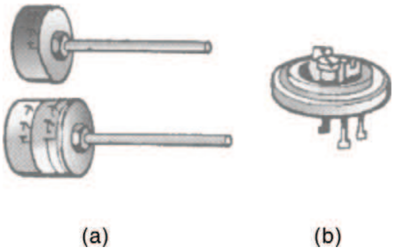

FIGURE 3.9 Potentiometers – illustrations: (a) front-panel fixing types – single- (top) and dual-ganged; (b) a preset potentiometer.

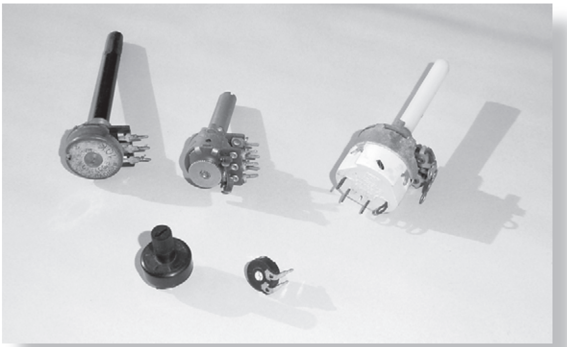

FIGURE 3.10 Photograph of various potentiometers: single-gang, dual-gang, switched single-gang, together with preset potentiometers.

Resistor colour code

Resistance value is occasionally printed numerically on a resistor's body, but normally it is designated in what is called the resistor colour code. The colour code is a collection of coloured bands (normally four bands, although five-band codes exist too) around the resistor body. Reading from left to right, with the first band being closest to the left-hand edge of a resistor, the bands signify:

- **BAND 1 — the first digit of the resistor's value**
- **BAND 2 — the second digit of the resistor's value**
- **BAND 3 — the figure to multiply the first two digits by**
- **BAND 4 — the resistor's tolerance.**

Figure 3.11 shows this graphically. Table 3.1 gives the bands' respective values.

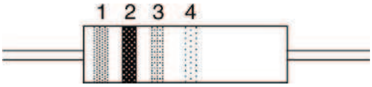

FIGURE 3.11 A resistor showing the four coloured bands that give its value according to the four-band resistor colour code detailed in Table 3.1.

Table 3.1 The four-band resistor colour code.

Colour	Band 1 1st figure	Band 2 2nd figure	Band 3 3rd figure	Band 4 tolerance
Black	0	0	x1	—
Brown	1	1	x10	1%
Red	2	2	x100	2%
Orange	3	3	x1000	—
Yellow	4	4	x10,000	—
Green	5	5	x100,000	—
Blue	6	6	x1,000,000	—
Violet	7	7	—	—
Grey	8	8	—	—
White	9	9	—	—
Gold	—	—	x0.1	5%
Silver	—	—	x0.01	10%
None	—	—	—	20%

Examples using the resistor colour code

Example 1 — let's say the four bands of a resistor are yellow, violet, orange, silver. The resistor value is 4 (yellow) 7 (violet) multiplied by 1000 (orange), which equals 47,000 ohms (more usually written 47 kΩ), with a tolerance of ±10% (silver).

Example 2 — if the four bands are grey, red, green, gold, then the value is 8 (grey) 2 (red) x100,000 (green), which is 8,200,000 ohms (more usually written 8.2 MΩ), with a tolerance of ±5% (gold)

Preferred values

Initially, when considering the resistor colour code, you may well think that it's a virtually impossible task to remember every single value of resistor together with its respective colour code. Calculating every resistor's value from the colour code under these circumstances will be a laborious task. However, it would be impossible for manufacturers to make, and for stockists to stock, resistors of all possible values — there would simply be too many to deal with effectively. As resistors are only made to certain tolerances anyway, and as circuit designers have a reasonable command over the components they specify for use within their circuits, it has become normal to use resistors of only certain values — these are called *preferred values*. The E12 standard range of preferred value resistances follows the series:

1, 1.2, 1.5, 1.8, 2.2, 2.7, 3.3, 3.9, 4.7, 5.6, 6.8, 8.2

As a result, your job of learning the colour code is made significantly easier — because these twelve values are the only ones you need to know. Any resistors you might use of higher values follow in this very same series merely by having a particular multiplying coloured band (eg, 1.8 x 1000 = 1k8, 4.7 x 1,000,000 = 4M7). After only a short while using resistors, you should find that you can almost instantly calculate any new resistor's value, and you won't even need to calculate resistor values you use most regularly — you'll know them!

Note though, that there are other preferred value ranges of resistors — notably the E24 range, which adds an extra twelve values above the E12 range (spaced in-between the E12 range values). You will rarely, if ever, encounter them however, and the twelve values of the E12 range will most likely be the only ones you need to know.

Special resistors

There are several other types of resistors you may encounter in your electronic travels. Some of these are covered elsewhere in the book, but for completeness the main ones are listed here:

Surface mount resistors — there has always been a trend to reduce electronic devices in size. The latest step in this trend is to use miniature components that are soldered directly to a printed circuit board's copper track ie, they are mounted on the board surface (see Figure 3.12), rather than with component leads that go through the board. As such, surface mount resistors are (by their nature) extremely small, so they are not as suited to hand assembly and soldering as conventional resistors with leads. However you may find yourself working with them occasionally.

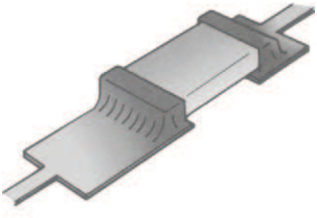

FIGURE 3.12 A typical surface mount resistor – colour coding or lettered markings may be used for component identification (but may not be...). Note that this is illustrated rather larger than full size – actual size is around 2 mm wide!

Thermistors — a thermistor is a resistor whose value changes according to heat. These are useful in applications that detect heat such as electronic thermometers. They vary in size and shape according to construction (they are actually made using semiconductor materials), and typical devices are shown in Figure 3.13. The symbol for a thermistor is shown in Figure 3.14.

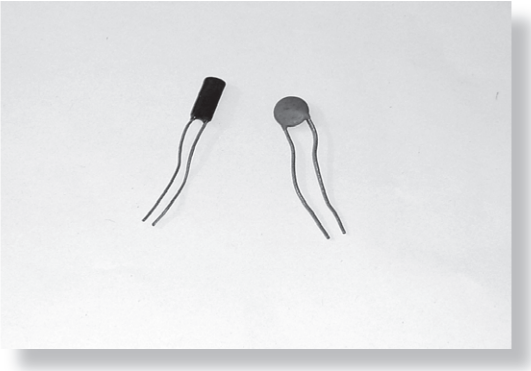

FIGURE 3.13 Typical thermistors.

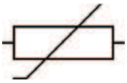

FIGURE 3.14 Thermistor circuit symbol.

Light dependent resistor — like the thermistor, the light dependent resistor (or LDR) is a resistor made from semiconductive materials (typically cadmium sulphide). Instead of its resistance varying with heat however, the light dependent resistor's resistance varies with applied light. Figure 3.15 shows a typical light dependent resistor — a device known as the ORP 12. The circuit symbol for a light dependent resistor is shown in Figure 3.16.

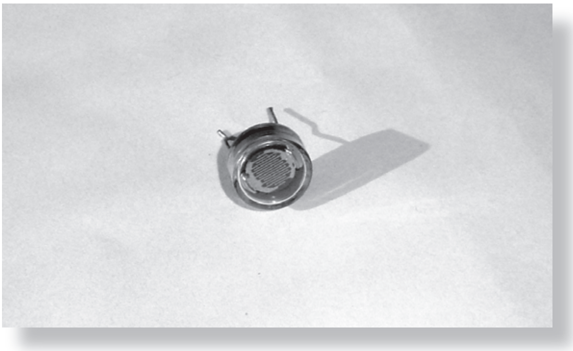

FIGURE 3.15 The ORP 12 light dependent resistor.

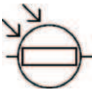

FIGURE 3.16 Circuit symbol of a light dependent resistor.

Capacitors

The second most common component used in electronic devices is probably the capacitor. The basic construction of any capacitor is of two metal (therefore conducting) plates, separated by an insulating layer which is called the *dielectric*. The size of the metal plates, together with the type and thickness of the dielectric, defines the capacitance of the component. Capacitance is measured in units of *farads*, named after the scientist Faraday, and given the abbreviation F. However, the farad is an extremely large unit, and capacitors used in modern electronic circuits are only minute fractions (millionths, thousand millionths, and million millionths) of a farad. One millionth of a farad is known as a microfarad (given the abbreviation µF — µ is the Greek letter *mu*, which is often difficult to produce on some computer systems, so the letter *u* is occasionally used instead), one thousand millionth of a farad is a nanofarad (nF), and one million millionth is a picofarad (pF).

It's useful to be able to switch between the three main sizes of capacitance units, as for example one thousand picofarad is the same as one nanofarad, and one thousand nanofarads is one microfarad. Table 3.2 shows the relationships between the three common units. You really need to be able to switch from one to the other easily, so it's worth getting to grips with it fairly early on in your electronics career. Fortunately, you'll get plenty of practice the moment you start to handle capacitors…

Table 3.2 Relationships between the three main capacitance units in modern electronics.

	microfarad (µF)	nanofarad (nF)	picofarad (pF)
microfarad (µF)	1	1000	1,000,000
nanofarad (nF)	0.001	1	1000
picofarad (pF)	0.000001	0.001	1

Electrolytic vs non-electrolytic

There are two main categories of capacitor — *electrolytic* and *non-electrolytic*. While this sounds tremendously complicated and worrying, all it actually means in practice is that electrolytic capacitors are polarized and must be inserted into a circuit the right way round. They will be marked with a positive and a negative terminal, and must be inserted so that the positive terminal is at a positive potential with respect to the negative terminal. (Note that neither the positive nor the negative terminal need to be at an *actual* positive or negative voltage respectively — they just have to be *more* positive or *more* negative than the other respective terminal!) If they are inserted the wrong way round the insulating layer forming the dielectric can be damaged hence won't work correctly, and the capacitor may even become a short circuit hence causing possible damage to the circuit in which it is installed. Non-electrolytic capacitors can be inserted into circuit either way round. Figure 3.17 shows some variations of electrolytic capacitors.

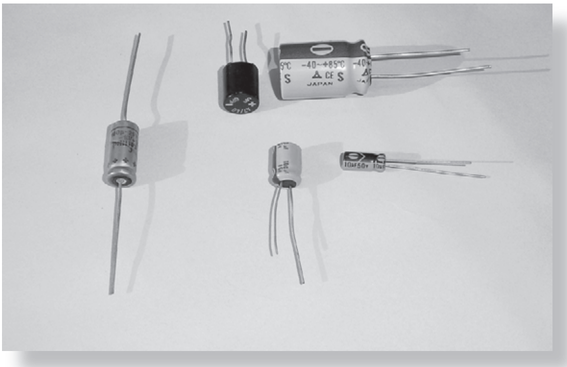

FIGURE 3.17 Electrolytic capacitors.

Electrolytic capacitors are always marked in some way — usually with a + symbol to indicate the positive component lead. Sometimes however, positive is marked with a ridged or ringed end on the component body.

Axial vs radial

Another way in which capacitors are categorized has to do with their shape, and is shown in Figure 3.17. Capacitors which are long, and have their component leads exiting from opposite ends of the body are known as *axial-leaded* capacitors. Capacitors where both component leads exit from one end of the capacitor body are known as *radial-leaded* capacitors.

Non-electrolytic capacitors

There are several categories of non-electrolytic capacitor, illustrated in Figure 3.18. Most of them are known simply by the substance that is used to make up their dielectrics. Common capacitors are *polycarbonate*, *polyester*, *polystyrene*, *ceramic*, *mica*, and *polypropylene*.

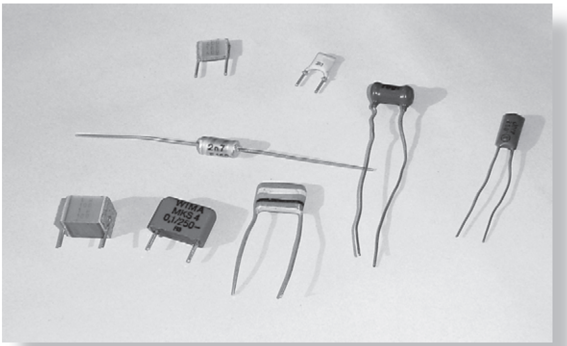

FIGURE 3.18 A variety of non-electrolytic capacitors.

Readers who have been paying attention might be wondering why it's necessary to use electrolytic capacitors at all if they're *that* awkward to use. Well, in theory, it doesn't matter which category of capacitor (electrolytic, non-electrolytic, or which type of dielectric) is used in any given circuit — a 47 nF polycarbonate capacitor has exactly the same capacitance as a 47 nF ceramic capacitor so, indeed, may technically replace it. However, the material used as a capacitor's dielectric has an effect on the capacitor's body size, shape, and component lead-out, so a capacitor of one dielectric simply may not fit into the space in a printed circuit board allocated to a capacitor of another dielectric. Also, in all but a few cases, it would simply not be possible to produce a large value capacitor from a non-electrolytic dielectric, without the resultant capacitor being huge.

Another thing to bear in mind is that the dielectric used (of both electrolytic and non-electrolytic capacitors) can have a significant effect on the component price. For example, *mica* capacitors (sometimes also known as *silvered mica*) are much more expensive to produce than, say, polycarbonate capacitors.

Finally, the dielectric has an effect on the maximum voltage a capacitor may be used at. Capacitors are rated (along with their actual capacitance) with a *working voltage* — which, fairly obviously I hope, should not be exceeded. It is up to the circuit designer to specify what the actual working voltage of the capacitor is. It is up to the constructor of the circuit to ensure that capacitors of at least this working voltage are used.

Variable capacitors

Like resistors and their variable counterparts (potentiometers), capacitors are available in variable forms. Usually though, variable capacitors are in preset form, set up when the electronic device is first made, then rarely touched afterwards. Figure 3.19 shows some examples.

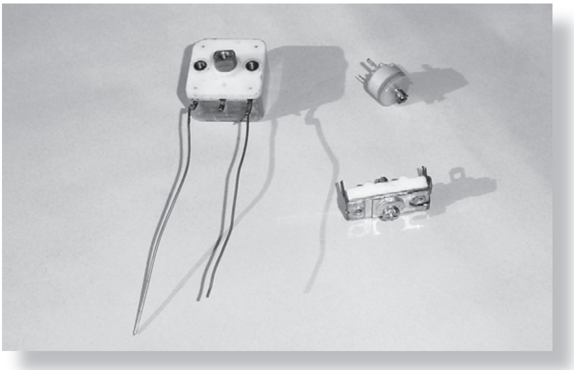

FIGURE 3.19 Variable capacitors.

Capacitor symbols

The symbols used for capacitors in circuits are shown in Figure 3.20, where Figure 3.20(a) shows the symbol for an electrolytic capacitor (note the positive lead is marked +), Figure 3.20(b) is the symbol of a non-electrolytic capacitor, and Figure 3.20(c) is that of a variable capacitor. They are fairly self-explanatory, graphically portraying the two plates of a capacitor separated by a dielectric.

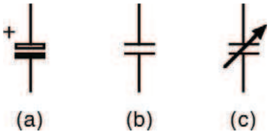

FIGURE 3.20 Symbols for capacitors: (a) electrolytic; (b) non-electrolytic; (c) variable.

Capacitor colour code

Very often, capacitors are marked with their value on the capacitor body. However, some capacitors are marked with a colour code in the same way that resistors are marked (see Figure 3.21), and the code (detailed in Tables 3.3 and 3.4) follows the same general method except that the value is marked in picofarads, not ohms.

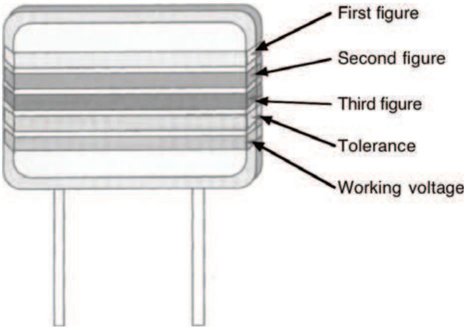

FIGURE 3.21 A capacitor marked with a colour code, showing the bands and their meanings according to the colour code of Tables 3.3 and 3.4.

Table 3.3 The capacitor colour code.

Colour	Band 1 1st figure	Band 2 2nd figure	Band 3 3rd figure	Band 4 tolerance	Band 5 working voltage (see below)
Black	0	0	x1	20%	
Brown	1	1	x10	1%	
Red	2	2	x100	2%	
Orange	3	3	x1000	—	
Yellow	4	4	x10,000	—	
Green	5	5	x100,000	5%	
Blue	6	6	x1,000,000	—	
Violet	7	7	—	—	
Grey	8	8	—	—	
White	9	9	—	10%	

Remember that to convert from picofarads to nanofarads simply divide by 1000. To convert from picofarads to microfarads divide by 1,000,000.

Band 5 of a colour coded capacitor gives its working voltage (ie, the highest voltage that should be applied to it). This does, however, vary with the type of capacitor. Table 3.4 lists capacitor types affected and gives the voltages according to the band colour.

Table 3.4 Capacitor types and working voltages according to the fifth band of the colour code of Table 3.3.

Capacitor type	White	Yellow	Black	Green	Blue	Grey	Pink	Red
Tantalum	3	6.3	10	16	20	25	35	
Polycarbonate		400			630			250
Polyester		400						250

Capacitor number/letter codes

Apart from colour coding, capacitors can also be marked with printed letters and numbers. Often these are fairly self-explanatory — a capacitor marked with the term 8p2 is obviously going to be an 8.2 pF device. However, there are some not-so-obvious variations. For example, a 680 pF capacitor is sometimes marked n68 — which means that it is 0.68 nF (which of course is the same as 680 pF). Sometimes a capacitor may be marked with just three numbers — say, 333. In such a case the first two digits indicate the first and second digits of the value, while the third digit indicates the multiplier (ie, number of zeroes to add at the end). So, the example of the capacitor printed with the number 333 would have a value of 33,000 pF, which is 33 nF.

Tolerances of capacitors are usually not very tight. Often 20% is an acceptable figure, although some capacitors with tolerances of 5% are available. Occasionally, tolerances are marked on a capacitor's body with a letter, such as J (which means 20%) or K (10%) somewhere alongside the value in numbers.

Semiconductors

There are many types of component which are grouped together and known as semiconductors. We'll take a look at some of them now, but it's important to remember that the category is huge, and there are many more semiconductors than we can possibly hope to cover here. However, there are some that are just *so* important that we can not afford to ignore them.

Diodes

Diodes are the first important component in the category known as semiconductors. Indeed they are the simplest semiconductor device. They get their name from the basic fact that they have two electrodes (di — ode, geddit?). One of these electrodes is known as the *anode*: the other is the *cathode*. Figure 3.22 shows the symbol for a diode, where the anode and cathode are marked. Figure 3.23 shows some typical diode body shapes — in which cathodes are identified as the banded or shaped ends.

The name *rectifier* is often used in place of *diode*. Strictly speaking, a rectifier is a diode that is used in high power applications, say, a mains power supply that converts mains alternating current to a low voltage direct current — the conversion from alternating current to direct current is called *rectification*. However, the two names are otherwise synonymous.

FIGURE 3.22 The circuit symbol for an ordinary diode.

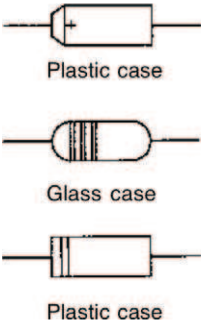

FIGURE 3.23 Some typical diode body shapes.

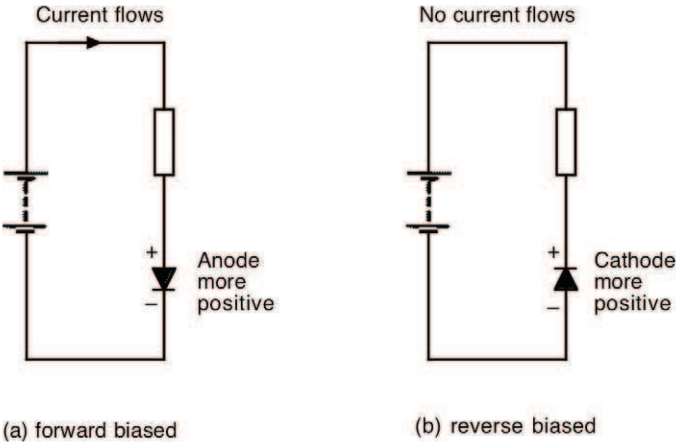
Figure 3.24(a) shows a diode whose anode is positive with respect to its cathode. Although we've shown the anode as positive with a + symbol, and the cathode as negative with a – symbol, they don't necessarily have to be positive and negative. The cathode could for example be at a voltage of +1000V if the anode was at a greater positive voltage of, say +1001V. All that needs to occur is that the anode is positive with respect to the cathode.

Under such a condition, the diode is said to be *forward biased* and current will flow, from anode to cathode.

When a diode is *reverse biased* ie, its cathode is positive with respect to the anode, no current flows, as shown in Figure 3.24(b). Obviously, something happens within the diode which we can't see, depending on the polarity of the applied voltage, to define whether current can flow or not. Just exactly what this something is, isn't necessary to understand here.

We needn't know any more about it here because we're only concerned with the practical aspects at the moment; and all we need to remember is that a forward biased diode conducts, allowing current to flow, while a reverse biased diode doesn't. Which way you should insert a diode into a particular circuit depends totally on the diode and the circuit. All you have to do is insert it the specified way round.



(a) forward biased

(b) reverse biased

Figure 3.24 Simple circuits for: (a) forward biased and (b) reverse biased diodes.

Unlike resistors and capacitors which have particular values, diodes vary only in parameters like the maximum current and maximum voltage they can be used with, and as such are usually specified by a type number — something like 1N4001 or 1N4148. Generally, diodes are marked with their type number, which makes it relatively easy to see what type a diode is. There is one important exception though, in that some diodes are colour banded in a similar way to resistors and capacitors, and use the same colours to indicate digits. However, the four colour bands merely indicate the four digits in the diode's type. Probably the only diode you'll see type-marked in this way will be the very commonly used diode — the 1N4148, which has bands coloured *yellow brown yellow grey* to indicate 4148.

Bridge rectifier

One use of diodes is as rectifiers — devices that convert alternating current to direct current — in power supplies. Usually (but not always), four diodes are connected together to create what is known as a *bridge rectifier*. These can be constructed from individual or discrete diodes, or obtained as a complete unit which mounts directly into the printed circuit board. Several varieties of these complete bridge rectifier exist, and a few are shown in Figure 3.25. Care must be taken when inserting a bridge rectifier into a printed circuit board that it is the correct way round. Markings on the device will indicate the two alternating current input connections (usually with the symbol ~), and positive (+) and negative (–) output connections. Like discrete diodes, the two important considerations when using bridge rectifiers are the maximum working voltage (actually the maximum alternating voltage applied across it) and the current required from it.

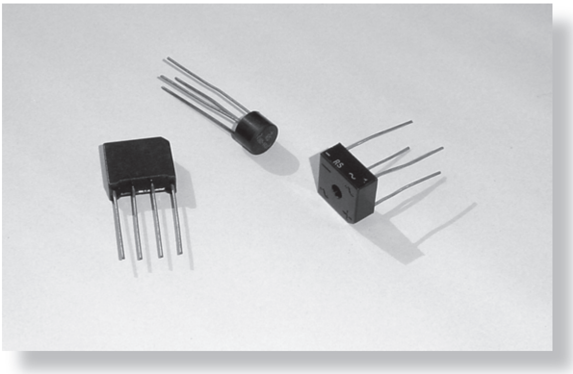


FIGURE 3.25 Various bridge rectifiers.

Transistors

The next important step up the semiconductor evolutionary chain is the *transistor*. Invented over 50 years or so ago, it has been the single most important electronic device ever to have been made. All subsequent electronic devices have been developed from the transistor, and even the most complex of devices such as a computer relies totally upon it still. Nowadays, however, individual transistors are rarely used. Instead several (hundreds, thousands, even millions!) are often combined into complete devices known as *integrated circuits* (we'll look at integrated circuits shortly) and used almost without knowledge or care of what is inside them.

Despite being used rarely, it's still just possible that you'll come across an individual transistor, so we need to look at them now, and fully understand them, so that you can also see how they are used in more complicated devices.

A transistor is shown in Figure 3.26. From the photograph, you'll see that it's pretty small and has three terminals. These terminals are called *base*, *collector* and *emitter* (often shortened to b, c and e). When you use transistors in electronic circuits it is essential that these three terminals go the correct way round.

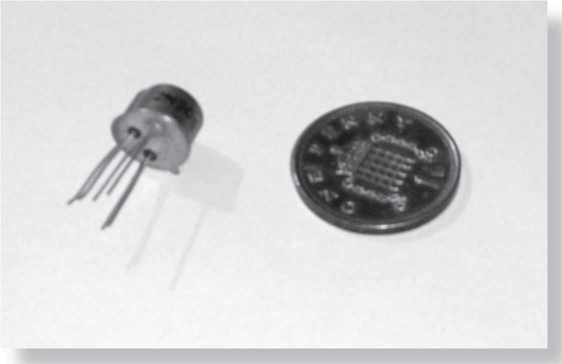

FIGURE 3.26 **A transistor next to a UK one penny coin.**

The problem arises in that different transistors have different body shapes (see Figure 3.27) and different terminal leadouts, so to make sure that the transistor is the correct way round, manufacturers supply them in a standard range of body shapes, and each body shape has a standard terminal lead-out. So, by knowing what body shape a transistor is you can work out its terminals from a chart. Common varieties you'll even learn by heart automatically, just by using them a couple of times.

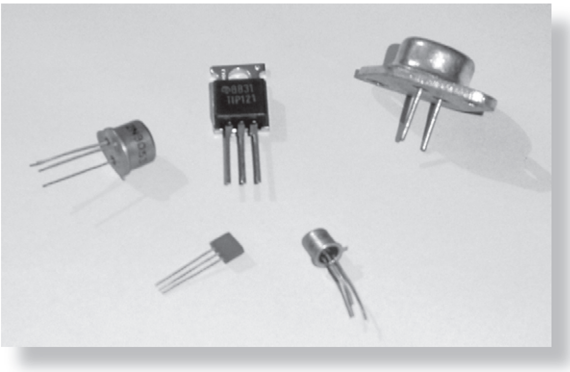

Figure 3.27 A selection of transistors, showing some of the variance in body shapes available.

Figure 3.28 illustrates leadout details for a selection of common transistors. From those shown, you can see that it's easy to work out terminals. For most transistors, leadouts are conventionally given as a plan view looking at the transistor's underside ie, with the transistor's leads pointing towards you. The exceptions are certain types of power transistors, where you view the transistor looking towards the metal pad of the transistor as an elevation view.

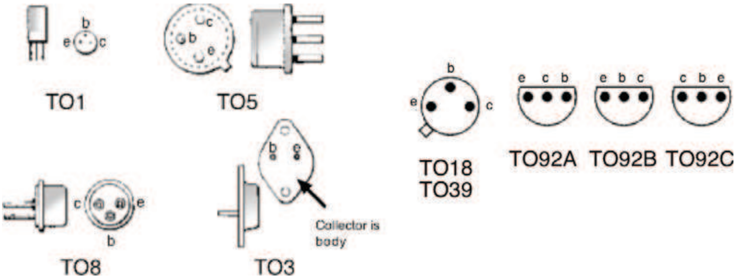

Figure 3.28 Leadouts of some commonly used transistors. Manufacturers of transistors can provide details of all their devices.

There are several different types of transistor, the most popular being what is called the *bipolar* transistor. These are constructed in two different ways, as three layers of semiconductor material — as a thin layer sandwiched between two thicker layers, as shown in Figure 3.29. The semiconductor layers are of two types — called *N-type*, and *P-type*. So the transistor can be made with a thin P-type layer sandwiched between two N-type layers, or with a thin N-type layer sandwiched between two P-type layers — which way defines the transistor's type as either an NPN transistor, or a PNP transistor.

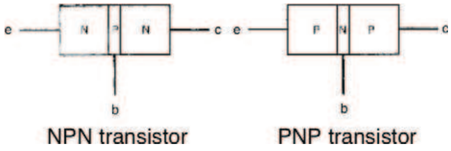

FIGURE 3.29 An NPN and a PNP transistor make-up.

The circuit symbols for the two types of bipolar transistor — NPN and PNP — are shown in Figure 3.30, along with their corresponding terminals. Usually, in circuit diagrams, terminals are not given, and it's taken as read that you will know which terminal is which.

Although the internal working of transistors is pretty complex, we can look on them quite simply — they are electronic switches, in which a small current through the base terminal creates a much larger current through the collector and emitter terminals. The small current through the base terminal is by convention called the *base current*. The much larger current through the collector and emitter terminals is called the *collector current*.

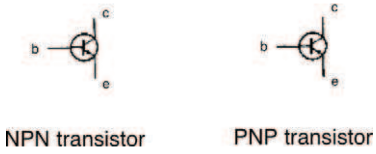

FIGURE 3.30 Symbols of NPN and PNP transistors.

The way bipolar transistors work is illustrated in Figure 3.31(a) for an NPN transistor, where the base current flows into the transistor's base causing a large collector current into the collector. Figure 3.31(b) shows a small base current out of a PNP transistor's base causing a large collector current out of the collector terminal.

FIGURE 3.31 Showing how both NPN and PNP bipolar transistors work – a small current causes a large collector current.

Field effect transistors

Another major group of transistors are called *field effect transistors* (abbreviated to FET), of which there are two main types: the *junction gate field effect transistor* (JUGFET, or J-FET) and the *metal oxide semiconductor field effect transistor* (or MOSFET).

Like bipolar transistors, FETs can be of N- or P-types, but are actually known as N-channel or P-channel types. The three terminal connection leads are the *gate*, *drain* and *source*, which are roughly the equivalent of base, collector and emitter. MOSFETS are available with two gate terminals, and are called *dual-gate MOSFETS* (or DG MOSFETS).

Figure 3.32 shows the circuit symbols of a range of FETs.

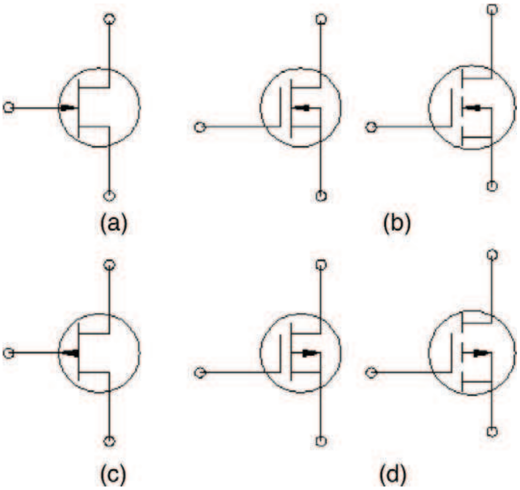

FIGURE 3.32 FET circuit symbols: (a) N-channel J-FET; (b) N-channel MOSFETs; (c) P-channel J-FET; (d) P-channel MOSFETs.

Thyristors

It's sometimes necessary to control current flow in circuits. A specific device to do this is the *silicon controlled rectifier* (or SCR), which also goes by the name *thyristor*. Much like a transistor in appearance, with the terminal *anode* (A), *cathode* (K) and *gate* (G), the thyristor operates like a rectifier or diode that can be switched on or off. Figure 3.33 shows the circuit symbol of a thyristor, while Figure 3.34 shows some common thyristor leadouts.

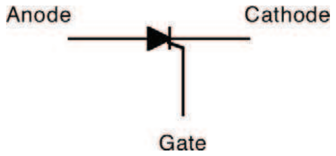

FIGURE 3.33 Thyristor circuit symbol.

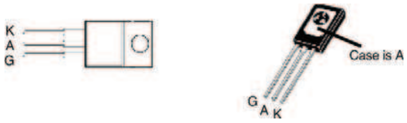

FIGURE 3.34 Some thyristor leadouts.

Triacs

Where thyristors are used to control direct current, *triacs* are used to control alternating current. Their terminals are known as *main terminal 1* (MT1), *main terminal 2* (MT2) and *gate* (G). Circuit symbol for a triac is shown in Figure 3.35, while Figure 3.36 shows some common triac leadouts.

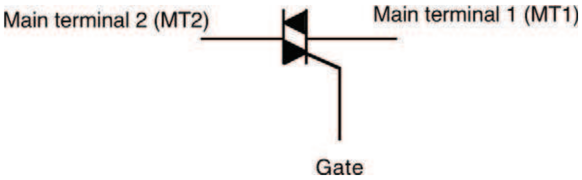

FIGURE 3.35 Triac circuit symbol.

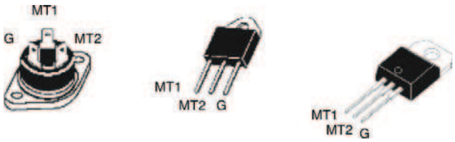

FIGURE 3.36 Some triac leadouts.

Integrated circuits

There are many, many different types of *integrated circuit* (abbreviated to IC) — far too many to describe in this book. Fortunately, at least for beginners to the subject of electronics, it's possible to generalize somewhat and identify perhaps a handful of integrated circuit types that are worthy of note.

For a start, most integrated circuits you'll come across are in a particular body shape — the *dual-in-line* integrated circuit (or DIL IC). These have two rows of terminal pins which are used to connect the internal circuit of the integrated circuit into an electronic circuit.

An example of a very common integrated circuit (the 555, as it happens) is shown in Figure 3.37, where you can see that it's got a total of eight terminal pins, ordered in two four of four. The rows of terminal pins of standard dual-in-line integrated circuits like the 555 are spaced 0.3 inch apart, and pins in the rows are 0.1 inch apart.

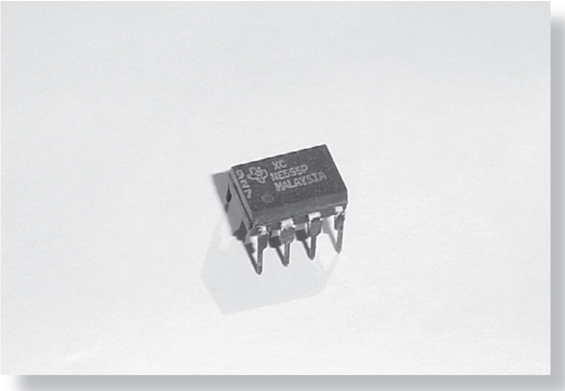

FIGURE 3.37 A 555 integrated circuit.

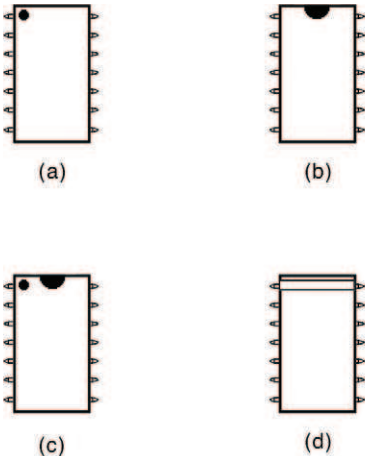
All dual-in-line integrated circuits like the 555 have their terminal pins numbered in the same way — pin 1 is top left, and all other pins follow in an anti-clockwise direction. All that's needed is to know which pin is number 1. Unfortunately, here, there is some difference between integrated circuits manufacturers. Figure 3.38 shows the most common methods of manufacturer markings for dual-in-line integrated circuits — note that (unlike transistors and their associated semiconductor components) integrated circuit pin diagrams are as viewed from the top of the integrated circuits.



(a) (b) (c) (d)

FIGURE 3.38 Terminal pin 1 on dual-in-line integrated circuits is indicated by: (a) a dot; (b) a notch; (c) a dot and notch; (d) a line. Manufacturers vary, so you need to know the various methods.

Integrated circuit types

Integrated circuits contain highly miniaturized electronic circuits — they can, in fact, contain literally thousands of tiny transistors inside their bodies. It should come as no great surprise then to learn that there are literally thousands of different types of integrated circuits, each one designed to do a slightly different job to its neighbours. The exact job an integrated circuit does depends almost totally on the transistors that make up the circuit inside it. As such, it might seem difficult to find out what all these many thousands of types of integrated circuits do.

Fortunately though, integrated circuits fall very roughly into two highly generalized main categories — *analog* (sometimes known as *linear*) and *digital*. Analog integrated circuits are those that can be used in the likes of audio circuits, or some forms of control circuits for example. Digital integrated circuits are those that would be used in the likes of computing circuits, and also some forms of control circuits for example.

As you might expect, there is some overlap between the two categories, which blurs the distinction between analog and digital integrated circuits somewhat.

Typical analog integrated circuits

Perhaps the most common forms of analog integrated circuits are those that comprise the family of integrated circuits known as *operational amplifiers* or *op-amps*.

Operational amplifiers are often illustrated in an electronic circuit diagram with the symbol shown in Figure 3.39(a), where it can be seen that the device has two inputs (marked + and –), and an output.

It's also common to see an operational amplifier illustrated in an electronic circuit diagram inside its integrated circuit body, showing its terminal pins as part of the circuit, as shown in Figure 3.39(b).

Sometimes, the operational amplifier would be shown in a circuit diagram with its actual terminal pins numbered, but the integrated circuit body is not actually shown (Figure 3.39c). All three methods are strictly correct, and it really just depends on the level of detail required in a circuit diagram, along with personal preference, as to which method is used.

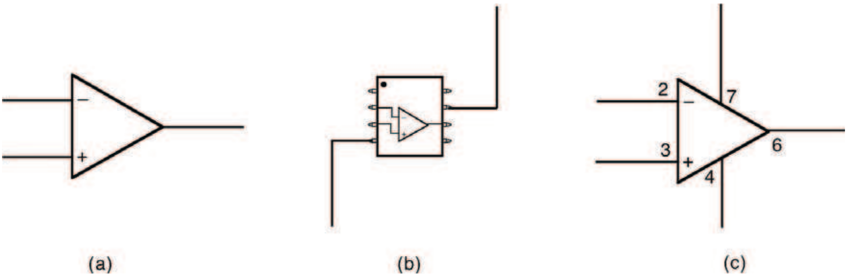


FIGURE 3.39 Circuit symbols for integrated circuits: (a) just the op-amp, with no pin numbers; (b) showing the op-amp complete with integrated circuit 'body' and pin numbers; (c) the operational amplifier with pin numbers.

FYI

While the symbol for an op-amp is relatively simple, you should realize that the op-amp itself may contain many hundreds of components inside the integrated circuit. Treating them collectively as a single component called an op-amp simply makes it easier for us to get our heads round it. An op-amp is a sort of 'black box' electronic component — we don't need to know how it's made up, just how it works. There are many other black box electronic components.

Many integrated circuit op-amps have identical terminal pins, so it's possible that one op-amp can be replaced by another in the same electronic circuit. But there are some differences, so before you use an op-amp, you should refer to manufacturers' data sheets for the op-amp to make sure it will fit in, and work in, the electronic circuit you are building. That being said, most integrated circuit manufacturers make a range of general-purpose op-amps that are sufficiently close in relevant characteristics that they may be classed as identical. For instance, most integrated circuit manufacturers make an op-amp called a 741. A 741 from one manufacturer should work in a 741 designed for another manufacturer's 741. For reference, Figure 3.40 (left) shows a 741 op-amp — it's in a standard 8-pin, dual-in-line integrated circuit format, while Figure 3.40 (right) shows the pin-out diagram for a 741.

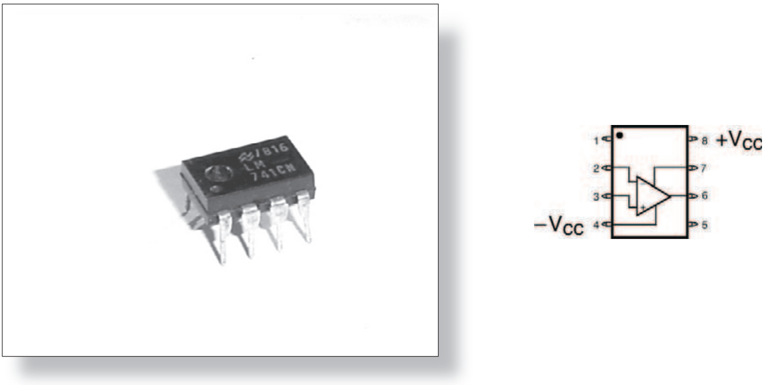

FIGURE 3.40 A 741 op-amp: (left) photograph; (right) pin-out diagram.

Typical digital integrated circuits

Perhaps the simplest forms of digital integrated circuits are those that make up digital gates. Like analog op-amps, these usually have a simple black box symbol, but in reality are made up from many individual transistors inside the integrated circuit. Common logic gates are shown in Figure 3.41. There are, however, many more types of logic circuits available in integrated circuit form. Also, like analog op-amps, logic gates are commonly shown in an electronic circuit with their pin numbers shown.

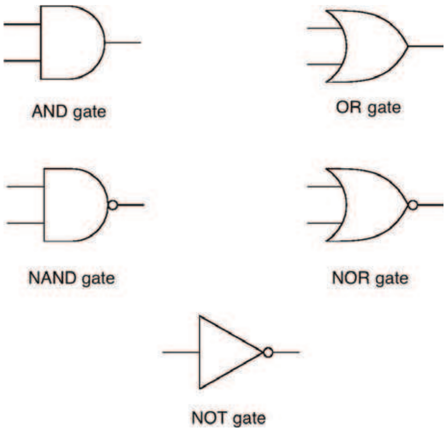

FIGURE 3.41 Common logic gate symbols.

There are several families of digital integrated circuits, generally based on their construction techniques. How the actual gates or logic circuits inside each integrated circuit in each family are connected through their respective terminal pins is defined in standard digital integrated circuit pin-out diagrams. Some digital integrated circuit pin-out diagrams are shown in Figure 3.42 (for digital integrated circuits in the 7400-series), and in Figure 3.43 (for digital integrated circuits in the 4000-series). These are the most common digital integrated circuit families.

Batteries

Electronic circuits need power of some sort to function. Power is sourced from either a power supply (usually mains-powered) or — particularly for portable equipment designs — batteries. Occasionally, a single cell might be sufficient to power an electronic circuit — the symbol is shown in Figure 3.44 (a) — but more usually multiple cells, or power pack batteries are used — the symbol of both is shown in Figure 3.44 (b). Note that the voltage should be shown beside either symbol.

Where cells or batteries are used to power electronic circuits, some form of connector must be used to clip the cell or battery into place. Various battery connectors are shown in Figure 3.45. The type used depends on the cells or batteries required, the circuit itself, and also the housing used to hold all the electronic circuit parts (including the cells or battery).

Indicators

Often, it's useful or necessary to show when an electronic circuit is turned on. This is usually done with an indicator of some sort — either a bulb, a neon, or most often a LED.

Bulbs

Not used very often, low-voltage bulbs can give an effective indication of an electronic circuit's function. However, problems associated with mounting the bulb normally preclude their use. Some bulbs and mounting methods are shown in Figure 3.46.

Neons

Largely for the same reasons we don't often use bulbs, neons aren't often used either — with the possible exception of some mains switches (see later) that contain an integral neon bulb to show when an electronic circuit's power supply is turned on. Figure 3.47 shows an example of such a mains switch.

LEDs

Light emitting diodes (LEDs) nowadays form the usual and best method of indication. They are easily used, and easily and cheaply mounted onto housings' front panels, so have become the preferred method. They are — as their name suggests — a particular form of diodes, and must be used with the same precautions as other diodes (see the section on diodes, earlier in this chapter), but when they are forward biased in a circuit emit light. Normally one side of the LED is marked in some way to indicate cathode. Different colours of LEDs are available (green, red, blue, white), and some forms emit light of different colours depending on connections. Figure 3.48 shows a typical round LED, although rectangular LEDs are also available.

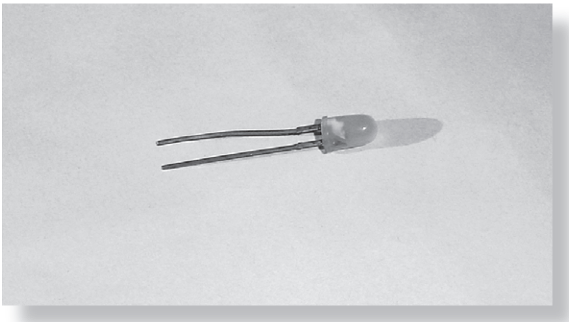

FIGURE 3.48 A typical LED.

Switches

There are many forms of switches used in electronic circuits, and they take many different shapes and sizes. They are all similar however, in that they are all mechanical devices which are physically operated by the user. Their main differences lie in how the internal contacts are arranged, and what form of mechanical device is operated by the user to switch contacts.

Contacts

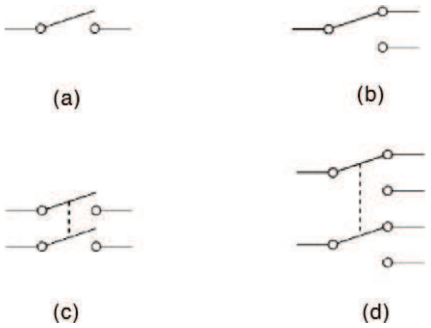
The simplest switch has two contacts, and a simple on/off mechanism. Its circuit symbol is shown in Figure 3.49 (a). As it can be used in only one connection within a circuit, it is called *single-pole*. Also, as it can be only on or off, it is called *single-throw*. So, in full, it is known as a *single-pole, single-throw* switch (shortened to *SPST*).

Where the switch has a third contact, so the central contact can be switched to either one state or another, it is known as a *single-pole, double-throw* (*SPDT*) switch, and is occasionally called a *changeover switch*, and its circuit symbol is shown in Figure 3.49 (b).

Commonly, switches can be joined (or *ganged*) together in one housing, to allow more than one connection to be switched at the same time. The simplest of these switches would be a *double-pole, single-throw* (*DPST*) switch, the circuit symbol of which is shown in Figure 3.49 (c). The broken line between the two individual mechanisms of the circuit symbol indicates that both mechanisms are mechanically joined, and as one switch operates the other does too.

Circuit symbol of a *double-pole, double-throw* (*DPDT*) switch is shown in Figure 3.49 (d), where the two joined mechanisms are of double-throw format. Again the broken line joining the individual mechanisms indicates that both mechanisms operate in unison.

While these four switch types shown in Figure 3.49 (a) to (d) are obviously not the only switch types, they form by far the most common types you will come across in electronics.



FYI

The switch types in Figure 3.49 are only the most common four. It's possible to get switches with many more poles, and many more throw mechanisms, for specific purposes.

Figure 3.49 Four main switch types: (a) single-pole, single-throw (SPST); (b) single-pole, double-throw (SPDT); (c) double-pole, single-throw (DPST); (d) double-pole-double-throw (DPDT).

Take Note

The contacts of switches of all types have only limited voltage and current ratings, and you must make sure that you do not exceed these contact ratings when using switches. If the circuit a switch is used in is battery-powered, it is unlikely that contact ratings will be exceeded, but if the switch is to be used to switch mains power then contact ratings should be carefully checked before use.

Mechanics

The most common mechanics used in switches in electronics are: slide, toggle, push, and rotary. Examples of all are shown in Figure 3.50. Each type may have a number of deviants, and is usually available in a range of sizes too. Switches may also be incorporated with other functions, such as a potentiometer (see page 31), or indicators (see page 58). Also, each mechanism type can have minor variants in operation — for example push switches can be *push-to-break* or *push-to-make*, and *switched* action or *momentary* action — so it's not hard to see that there are many hundreds of switch types to choose from.

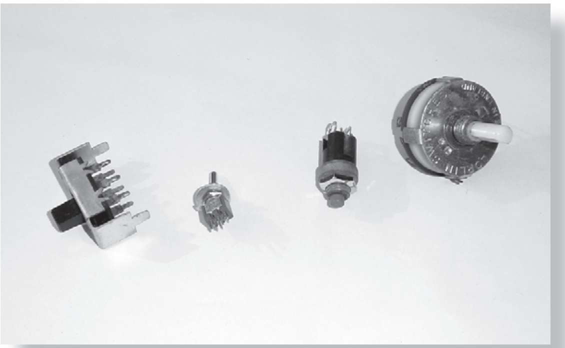


FIGURE 3.50 A range of switches, according to mechanism types, from left to right: slide, toggle, push, rotary.

Relays

Relays are just switches that are operated electro-mechanically. Thus, where an ordinary switch may be operated by you pushing a button, or flicking a toggle, a relay is operated by merely applying an electric current to an electro-magnetic coil. This current creates a magnetic field that flicks the relay's internal switch mechanism. The advantage is pretty obvious — an electronic circuit can operate the relay automatically, without human intervention. A circuit symbol for a single-pole, double-throw relay is shown in Figure 3.51.

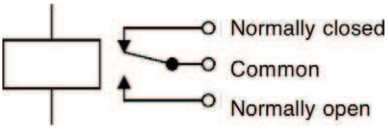

FIGURE 3.51 Circuit symbol of a single-pole, double-throw relay.

Generally, relays are mounted on an electronic circuit's printed circuit board, so are quite small. Several variants exist, and usually it is simply a matter of choosing the relay to suit in terms of number of switch poles and throws, contact ratings, coil operating voltage and current, and size. An example of a relay — a miniature, printed circuit board mounting relay — is shown in Figure 3.52.

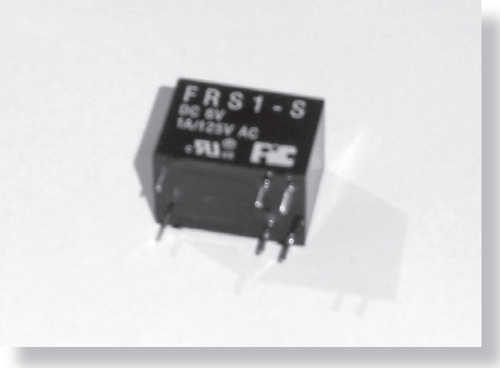

FIGURE 3.52 A miniature, printed circuit board mounting relay.

Loudspeakers and other sound output devices

In an audio circuit, it's often required that we can hear the audio signal. The usual way to do this is either with an in-built loudspeaker, or using earpieces.

Loudspeakers built in to electronic circuits are usually fastened to the housing of the circuit, and once in place are pretty robust. However, they do require some precautions in handling. They work because a cone of some material is vibrated electro-magnetically (due to an electric current passing through an attached coil of wire that is situated in a magnetic field). Problems can arise because the cone is easily damaged or split if mishandled. A couple of examples of loudspeakers for use with electronic circuits are shown in Figure 3.53.

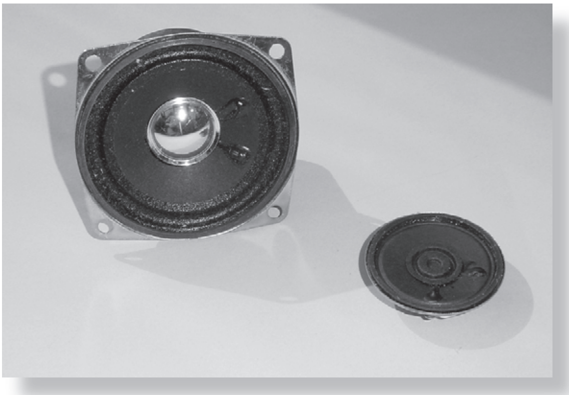

FIGURE 3.53 Loudspeakers typically used in electronic circuits.

Sometimes, while audio sound is not outputted from a circuit, some form of noise is — say, a buzz, or beep. There are several forms of devices for doing this, but only two main groups: *buzzers* and *sounders*.

Buzzers are generally electro-mechanical or piezo-electric sound sources which, when a voltage (generally of direct current) is applied across their terminals, vibrate at a fixed frequency, causing a sound. They come in various shapes and sizes and amplitude levels, some of which are shown in Figure 3.54. The circuit feeding the buzzer merely needs to switch a current to the buzzer to make it work.

Sounders are more like loudspeakers in operation (some are shown in Figure 3.54), and require some form of alternating current signal. Unlike loudspeakers, however (which can successfully operate over a range of frequencies — so can reproduce audio quite well), sounders require a fairly specific frequency signal to generate the loudest sound possible. The circuit feeding the sounder must produce an oscillation at the frequency required by the sounder, to make it work.

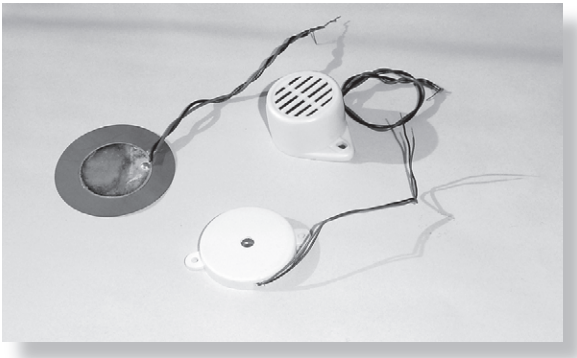

FIGURE 3.54 A buzzer with two types of sounders.

Microphones

Microphones are, in essence, the opposite of loudspeakers and sounders. They convert a sound into an electrical signal, for use by an electronic circuit. They are common in two main forms: *dynamic* and *electret*. Dynamic microphones are just like loudspeakers in reverse; they feature a diaphragm (that is much like a loudspeaker's cone) which vibrates as sound waves hit it, connected to a coil of wire that moves through a magnetic field, producing electric current.

Electret microphones (sometimes known as *condenser* microphones) operate in a vaguely similar way in that they have a polymer diaphragm that creates an electric signal as it vibrates due to impinging sound. However, this signal is too small to be used raw, so they also include an amplifier inside the microphone housing to amplify the signal. While this produces an extremely high quality and small microphone, the downside is that the amplifier must be powered somehow, but a simple low-voltage connection is all that is required (and, as most electronic circuits are powered by a low voltage, extremely easy to include).

The circuit symbol for a microphone is shown in Figure 3.55, while Figure 3.56 shows microphones of the two main types.

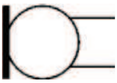

FIGURE 3.55 Circuit symbol for a microphone.

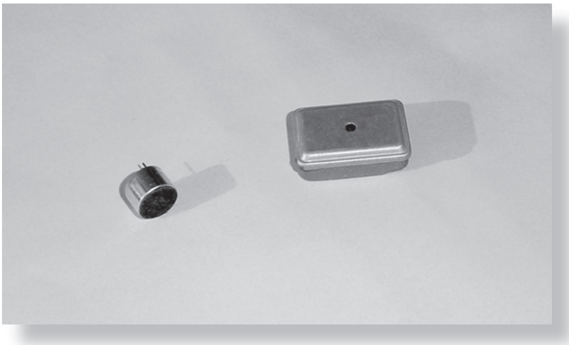

FIGURE 3.56 An electret microphone, and a dynamic microphone.

Coils and inductors

Technically, any coil of wire that has a current applied to it becomes an inductor. So, any electronic component that comprises a coil can also be classed as an inductor. That being said, it's not often that simple coils are used in an electronic circuit (normally only in radio frequency circuits). In most instances, you may even not realize that the component you use features an internal coil.

Examples of coils in common use that you may use are transformers (used, say, in mains power supplies), loudspeakers, and relays (see earlier).

Connectors

Any electronic circuit depends on connectors of many types: to get signals into and out of the circuit; to connect to controls that are on a housing's front panel; and to obtain power from a battery or power supply. The range of connector types is huge, and can't fully be covered here, but we can at least look at a range of common connectors you will almost certainly come across. Connectors are generally (as far as we're concerned here) used either on a printed circuit board, or on the housing used to house a printed circuit board.

Some typical plug and socket connectors for use on printed circuit boards are shown in Figure 3.57. Some typical connectors for mounting on a circuit's housing are shown in Figure 3.58.

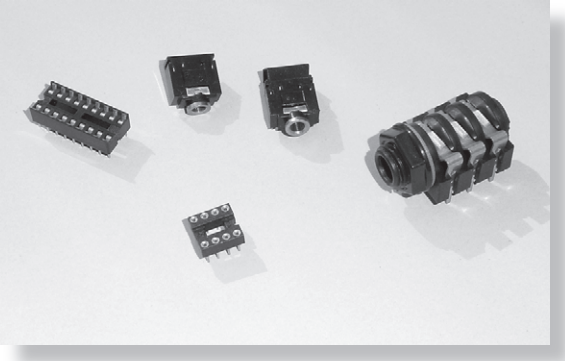

FIGURE 3.57 Typical printed circuit board connectors.

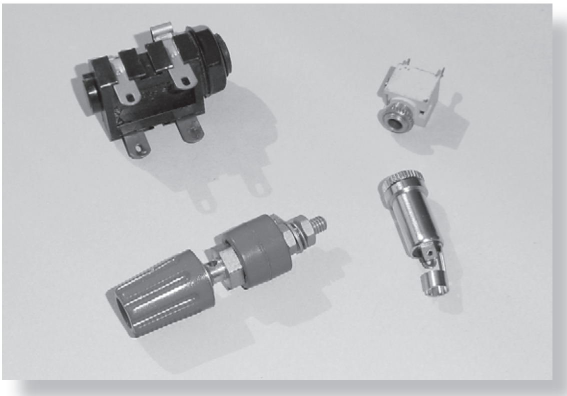

FIGURE 3.58 Connectors used on housings for front- or rear-panel mounting.

Integrated circuit holders

Where integrated circuits are to be fitted to printed circuit boards, it's common not to solder them in. Integrated circuits are, of course, complex, miniaturized devices. Excess heat when soldering may damage them (although some are less sensitive to heat damage than others), so an alternative is to use *integrated circuit holders* (sometimes called *integrated circuit sockets*), which *are* soldered into the printed circuit board. Integrated circuits are then push-fitted into the holders afterwards.

Figure 3.59 (left) shows an integrated circuit holder in place on a printed circuit board, while Figure 3.59 (right) shows the holder with an integrated circuit fitted. Integrated circuit holders are sized the same way that integrated circuits themselves are, so you would use an 8-pin holder for an 8-pin integrated circuit, a 14-pin holder for a 14-pin integrated circuit, and so on. Holders are not expensive — about 15p each — so it's worth buying a few of each common size (8-pin, 14-pin, 16-pin) for your component box.

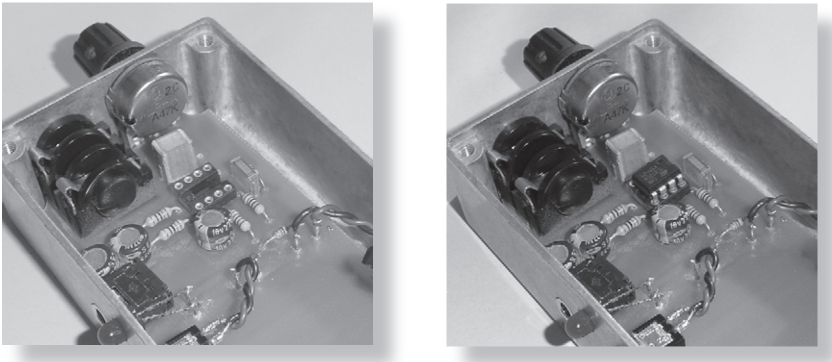

FIGURE 3.59 **Using integrated circuit holders: (left) the holder itself, in position in a printed circuit board; (right) showing an integrated circuit in the holder.**

Terminal pins

One of the main problems with a printed circuit is how to connect any external controls, switches or connection sockets. Often, it's possible and easy to use a connection lead, from the component side of the board to the track side, soldered into place at a junction in the copper foil track. Indeed, Chapter 5 shows in detail how to do this. However, if a printed circuit board has been mounted in a housing (see Chapter 6) then it's not easy to get to both sides of the board to do this.

It's therefore a good idea to use terminal pins. These push through from the copper track side of the printed circuit board to the component side. They are then soldered to the copper track. Thus, when the printed circuit board is mounted in its housing, it's still easy to solder a connecting lead to the pin connection (which is on the component side ie, the upper side, of the board). Chapter 5 shows how to solder a connecting lead to a terminal pin, but in order to do that, of course, you need to buy some terminal pins. They are usually sold in packs of 100 and cost only a few pounds a pack, so are well worth the investment. Various sizes are available, and various types, but the most common 1 mm diameter, single-sided, pre-tinned type is all you'll need, unless you are constructing a circuit that calls for anything more unusual.

Take Note

Don't buy gold-plated terminal pins – they are much more expensive, and in all but the most critical of situations, provide no benefit.

Figure 3.60 shows terminal pins, soldered in place in a printed circuit board.

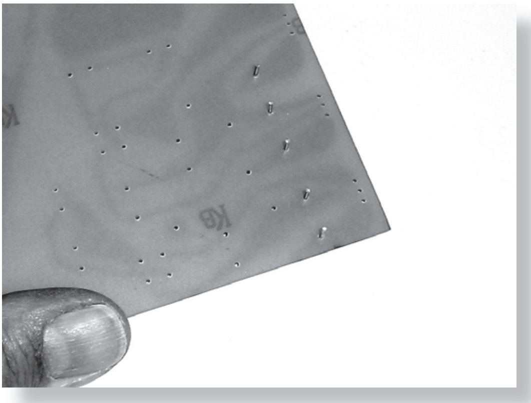

FIGURE 3.60 **Terminal pins in a printed circuit board – the pins are push-fitted into the board, then soldered in place.**

FYI

Terminal pins have a knurled ridge that holds the pin in place in the printed circuit board. The knurled ridge makes them a little hard to push into place however. Pliers, or a hammer, will do the job if you are careful. However, you may think it worth buying a terminal pin pushing tool to help with this job — see Chapter 2.

Printed circuit board links

While hardly being an individual component, it's best to take a look at the use of printed circuit board links. These are used on a printed circuit board if a connection in the circuit needs to be made, but the design of the copper foil track is such that it cannot be made using the copper foil.

In such cases, it's common to use a small link of wire that jumps from one connection point to another on the printed circuit board.

Many connections in the copper foil track can be run underneath the link, so it forms a useful method of bridging parts of the printed circuit board.

Figure 3.61 shows a printed circuit board with several links in place — the board shown is actually the Heart Flasher project printed circuit board, detailed in Chapter 8.

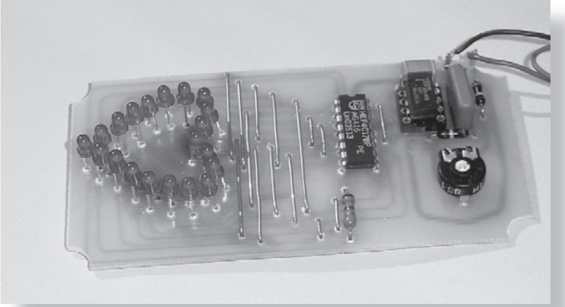

FIGURE 3.61 Links on a printed circuit board.

Printed circuit board links *can* be made with insulated connection lead, but this tends to make a rather messy board. Instead, it's best to use uninsulated single-strand wire. Being rigid, links don't bend and become untidy the way insulated wire would, and there is little risk of links touching other links or neighbouring components. Buy a reel of single-strand wire, then cut short pieces off to make links — see Chapter 5 for details.

Take Note

When designing a printed circuit board which requires links, make sure that links run parallel – in this way there is no danger they will touch other links close by.

4

Printed circuit boards

Most of the projects you'll ever want to make up from electronics magazines or electronics books like this one are constructed on printed circuit boards (PCBs). Without any doubt printed circuit boards help you make really neat and reliable projects, simply because they hold all the components of the projects in a fixed and long-standing way, with strong soldered joints giving the good electrical connections required in the circuits. You've only to take the back off any modern electronic appliance such as your television, radio, hifi amplifier, computer (carefully — and after you've unplugged it from the mains and assuming it's yours!) to see that it's not just book and magazine projects which use printed circuit boards, but manufacturers of electronic appliances do, too. Figure 4.l shows a printed circuit board in a typical modern appliance.

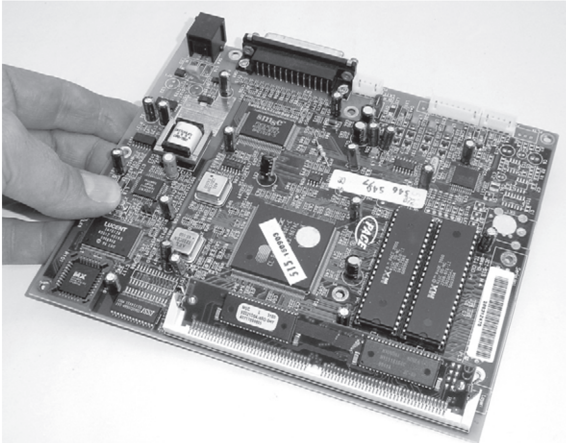

FIGURE 4.1 A printed circuit board - the type you might find in a television or other modern electronic appliance.

There are loads of benefits when using printed circuit boards:

NUMBER 1 Positioning components. Each component in the circuit has its own special little place on the printed circuit board — if you've forgotten to insert it, it's fairly obvious there's something missing because there is a space and a couple of holes

NUMBER 2 The components fit close up to the board. Component leads go through holes in the board to the other side, where they are soldered to strips of copper — in other words, the components are rigidly held so they can't easily work loose, and there's not much chance of one component lead shorting against another

NUMBER 3 Size. Yet another benefit is simply the sheer compactness of the completed assembly — as connections are made with copper tracks on the underside of the board (some printed circuit boards have copper tracks on both sides — and are called, naturally enough, double-sided printed circuit boards) and as components can be very close together without the risk of short circuits, the size of the printed circuit board need be very little more than just the total surface area of the components.

If you have an old valve radio or television around the place, you can compare equipment with modern printed circuit boards to the method used then; where all the components were simply strung between connection points on 'tag strips' underneath a metal chassis, in a seemingly haphazard arrangement. While such methods served their purpose in their day, no one can doubt that printed circuit boards are infinitely better.

Copper-clad printed circuit board

So what exactly is a printed circuit board, what's it made of, how's it made, and how do we set about getting it?

Well, the photograph in Figure 4.2 shows a small piece of printed circuit board, directly as it would be obtained from a printed circuit board manufacturer, or as you might buy from an electronics components shop. This small piece would have been cut from a much larger sheet (typically a few metres square). In its raw state like this, the printed circuit board is

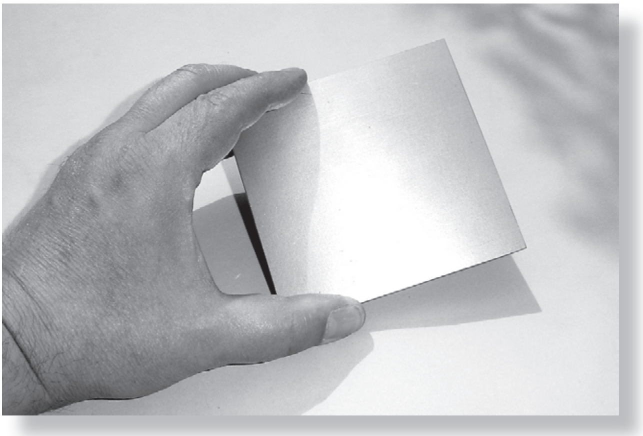

FIGURE 4.2 Raw printed circuit board, comprising a thin layer of copper on a insulating material baseboard.

called *copper-clad board* and it comprises a thin baseboard (about 1.5 mm) of insulating material such as resin-bonded paper or, more likely, fibreglass, with an even thinner layer of copper (about 0.2 mm) on one surface (or both, if it's double-sided copper-clad board). Figure 4.3 shows an enlarged cross-section of a typical piece of copper-clad board.

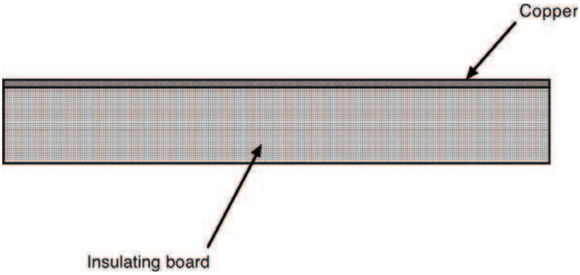

FIGURE 4.3 Enlarged cross-section of copper-clad printed circuit board

▷ FYI ◁

Apart from basic copper-clad printed circuit boards like this, industrial manufacturing often makes uses of double-sided copper-clad printed circuit boards (in which a circuit is made up from copper connections on both sides of the board) and multi-layered printed circuit boards (which comprise several internal layers of copper connections as well as those on one or both surface sides of the board) — typically these would be used in only the most complex of circuits, where space is at a premium!

This copper-clad board must now be turned into a usable printed circuit board, so some way must be found to remove excess areas of copper, leaving behind only those areas which we need to connect the components to. The areas left behind form what's called the copper track or the copper foil. Figure 4.4 shows such a printed circuit board where the copper track or foil is clearly visible.

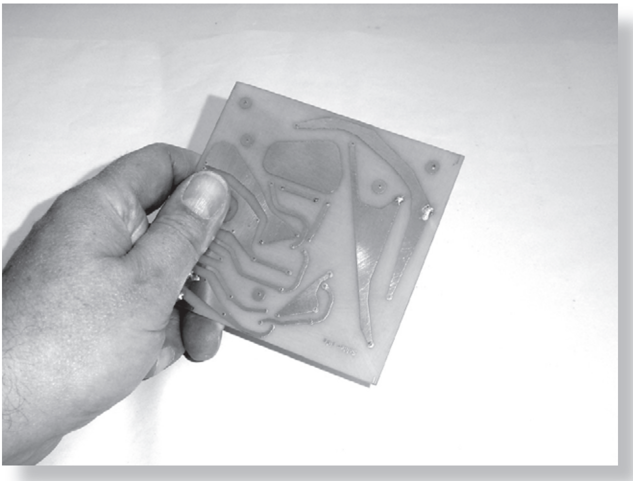

FIGURE 4.4 **Once the excess copper is removed from copper-clad board, the copper track or foil remains.**

Once a printed circuit board has been created, complete with a copper track, it is then a relatively simple task to drill the holes in the printed circuit board for the component leads to fit through, and then solder them in.

But we shouldn't go too far, too fast. We should really stop and think for a minute about what's just been said. Somehow a piece of copper-clad board (which consists of a thin layer of copper stuck onto the surface of a thin insulating board) must have areas of copper removed, leaving behind a copper foil which follows the foil pattern required on the printed circuit board for the project. Just exactly how do we remove the copper?

Don't worry, the answer's not quite as difficult as you might imagine — we simply dissolve it away using an acid-type etchant.

But doesn't the etchant dissolve away the copper foil, too? Well, no — because first we have to coat the areas of copper that are to make up the copper foil with something which will resist the etchant, preventing the copper underneath from being dissolved. Figure 4.5 shows the idea.

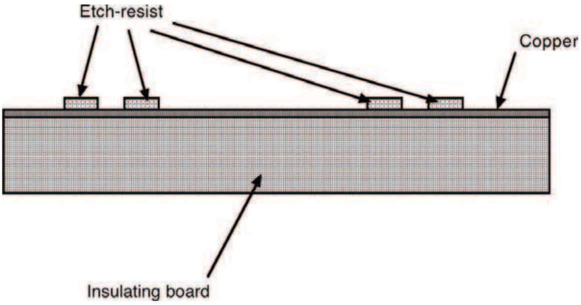

FIGURE 4.5 **Coating the copper surface with an etch-resistant material means that the copper under the material is protected from attack from etchant.**

After etching (Figure 4.6), the unwanted copper has been dissolved, but the copper foil under the etch-resist remains.

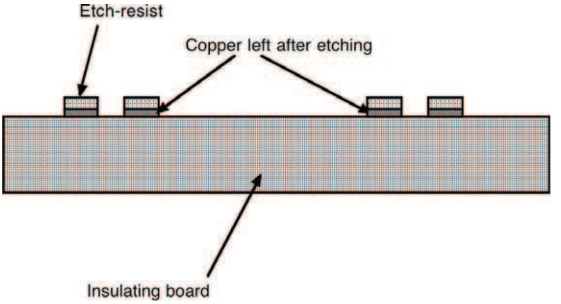

FIGURE 4.6 **Once the board of Figure 4.5 has been etched, only the copper underneath the etch-resistant material remains.**

After removal of the etch-resist, the printed circuit board is ready for drilling (Figure 4.7), component insertion (Figure 4.8), soldering (Figure 4.9), and finally component lead trimming (Figure 4.10).

Component

FIGURE 4.10 *Component leads are trimmed, leaving a neat soldered printed circuit board.*

In summary, the steps to making a printed circuit board are:

- **OBTAIN** or design the foil pattern for the circuit
- **APPLY** etch-resist to copper clad board in the shape of the foil pattern
- **ETCH** away the unwanted copper
- **REMOVE** the etch-resist and drill the component lead holes
- **INSERT** the component leads
- **SOLDER** the component leads to the board
- **TRIM** the excess component leads.

Later in this chapter these steps are described in full, and the various methods that you can use to create your own printed circuit boards are detailed.

Other boards

There's no doubt that printed circuit boards give a much better way to build circuits, and it's the way recommended wholeheartedly by this book and by anyone else who knows anything about basic electronics and who seriously wants to help people like you — the reader — to use the best methods.

However, printed circuit boards aren't the *only* method of building electronic circuits. So, we're going to take a short break from printed circuit boards, to look at a couple of other methods. That way, you'll see the differences, and see why printed circuit boards are best.

Matrix board

Made from a plain board of insulating material, with holes at 0.1 inch horizontal and vertical distances, matrix board is merely a way of holding components on a board. A plain piece of matrix board is shown in Figure 4.11.

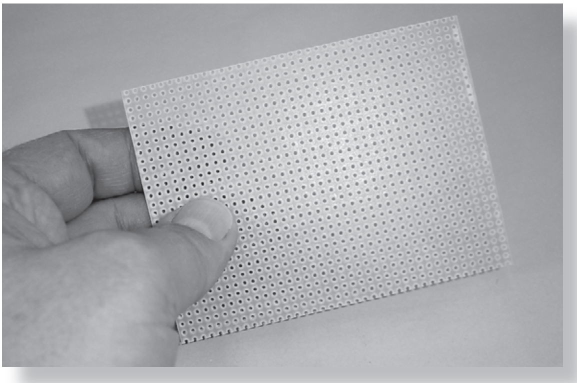

FIGURE 4.11 A plain piece of matrix board.

As with printed circuit boards, component leads are inserted through the holes on matrix board, but there the similarity ends. There is no copper on the underside of a matrix board as there is on a printed circuit board, so all connections between components must be made by either bending component leads to the next component or by adding extra wire to do the same. Where component leads or wires join, the joint must be soldered.

Overall, matrix board is useful for prototyping a simple circuit to make sure it works. It can also be useful where the circuit is being designed as it's built — it's quite easy to add extra components if a change is required, and it's also quite easy to adapt the circuit as you go. Indeed, when using matrix board *the whole layout* is usually designed as you go! However, it's not the ideal construction method for a finished electronic circuit as it is hard to replicate, and is tricky to use if the circuit is complex.

Stripboard

Stripboard is a sort of cross between matrix board and printed circuit board, so has advantages from both methods of construction. For a start, the underside (shown in Figure 4.12) has strips of copper to make connections between components. Also, the board is pre-drilled, with holes at 0.1 inch horizontal and vertical distances, just as with matrix board. As a result, it's quite easy to make a simple electronic circuit by inserting components, and soldering them in place. Also, as the copper strips are pre-defined, and unlike the earlier matrix board construction method, it's perfectly possible to design a layout on paper first, so that circuits can be replicated fairly easily. For this reason, stripboard circuit layouts are sometimes given in electronics magazines and books, particularly for simple circuits. They are not, however, ideal.

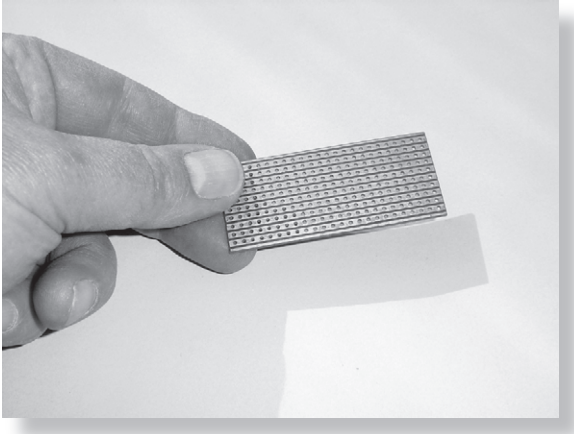

FIGURE 4.12 A plain piece of stripboard, showing the strips of copper. Pre-drilled holes in the strips mean that component insertion is straightforward, if defined.

Hint

When using stripboard it's often the case that only a couple of holes on a copper strip are used to connect components – the rest of the copper strip is then unusable. Also, where components like dual-in-line integrated circuits are to be used, the copper strips of plain stripboard would directly connect the integrated circuit's two rows of pins.

The answer is to cut the copper strip, effectively splitting it into parts. A sharp knife such as a craft knife could be used to split the copper strip, but a purpose-made tool – the spot-face cutter – is best used. To use the spot-face cutter just position it onto a hole in a copper strip, then twist it backwards and forwards two or three times, until the copper strip has been cut away (shown in Figure 4.13).

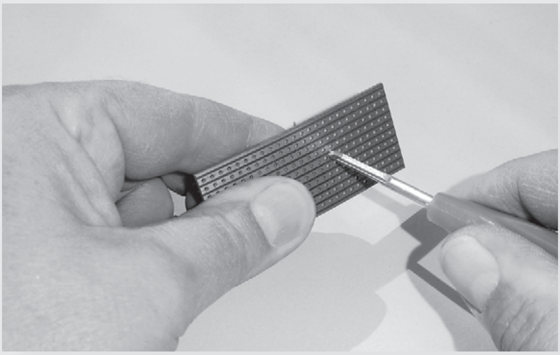

FIGURE 4.13 Using a spot-face cutter to split a copper strip on a stripboard.

There are variants of the plain stripboard, designed particularly for integrated circuits, in which the copper strips are organized to accommodate the rows of dual-in-line pins common to integrated circuits.

Nevertheless, other than being quite a useful method for the making of simple electronic circuits or for prototype circuits, stripboard is still not the ideal contructional method. Printed circuit boards remain the best method and should be the ideal you strive for.

Making your own printed circuit boards

Many people take advantage of the various printed circuit board services that electronics magazines offer, through which they can purchase ready-made printed circuit boards from the magazine publisher, complete and ready to build their projects onto. If you don't fancy making your own boards, these services are ideal.

Hint:

When electronics books and magazines give printed circuit boards for projects, they do so by printing what is called the foil patterns of the projects. It's the foil pattern of any particular project, of course, which is the shape of the copper to be left on the printed circuit board when the excess areas are removed. When you make a project given in a book or magazine you have the foil pattern to create the printed circuit board. If you want to design and build any other circuit, you must design the foil pattern yourself.

On the other hand, you may be trying to build a project taken from a book (like this one) or — simply — you may like to have a try making your own. Making your own printed circuit boards is certainly more rewarding than buying them ready-made — but it is a little more complex. However, it's nothing the average newcomer to electronics can't handle; as long as you follow the few simple rules which we'll now give you.

Right from the very beginning — the foil pattern

Let's assume that you have a circuit, which you may have designed yourself or somebody else may have designed it, but you have no printed circuit board foil pattern for it. Figure 4.14 is a typical circuit which you may recognize as being a multivibrator, and will do nicely for our purposes here.

At this point you need some basic tools — all of which you probably have at hand — paper (plain, tracing and graph), a pencil and a rubber, and a ruler. You'll also need a selection of one of each type of the components in the circuit eg, one resistor, one capacitor, one transistor, one integrated circuit etc, or their physical dimensions. This is because you need to know how big each component is so that when designing the foil pattern you know what distance to leave between component lead holes.

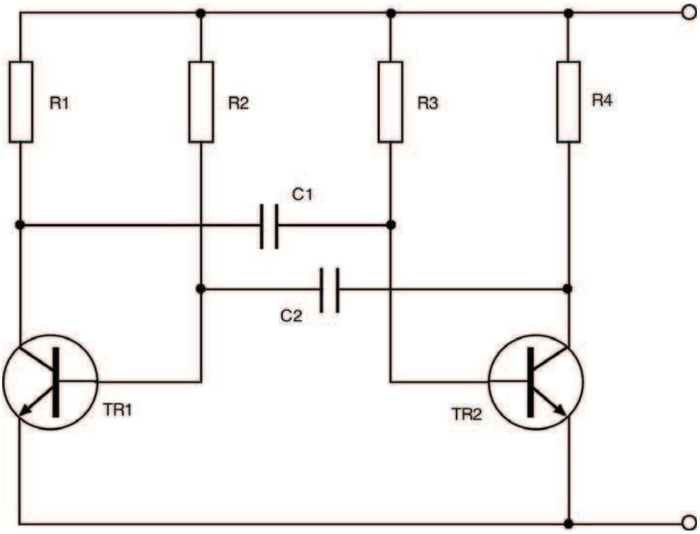

FIGURE 4.14 A simple circuit which we'll use to show how to design your own printed circuit boards.

Although this may seem daunting at first, don't worry, because if you design more than just a couple of foil patterns, you'll begin to remember the sizes of all but the most unusual components. Lay everything out on a desk or clean workbench.

Now the difficult bit (not really!): designing the foil pattern. What you have to remember here is that the components go into one side of the printed circuit board, but the copper foil making the connections is on the other side of the board.

Begin by choosing a component, fairly central to the circuit (we'll choose transistor TR1). Now draw its approximate shape (as viewed from above) onto a sheet of plain paper, as in Figure 4.15.

Just as we've done, mark where its connection leads will enter the paper 'board' and label it (TR1 in our example). Also, if it's anything other than a simple resistor or capacitor, you should mark the leads, too (*e*, *b*, and *c* if it's a transistor).

Now draw a few more components onto the paper, alongside the first, similarly marking them as you go (Figure 4.16). Don't be afraid to position them close together; a spacing of only 2 mm or so between components is normally ideal.

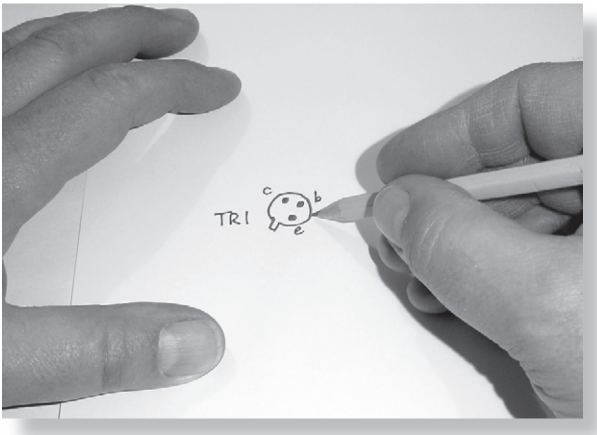

FIGURE 4.15 First steps: marking the first component onto plain paper. Also mark its leads – as it's a transistor, the leads should be named e, b and c to show the emitter, base and collector.

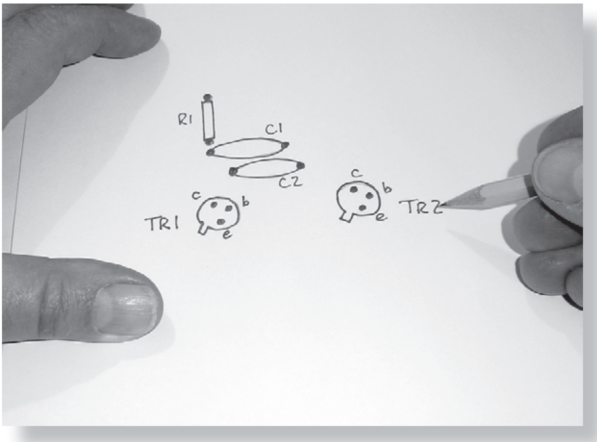

FIGURE 4.16 Add further components to the layout, by marking them on the paper – they can be quite close.

At this stage you may find it helpful to more or less follow the general pattern of the circuit diagram when positioning components, although this is by no means essential — it's probably just easier for a newcomer to do.

When you gain confidence in making printed circuit boards you probably won't follow the pattern of the circuit diagram at all — it really doesn't matter; as long as the connections follow the circuit diagram, the pattern can be like the Union Jack if that's what you want.

When you have drawn in a few components, begin to pencil in 'connections' corresponding to the copper track required, as in Figure 4.17, so that they will be electrically joined by these connections on the finished printed circuit board.

Don't worry if you get stuck, or even make a mistake, that's why you have the rubber! Simply rub out the error and start again.

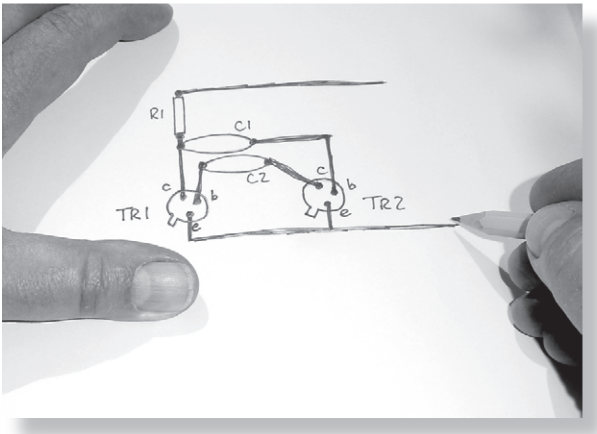

FIGURE 4.17 Connections between component leads should be drawn in now.

Build up the layout, putting in more and more components, and more and more 'connections'.

Remember that the finished printed circuit board will have its foil pattern on the other side to its components, so tracks can actually pass underneath components, as in Figure 4.18. There is also no reason at all why two, or even three, tracks can't pass underneath a component, so long as the tracks don't touch each other or touch the component lead holes.

If you were worried about your foil pattern being untidy, now's your opportunity to change all that. Place a sheet of tracing paper over a sheet of graph paper and tape the two together along the edges.

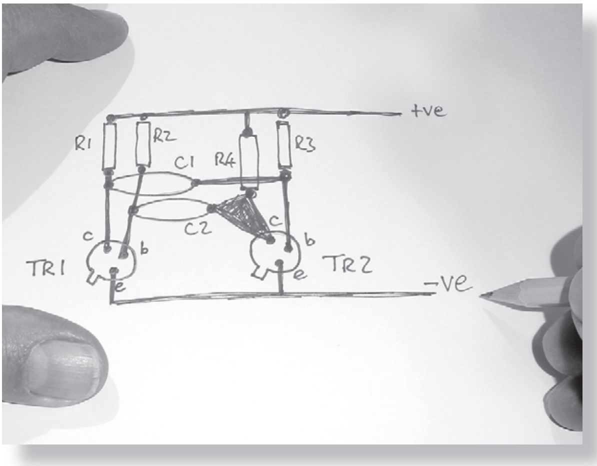

FIGURE 4.18 As the copper will be on the other side of the board to the components, there's nothing to stop you designing the printed circuit board so that copper tracks actually run beneath components.

Using the graph paper grid to align your components and connections accurately, redraw the layout on the tracing paper. This time, however, use two different colours of pencil, say, red for the component shapes and black for the connections. In this way you can instantly tell which is the 'top' and which is the 'bottom' of the board. The graph paper allows you to accurately get the sizes of components right, and position them as they will be on the final printed circuit board. Check, as you redraw the foil pattern, that it is correct with regard to the circuit diagram, and check you've remembered all components and got their polarities right.

And that's it! You've designed your own foil pattern.

You should now detach the tracing paper from the graph paper and keep it safely.

Pattern pending

This is the section which tells you how to transfer your pattern onto the copper-clad board, ready for etching.

As we saw before, the foil pattern must be put onto the board using etch-resistant materials. The form of this resist may be one of many: the simplest (and definitely the cheapest) can be ordinary household enamel or gloss paint, applied with a fine brush (messy); the most complex is photographic resist, developed on the circuit board much like your summer holiday piccies are developed on film and photographic paper (assuming you've not got a digital camera, of course). The one you use will depend on how much you're prepared to pay.

You can expect to pay about (gulp) £100 for a basic photographic system; this will let you make really ace printed circuit boards, but it won't do your pocket a lot of good — it's the sort of system which is likely to be used by schools and colleges where large numbers of one-off printed circuit boards are needed, so ask there first to see if they wouldn't mind you using theirs occasionally.

If you haven't got that sort of free cash around and can't find anyone willing to let you use their photographic system (ooh, the meanies) then you'll have to make do with a cheaper method.

Let's run through some of the methods now, so at least you know what the choice is.

Paint

The cheapest method of transferring your foil pattern onto the board is to use paint and a fine paint brush to hand-paint all the tracks and component holes. This is extremely messy, however, but will work quite well indeed, if a little care is taken.

A variant of this method is probably better though, where clear self-adhesive plastic has the image of the track pattern cut out of it (before the paper backing has been peeled off). The straight tracks can be cut out first, using a sharp craft knife and straight-edge, then the component holes can be punched out with a punching tool.

When the foil pattern is complete, you can peel off the paper backing and stick the plastic to the copper-clad board.

Now you effectively have a stencil, exactly the shape of your required foil pattern. There's no need to use a fine paint brush now; just paint over the whole plastic sheet with a much broader brush. After you've done that, carefully peel off the plastic and you're left with the foil pattern of painted resist.

Clever, eh?

Ink

Pens are available (ask at your local electronics store) which are loaded with special ink, resistant to the circuit board etchant.

With these pens it is quite an easy job (shown in Figure 4.19) to draw the foil pattern directly onto the copper-clad board. You won't make a perfectly neat printed circuit board using this method, but it does allow a quick and easy route to a semi-acceptable finished job. Final quality, however, depends totally on your artistic talent (or, at least, how steady your hand is!).

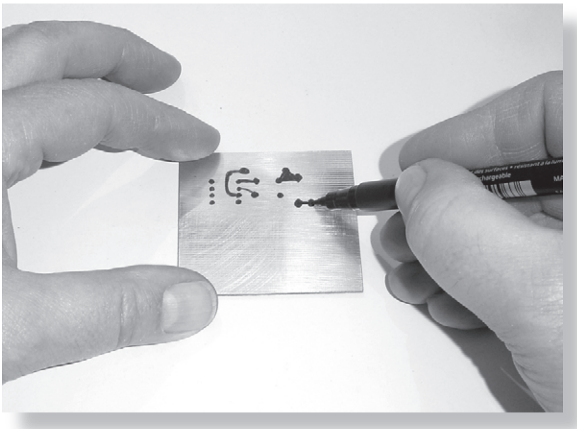

FIGURE 4.19 **Drawing copper foil pattern directly onto the copper surface of a copper-clad board using an etch-resistant ink pen.**

Hint:

In all these manual methods of applying resist it's sometimes a bit tricky to estimate where on the copper board the component leads go, before filling in the connecting etch-resistant bits. A useful trick is to put your tracing paper copy of the foil pattern upside-down onto the copper (the pencilled connections are to go on the bottom of the board, remember), and using a sharp pointed instrument such as a scriber or a compass point, prick through the tracing paper into the copper at every component hole location.

When you remove the tracing paper you will find a network of little holes, corresponding to each component lead hole.

Now you can put on the resist (whichever method you choose) knowing where the positions are.

Transfers

Probably the best method of printed circuit board manufacture for the amateur is shown in Figure 4.20, where you can see that rub-down transfers are being used as resist, for component holes. You can buy transfers for all kinds of shaped holes, too — for integrated circuits, or edge connectors, or even specially shaped ones for transistors.

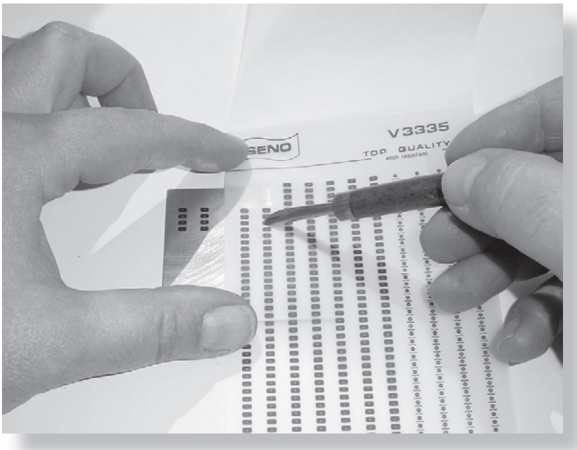

FIGURE 4.20 Rub-down transfers of all component shapes and sizes make an effective method of applying etch-resist.

When all the component locations are done, the connections can be made using straight-lined, or curved transfers, until the resist on the copper has the same shape as your foil pattern drawing.

Hint

A word of caution here: be extremely careful as you do this job, because any small cracks or breaks in the transfer resist will mean that a corresponding crack or break will occur in the copper when the board is etched.

▷ FYI ◁

You don't have to stick to just one manual method of resist application. It's perfectly possible to combine two or more of these methods to good effect. For instance, you can use rub-down transfers to apply the component lead positions (particularly useful for integrated circuit positions) but use a resist pen, or paintbrush and paint, to make the other connections.

Hint

If you make any mistakes at this stage they can be removed using the corner of a small piece of sticky tape – but once you have etched the board your mistakes are permanent.

One minor variant also in this method is to substitute reels of special, thin, self-adhesive tape for these straight-lined or curved rub-down transfers, as the tape can be stuck to the copper surface in either straight lines or formed quite easily around curves as you stick it down. For obvious reasons, this is often referred to as the 'dots-and-tape' method of making printed circuit boards.

Photographic method

Using the photographic method, the highest quality printed circuit boards can be made.

What's more, as it *is* a photographic method, you can make more than one printed circuit board from it (just as you can get reprints of your holiday snaps).

Firstly you need a full-sized master copy of the foil pattern, on film. There are two methods here: where the master copy is a negative (as from a camera film); or where it is a positive. Both methods are used in printed circuit board making, but the positive method is the most popular, for no other reason than because it's easier to make a positive master than a negative one, so we'll stick with that one.

Hint:

You can make a positive master from your foil pattern by laying a sheet of acrylic film (which you can get from drawing-office suppliers) over the tracing paper or magazine foil pattern.

Now, using the rub-down transfer or dots and tape method described earlier, make up the foil pattern directly onto the acrylic film. When complete, this film is your master copy – so keep it safe!

FYI

If your foil pattern is taken from a magazine or book, and you have a computer with a scanner and printer, you can make your master copy a little more accurately. Simply scan in the magazine foil pattern, then print it onto some acetate film. You'll need to check that the output size is the same as the source foil pattern and adjust as necessary. Note that some printers aren't capable of printing onto acetate film, however. Later there is more information about using computers to aid electronics construction.

Hint

If you are creating your own printed circuit board foil patterns for your own circuits, and you have a computer, then it might be worth looking at one or more of the many available programs for printed circuit layout. While these aren't always the easiest programs to use, they can give very good results, and if you intend making several printed circuit boards over the years, they are often worth the learning curve you have to climb. See later for details.

Resist-coated copper-clad board

The copper-clad circuit board you need now is not just ordinary board, but has a thin layer of *photographic resist* (sometimes shortened to *photo-resist*) over the copper, as illustrated in Figure 4.21, which — just like camera film — needs to be exposed to light. You can't just expose it to any old light, as you do with your camera film, though.

The only type of light which will affect the photo-resist is ultra-violet (UV) light.

Special light boxes (one is shown in Figure 4.22) are obtainable (it's these light boxes which cause this method to be expensive — they cost upwards of £80) in which the photo-resist coated board and the master foil pattern are placed, to expose the board, as illustrated in Figure 4.23.

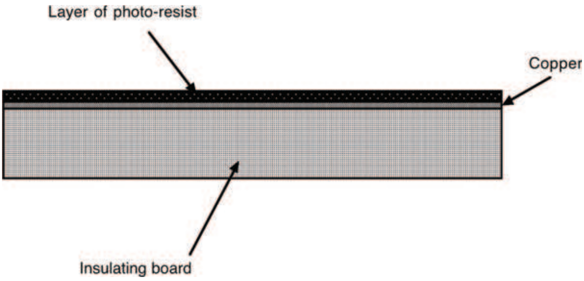

FIGURE 4.21 Photo-resist coated copper-clad board.

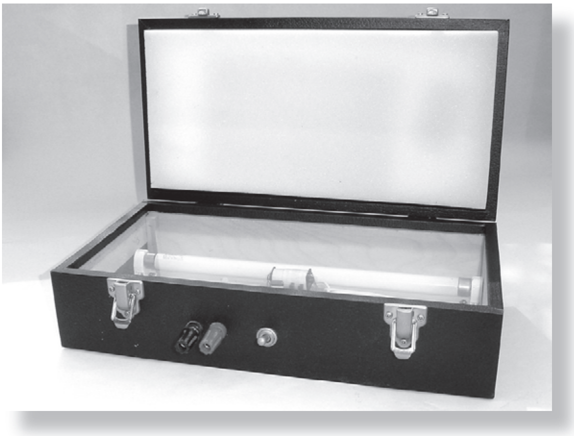

FIGURE 4.22 An ultra-violet light box.

FYI

UV light is harmful to the human eye, in quantity, so these light boxes typically have a lightproof seal, although the power of radiation emitted by the internal UV tubes is not high anyway.

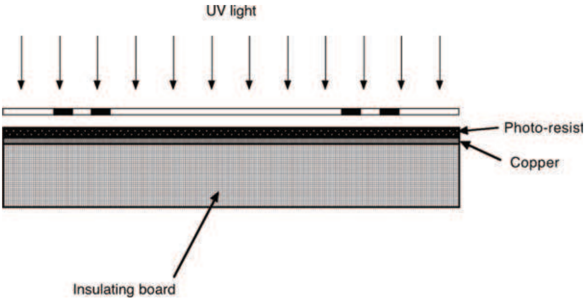

FIGURE 4.23 Exposing the photo-resist coated copper-clad board.

You must make sure that your foil pattern is the right way up here, because if it isn't your printed circuit board's track will be 'upside-down' or mirror-image, and the printed circuit board will be unusable!

After exposing the board through the master foil pattern, for the correct time (which depends on the strength of the UV tubes and the thickness of the layer of photo-resist, but is usually around five minutes or so), the board must now be developed.

The actual developing chemical depends on the photo-resist but is often a water solution of sodium hydroxide, and the exposed board is simply washed in a bath of it, as shown in Figure 4.24. As shown, the developing solution can easily be contained in a photographic-type developing tray, as it's not particularly hazardous.

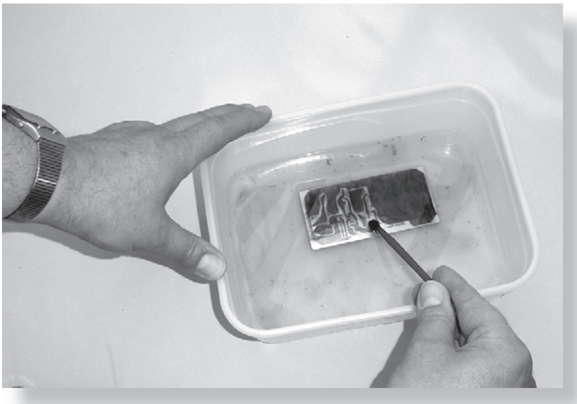

FIGURE 4.24 Developing an exposed, photo-resist coated, copper-clad board.

During development, the exposed areas of the board ie, the parts where no component holes or track connections were, soften and wash away. Meanwhile, the non-exposed areas corresponding to the foil pattern itself harden and remain in place, leaving the copper-clad board, complete with printed foil pattern.

Hint:

At this point in making a printed circuit board, it's always useful to check the foil pattern (which should be totally covered in etch-resist) to make sure that no breaks in coverage occur. If so, use a printed circuit board pen to patch broken areas.

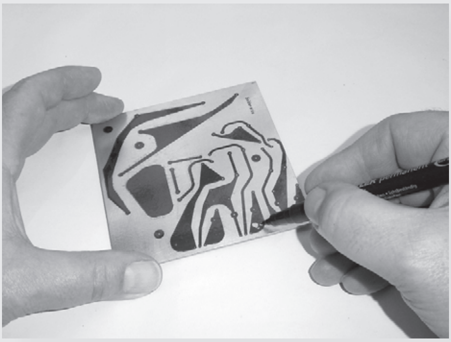

FIGURE 4.25 Touching up etch-resist with a printed circuit board pen.

If you wish to make more than one printed circuit board, you can use the acrylic film master foil pattern over and over again to expose other pieces of photo-resist coated board.

Using computers

The design of a printed circuit board copper foil track layout, and the later production of the printed circuit board from that copper foil are areas of electronics where accuracy is important. They are, indeed, almost sciences, rather than arts, although it can often help to have a steady hand.

As such, copper foil track layout is one particular area (there are others, some of which we'll see in this and other chapters) in electronics where computers can be put to good use, and there are several programs that can do this for us. Many of these programs form part of expensive industrial packages that take control of electronic device manufacture from initial marketing brief to late production stages. These packages are, needless to say, very expensive, and far more complex than we need to consider in this book.

On the other hand, there are several programs that are considerably cheaper than this, and even some that cost nothing at all to individuals.

Figure 4.26 shows a program called Crocodile Technology, which is an electronics simulator that allows us to build theoretical electronic circuits up on computer screen, testing them for function as required.

FIGURE 4.26 Crocodile Technology – an electronics simulator (available for Windows and Mac OS) that allows us to develop and construct circuits, on computer screen (Crocodile Clips).

By itself, Crocodile Technology doesn't aid us in producing copper foil track layouts for a printed circuit board, until it is used with a sister computer program called realPCB, which does just that — producing printed circuit board copper foil track layouts from the simulated circuits within Crocodile Technology. Figure 4.27 shows a portion of a printed circuit board layout produced using realPCB.

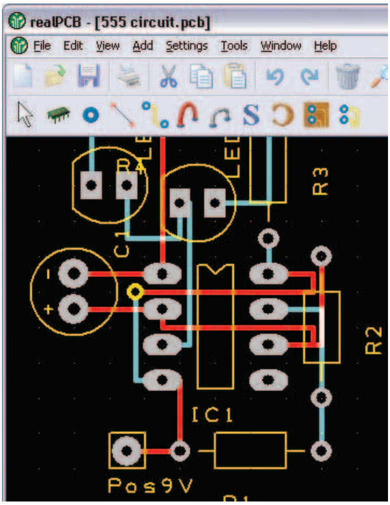

Figure 4.27 Part of a printed circuit board layout created using realPCB (Crocodile Clips).

While Crocodile Technology is available for Mac OS computer users, realPCB isn't available in Mac OS format. However, there are many alternatives for Mac users, one of which — Osmond — is a free program ideally suited for printed circuit board copper foil track layout.

Figure 4.28 shows a printed circuit board produced using Osmond — actually, the Bench Power Supply project's printed circuit board, in Chapter 8.

Programs such as realPCB and Osmond feature libraries of components, so that creating a printed circuit board layout is really just a matter of defining which components you want to use, then effectively joining the dots.

FIGURE 4.28 The Bench Power Supply copper foil track layout (see Chapter 8 for project details), produced using Osmond.

From screen to board

Producing a copper foil track layout on computer is one thing — but using that layout to make the actual printed circuit board is another! However, it is another area where computers can be helpful. As the computer can output to a printer, and as any printed circuit board layout program worth its salt can print its design, there are several ways that the computer can help us transfer the layout design onto the copper of copper-clad board, ready for etching.

Photographically

If you intend to use the photographic method detailed earlier, then it's a relatively simple process of printing the computerized copper foil track layout to film, ready for combination of the film with photographic resist-coated printed circuit board and an ultra-violet light box.

Purpose-produced translucent acetate sheet films are available for both laser and ink-jet printers (LaserStar for laser printers, JetStar for ink-jet printers). Figure 4.29 shows such a film that has been printed directly from a computer to a laser printer.

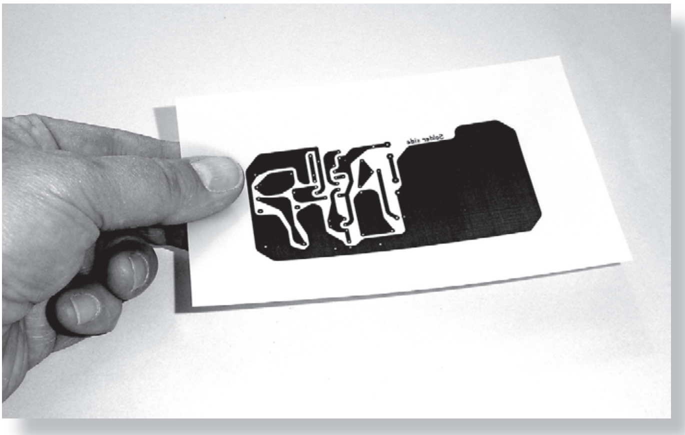

Figure 4.29 A printed circuit board design printed using a laser printer, on LaserStar translucent acetate sheet. JetStar sheets are used with ink-jet printers.

These translucent sheets are transparent to ultra-violet light (so are ideal for the purpose of ultra-violet light box exposure), but allow solid and dense areas representing the copper foil. Figure 4.30 shows the printed circuit board design of Figure 4.29 being used with an ultra-violet light box and photographic resist-coated printed circuit board.

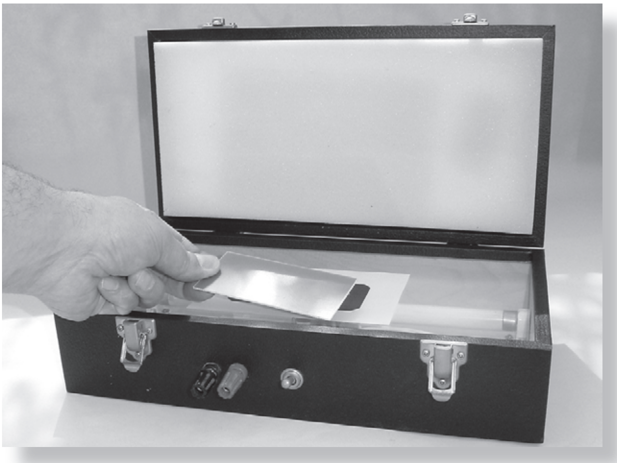

Figure 4.30 Placing the LaserStar film and photographic resist-coated printed circuit board into an ultra-violet light box, ready for exposure.

Printed circuit boards of the highest quality can be made using this method, direct from a computer.

Non-photographically

If you don't have access to the ultra-violet light box photographic method of making printed circuit boards, there is an excellent alternative. Like the photographic method, it comes in the form of a specially-formulated acetate film that can be used with a printer (there is, though, only one type, that must be used only with a laser printer — it will not work with an ink-jet printer). The method is called Press-n-Peel, for reasons which will become clear.

The system is very easy to use, albeit a little tricky, and may take a few practice runs to get right.

First, print the printed circuit board copper foil track layout design, from whichever computer program you use, onto a Press-n-Peel sheet in a laser printer. Next, invert the sheet and place it onto the copper side of a piece of ordinary (ie, non photographic resist-coated) copper-clad printed circuit board, as shown in Figure 4.31.

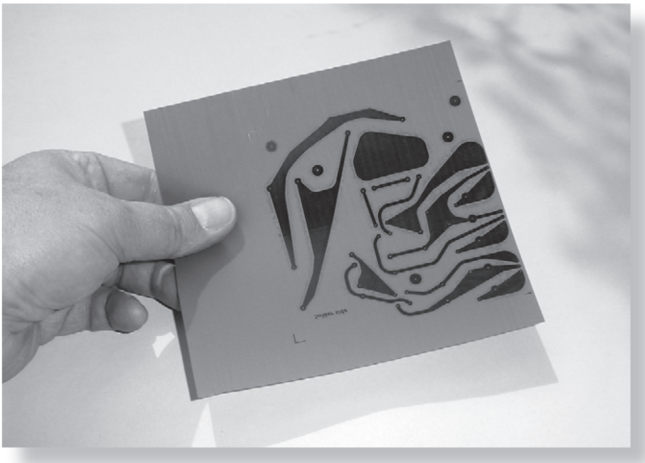

FIGURE 4.31 Lay the Press-n-Peel sheet over the plain copper surface of the copper-clad board.

Next, lay a piece of plain paper over the top. Using a hot iron, press onto the paper to transfer the copper foil track layout image from the Press-n-Peel sheet onto the printed circuit board copper surface, as shown in Figure 4.32.

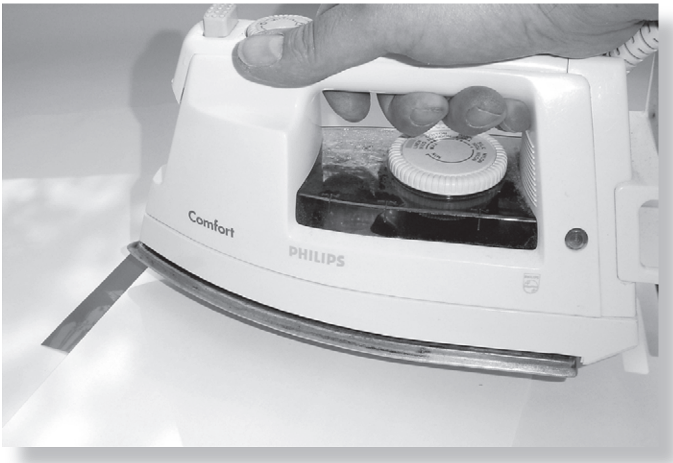

FIGURE 4.32 Using an iron to transfer the image from a printed Press-n-Peel sheet onto the copper surface of plain copper-clad printed circuit board.

The iron must be hot (275–325°F) and you must keep it moving at all times to prevent the sheet melting.

After a short while, remove the iron and paper, then cool the printed circuit board and Press-n-Peel sheet under running, cold water. When the board is cold, peel off the Press-n-Peel sheet (Figure 4.33).

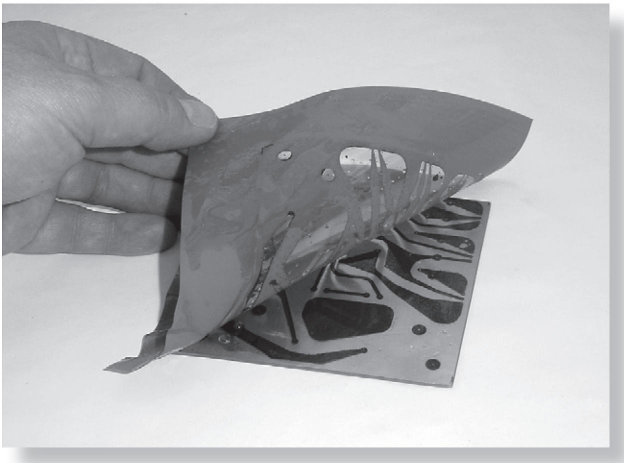

FIGURE 4.33 Peeling off the Press-n-Peel sheet, following ironing and cooling.

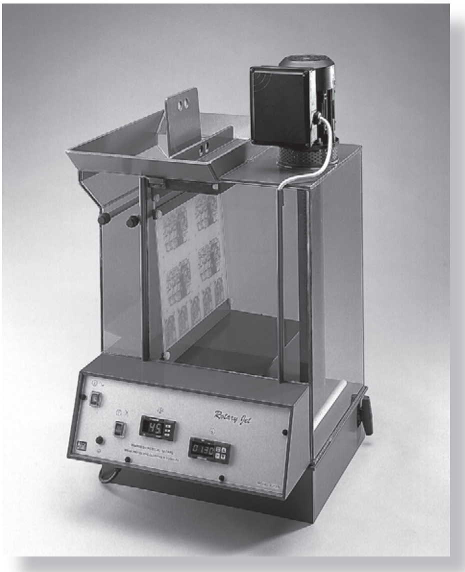
Come up and see my etchings...

Finally, it only remains (did that man say *only?*) to etch the board and it's then ready for drilling and component insertion.

The etchant used to etch printed circuit boards is not actually an acid as you might expect, but ferric chloride — a horribly messy fluid — but it does its job well. Most local electronic stores will sell it bagged as crystals or granules and you simply mix them with water to give an etchant solution. A note of caution before you touch this stuff however: it is a very dangerous fluid and a strong solution of it will merrily eat its way through your clothes, the carpet, or even the stainless steel kitchen sink. So, please be careful and don't say I didn't warn you.

The etching process takes place more rapidly when the ferric chloride solution is warm and constantly moving, and for this reason you can buy specially built containers called *etching baths* to hold the solution. These etching baths are fitted with heaters to maintain a high temperature, and with agitators to keep the solution moving (vital to stop the build-up of copper oxide on the surface of the copper, which prevents further etching). Some top-of-the-range etching baths use a spray technique to maintain a high level of agitation — an etching machine of this type (which can actually be used with developer, too) is shown in Figure 4.34.



FYI

While historically ferric chloride has always been the etchant of choice in printed circuit board making, there are alternatives. While being somewhat less corrosive and nasty to use, these alternatives do tend to be a lot more expensive than ferric chloride however.

FIGURE 4.34 **The Rota-Spray etching/developing machine (Mega Electronics UK).**

After etching a number of printed circuit boards, the etchant will become exhausted and require renewal. You will notice this as a gradual increase in the time it takes to etch. When new, etchant may take only five or six minutes to etch a printed circuit board (particularly if the etchant is heated), whereas at the end of its working life etchant may take twenty minutes or more to do the job. The number of printed circuit boards a batch of etchant will successfully etch depends on the size of the printed circuit board and the area of copper foil to be etched, but you should realistically expect to be able to etch twenty or more printed circuit boards per batch.

Hint

Etching baths complete with heaters and agitators are (you guessed it!) expensive, but there's nothing to stop an enterprising reader making one, from nothing more complicated than a plastic container, aquarium heater, and a toy motor with plastic propellor. Just make sure that nothing metal is inserted into the etchant – for obvious reasons!

At the other end of the scale, a plastic photographic-type developing tray or similar can be adequately used as a makeshift etching bath, to hold the ferric chloride during etching, as shown in Figure 4.35. But as you'll have to keep rocking the bath gently, to agitate the etchant over the printed circuit board, this method is fraught with hazards — it's all too easy to splash some of the etchant.

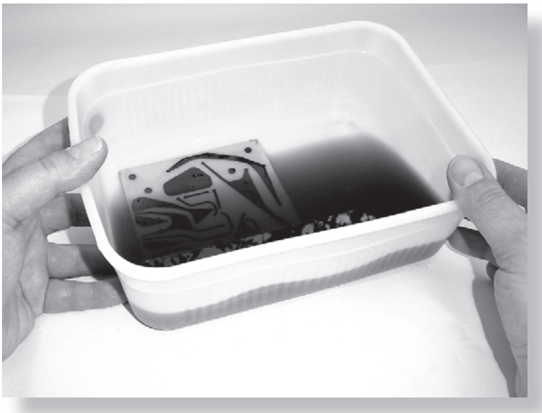


FIGURE 4.35 A makeshift etchant bath – an old ice-cream container, in which the etchant is manually agitated by rocking the tray gently. A good excuse to have some ice-cream!

However you choose to do this job, it's wise to wear old clothes or overalls, and do the job outside, or at least in an uncarpeted workshop. Also, wear rubber gloves because it can do some pretty ghastly things to fingers — it'll certainly stop anyone's nail-biting problem, as it'll leave no nails at all to bite!

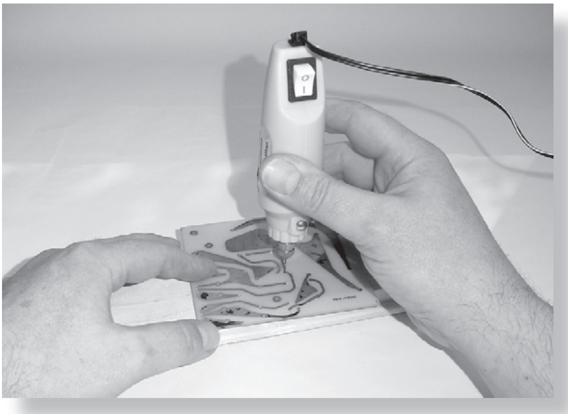
After etching, wash the board thoroughly in water to get rid of all traces of the etchant. Also, make sure that any etching solution has been either washed away or properly returned to its lidded container, and is not left where anyone (or even your cat, for that matter) can accidentally spill it.

Drilling for oil

Now is the point where all the component holes in the printed circuit board should be drilled so that components can be inserted and soldered. You can do this with a hand drill, or even a standard electric drill, but neither of these are particularly accurate and so may be the cause of irregular or misshapen holes.

A far better type of drill is the hand-held electric rotary tool commonly found in DIY and hardware stores. Being of quite high speed and easy to use they can make an excellent job.

Follow standard drilling practice when drilling a printed circuit board — put a block of wood under the printed circuit board as shown in Figure 4.36, so that you drill through the printed circuit board into the wood. This helps prevent the drill tip breaking roughly through the printed circuit board, and also helps prevent any damage to the worksurface.



FYI

Make sure the drill bit (of whatever size you use) is perfectly sharp. A blunt drill increases drilling time, overworks your hand-held drill, and creates holes with burrs.

Figure 4.36 Hand-drilling a printed circuit board – rest the printed circuit board to be drilled on a block of wood. Hold the drill upright.

Irresistible

At this point, the etched and drilled board still has a coating of resist over the copper tracks of the foil pattern. Depending on your method of making the printed circuit board, you need to remove this resist prior to inserting the components and soldering. Resist removal can be done chemically using a solvent as shown in Figure 4.37.

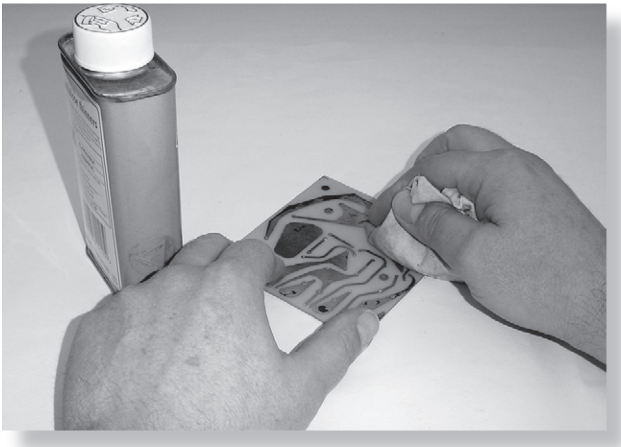


FIGURE 4.37 Removing etch-resist with a chemical.

Hint:

Some types of photo-resist coated boards actually allow soldering direct to the resist – in fact, the resist acts as a solder flux. If the resist-coated board you buy has such a resist, there is no requirement – other than personal preference – to remove it.

Such solvents are not cheap, so you can choose to remove the resist mechanically using an abrasive removal block (Figure 4.38) which you rub over the copper track to take off the resist. An alternative to a removal block is the fibreglass propelling pencil-type of abrasive cleaner, shown in Figure 4.39.

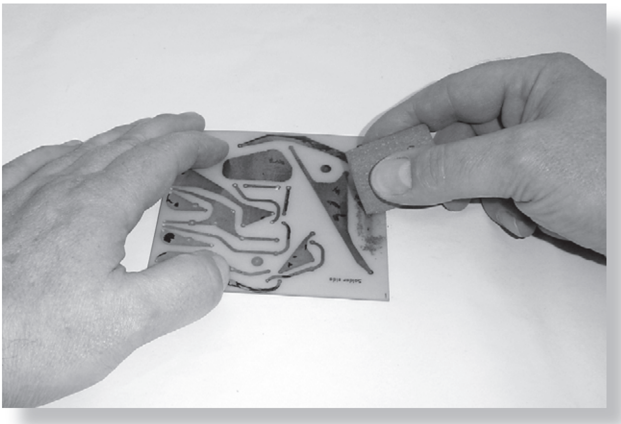

FIGURE 4.38 Removing resist using an abrasive block.

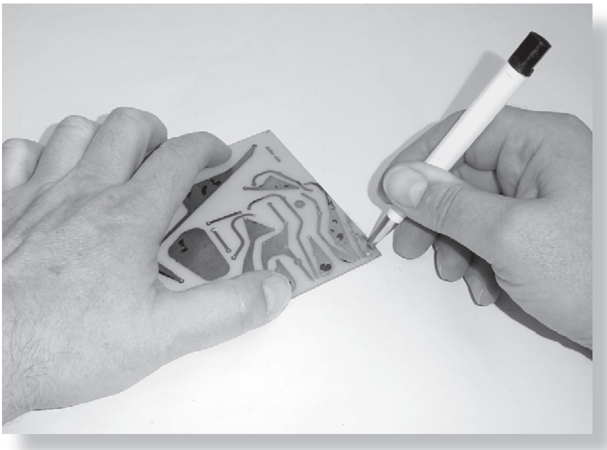

FIGURE 4.39 An abrasive cleaner in the form of a fibreglass propelling pencil-type of holder can also be used to remove resist.

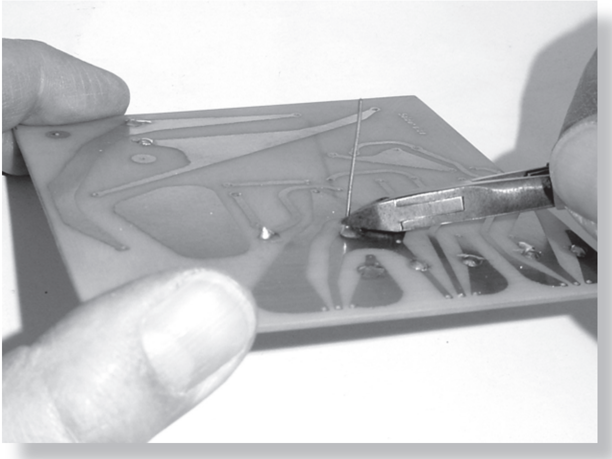
Component insertion

As a rule of thumb, components should be inserted and soldered according to whether they can be damaged by heat. So, passive components like resistors and capacitors should be inserted and soldered first, leaving active components like integrated circuits until later.

Insert and solder only a few components at a time — no more than three or four at once for example. This means that components are less likely to slip out of their positions before solder is applied.

Once soldered into positions, trim all leads close to the soldered joint as shown in Figure 4.40. This prevents short circuits occurring between component leads.



FYI

The process of inserting components into a printed circuit board is often — particularly in industrial electronics manufacturing — called (for fairly obvious reasons) stuffing.

FIGURE 4.40 Trim all component leads down after soldering. Use your side-cutters for this task.

Soldering

Soldering of components into a printed circuit board is actually quite an easy job, but there *is* a bit of a technique to it, and you need to be aware of the problems that incorrect soldering can create. Chapter 5 covers soldering in depth.

5

Soldering

The single most important process in electronics is soldering. It is — quite literally — the glue that holds all other processes together.

Soldering is the main means of:

- **HOLDING components in their positions on the printed circuit board**
- **CONNECTING components to other components in the circuit.**

What is solder?

Solder is a metallic compound which possesses a relatively low melting point. It has been used to join metals for thousands of years, since Roman times at least. Historically, one of the main constituents of solder has been lead. Indeed, the Latin name of lead — *plumbum* — gives a clue to one of solder's main uses, in plumbing, to join water pipes and fitments.

In electronics, solder's main use is to join component leads to printed circuit boards, in what is called a *soldered joint* — occurring between the component lead and the copper foil track of the printed circuit board. The copper foil track in turn allows that soldered joint to connect to other soldered joints (also formed by other component leads and the copper track), so that the complete electronic circuit can be made up on the printed circuit board. As a by-product, the rigidity of the soldered joints making up the circuit means that all components are also held securely in place.

The components of solder

Except in its very earliest uses, when pure lead was used, solder has always been a mixture of two or more substances. The Romans are known to have used a tin/lead alloy to joint lead water pipes. This is mainly because a tin/lead alloy has a lower melting point than lead itself. For example, pure lead has a melting point of 327°C, whereas an alloy of 62% tin and 38% lead has a melting point of 183°C — so it's possible to joint lead pipes, without actually melting the pipes themselves.

As soldering has evolved, and the uses to which it is put have changed, different solder alloys have been created for different purposes. In fact, soldering is still evolving — and is actually in the middle of quite a large evolutionary step — as we shall see here.

The 62% tin/38% lead solder alloy mentioned already, is known as the *eutectic composition*, and the melting point of 183°C (the *lowest* melting point of any tin/lead solder alloy) is correspondingly known as the *eutectic point*. It's not hard to understand that — purely in terms of soldering component leads to printed circuit board copper foil tracks in electronics — this has inevitably been viewed historically as a very useful, if not the ideal solder alloy.

However, times are changing. For a start, the world's resource of tin is depleting rapidly — only around 50 years' worth at current usage rates is left! More important though, is that lead is not exactly viewed as a safe substance, being a toxic, poisonous metal. For this toxicity reason, the world's electronics industry — along with other industries that currently use lead — is undergoing a revolution at present, to completely and permanently eliminate the use of lead in any of its processes and components.

Several new solder alloys have been developed to replace the old tin/lead alloys, in which various other elements — silver, bismuth, zinc, copper — have all been used with tin to form these new *lead-free* solder alloys.

While being inherently safer to both us *and* the environment, these lead-free solders all have a major disadvantage practically over the old tin/lead alloys in that the new alloys have higher melting points (around 30–40° higher!). This means that their very use may harm the electronic components being soldered, and they can be more difficult to use in general. Nevertheless, the electronics industry aims to be lead-free by 2006.

Effects of lead-free solder on us

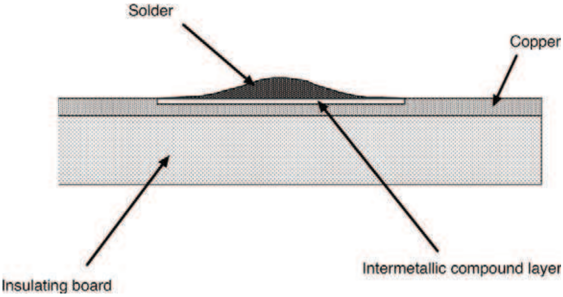
The use of lead-free solder is mirrored in the non-industrial areas of electronics that readers of this book will be most interested in — in the home, school, college or university. Already lead-free solders are available off-the-shelf for personal use, and we can expect that tin/lead solders will be unavailable very much sooner rather than a little later.

The good soldered joint

Whatever the actual solder alloy used, the principles of making a soldered joint are the same. Solder is applied to a heated area of metal, whereupon the solder alloy melts and *wets* the metal to form a joint. Note that the term *wet* is used, and in some respects means much the same as a liquid such as water wetting a surface — it flows over the surface.

Wetting in soldering terms, on the other hand — unlike water wetting a surface — is a process where the solder comes into direct metallic contact with the metals to be soldered together into the joint. At the junction between the solder and the metal, a specific compound of both the solder and the metal is formed — known as an *intermetallic compound* — and occurs in a very thin layer between the two. Sometimes, the bond at that point is called the *intermetallic bond*. Interestingly, once this intermetallic compound between solder and metal has been created, it cannot be removed — you cannot remove solder from metal once it has been wetted!

Figure 5.1 shows a cross-section of a soldered joint, illustrating the main details. Figure 5.2 shows a micro-section of an actual soldered joint, in which can be seen the solder, the metal — copper — and the intermetallic compound layer between the two.



FYI

Note that we are talking about soldering joints with copper. Don't even think about trying to solder to aluminium — it just won't work — if you need to make an electrical connection to aluminium, do it with a nut and bolt!

FIGURE 5.1 Wetting takes place when solder comes into intimate contact with the surface metal, to form an intermetallic compound at the junction between solder and metal.

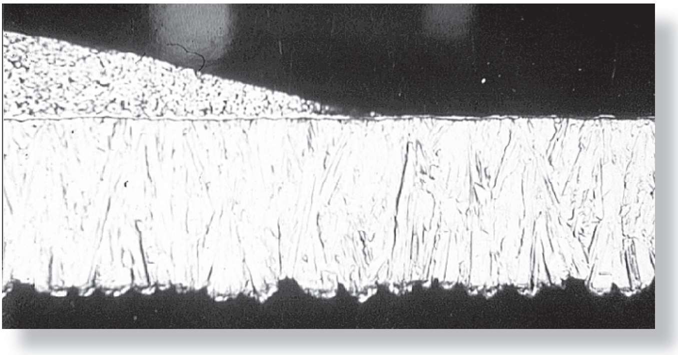


FIGURE 5.2 Micro-section through an actual soldered joint, where the intermetallic compound layer between solder on top and copper beneath is clearly visible.

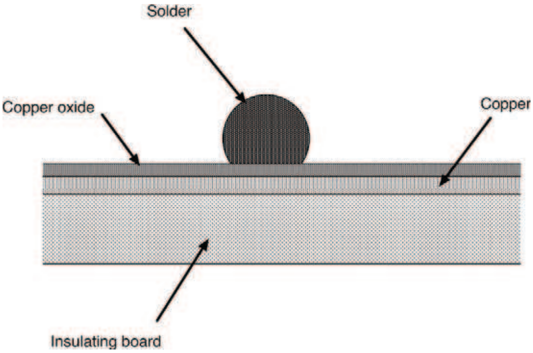
The bad soldered joint

The condition for a good soldered joint to take place — illustrated previously in Figure 5.1 and shown photographically in Figure 5.2 — is that solder comes into contact with metal to wet it. Anything that *prevents* solder from coming into contact with metal, therefore, can work to prevent a good soldered joint from taking place.

The converse of the good soldered joint is one where the solder does not wet the joint, so does not come into contact with the metal. Such a bad soldered joint is shown in Figure 5.3.



▷ FYI ◁

Many conditions can occur that create a bad soldered joint, and there are many types of bad soldered joints, so it is not always easy to specify exactly what has gone wrong in the soldering process. However, the usual problem is that the metal surface is not clean. Any number of contaminants may prevent a good soldered joint from taking place — dirt, grease, metal oxide, being the main ones.

FIGURE 5.3 A bad soldered joint – where a layer of metal oxide on the surface of the metal has prevented wetting of the solder to the metal taking place.

In practice, there are several levels of wetting which do not make a good joint, and these are worth considering as they give a clue as to the problems that we can experience in soldering electronic circuits.

All the various levels of wetting are described underneath, and Figure 5.4 shows the main levels by way of visual comparison.

- **NON-WETTING.** Pretty obvious to the eye — solder does not flow on to the metal at all. It will not adhere to the printed circuit board's copper foil track at all. A circuit built with no-wet joints will probably not work at all
- **PARTIAL WETTING.** While not flowing and completely wetting the metal surface, a partially wet joint will appear to be solid. However, it is unreliable, and may easily break off with time or vibration. Interestingly, the circuit itself may work initially when partially wet joints are present, but may not work for more than a short time
- **DE-WETTING.** Such joints may appear to have been created properly, but in the cooling phase after heat has been removed, the solder retracts — often leaving small solder balls around the joint. As in partial wetting, the joint may initially cause a circuit to work, but will break down fairly quickly
- **TOTAL WETTING.** Gives good joints, of course, which will create circuits that work and continue to do so. Note the difference between totally wet joints, and all the other wetting variants. A totally wet joint is concave in appearance (and will actually be quite shiny to the naked eye). All other wetting variants of joints will be convex (if not rounded) and may be dull in appearance to the naked eye.

Hint:

As you can see here, one of the main causes (if not the main cause) of faults in electronic circuits, is bad soldering. Therefore, it makes sense to be able to solder well. Practise it before you attempt to build an electronic circuit till you are able to make good joints every time. Don't bother using printed circuit boards for this, instead use a few bits of stripboard (see page 81 for details) – even just a couple of boards give you many holes and copper strips to practise with. By the time you've soldered a couple of handfuls of components and a few short lengths of lead to the stripboards, you'll be a past master at the art of soldering!

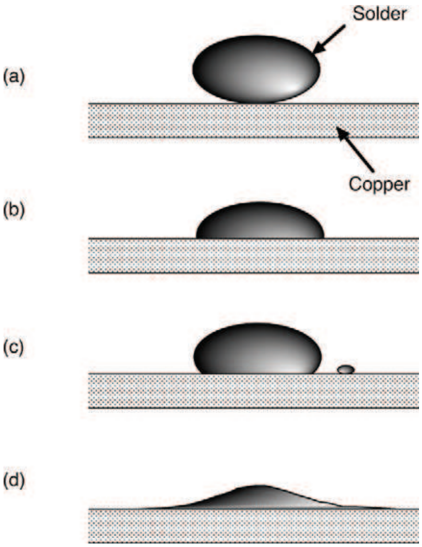


FIGURE 5.4 Four extremes of soldered joint: (a) non-wetting; (b) partial wetting; (c) de-wetting; (d) total wetting.

Flux

As we've seen, it's essential that the metal to be soldered is clean. The problem is that copper, the metal used to make copper-clad printed circuit boards that we use in electronics, oxidizes. A minutely thin surface layer of copper oxide forms on top of the copper-clad layer of the printed circuit board that makes up the copper foil track pattern very rapidly. So no matter how we clean the copper surface, the oxide layer builds up before we can get a soldering iron to it. And copper oxide cannot be soldered!

Further, every time a printed circuit board is handled it picks up dirt and grease, both of which work to prevent solder from wetting the board's copper track.

The key to making sure that the copper is returned to pristine condition in order that solder can wet it is a substance called *flux*.

Fluxes are chemically active — that is, they work on the surface contaminants (copper oxide, dirt, grease) on the copper track of the printed circuit board to dissolve them. This occurs when the copper is heated by a soldering iron, in the first stage of the soldering process. Once the copper surface is clean, solder can be applied.

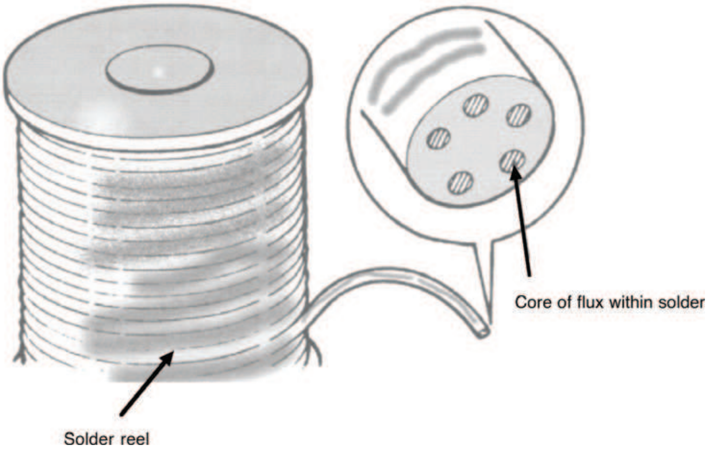
▷ FYI ◁

There are many types of flux, judged usually by the level of chemical activity they have. Generally, the fluxes used in the solder used for hand soldering are of low activity. They are typically made by distilling the sap (or resin) from pine trees. The residue is then dissolved in a solvent, making it easier to apply.

At first sight, it might seem that co-ordinating all this (heating the copper, applying the flux, waiting till the copper is clean, applying the solder) is a tricky matter, best left to the professionals and their industrial soldering processes. However, the *real* trick is that it can all be done by hand in a single smooth process by anyone, as long as a few simple steps are followed.

Key to the whole process is that modern solder, used to solder printed circuit boards by hand, already contains the flux needed to clean each joint to be soldered.

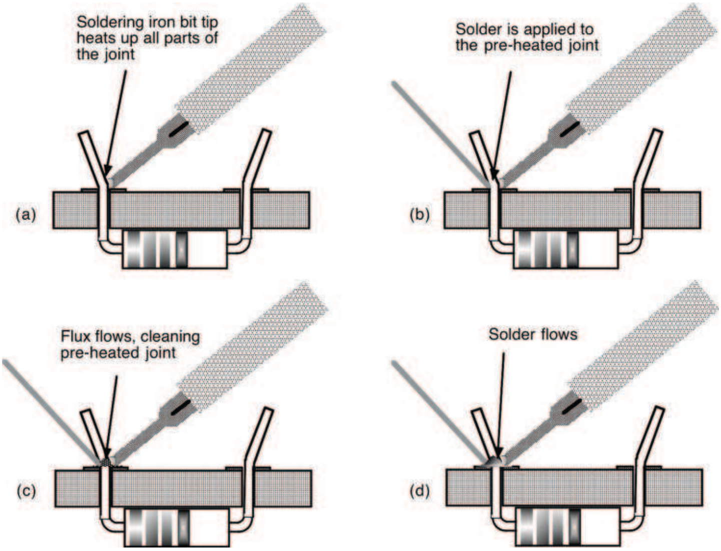
The solder used has cores (usually four or six) throughout its length which are filled with flux — as illustrated in Figure 5.5. Diameter of the whole flux-cored solder lead is usually around 1 to 2 mm.



Core of flux within solder
Solder reel

FIGURE 5.5 **Cored solder, obtained in reels, appearing much like thin flexible wire. Flux is present in cores within the solder.**

So how does it work? After all, having the flux inside the solder like this means that the flux is presented to the joint to be soldered at the same time as the solder is, rather than before it — which would suggest it has no time to clean the joint. However, the flux has a much lower melting point than the solder has, so the flux melts and flows onto the joint first. It therefore has the time to coat the metal surfaces of the joint and clean them, before the solder melts and flows over the joint to make the soldered joint, as shown in Figure 5.6.



Soldering iron bit tip heats up all parts of the joint
Solder is applied to the pre-heated joint
(a)
(b)
Flux flows, cleaning pre-heated joint
Solder flows
(c)
(d)

FIGURE 5.6 The main stages of hand soldering a joint: (a) the soldering iron is applied to the joint, to heat it; (b) while maintaining the soldering iron's position, cored solder is applied to the joint; (c) flux melts quickly and flows from the cored solder onto the joint's metal surfaces, to clean them and protect them; (d) the solder melts, and flows over the joint's metal surfaces.

FYI

This whole process, from first applying the soldering iron to the solder flowing over the joint surfaces, takes only a few seconds (depending mainly on the size of the joint and how powerful the soldering iron is). If a joint takes longer than just a few seconds to make, there's a good chance the soldering iron isn't powerful enough.

Take Note

Throughout this chapter we look at processes involved in soldering various joints on printed circuit boards (ie, those circuit boards made from copper-clad board, with copper foil tracks). The processes – however – are actually identical whatever sort of circuit boards you use.

Key points when soldering

Being able to use a soldering iron isn't the only thing you need to know when soldering. The whole process depends on several aspects:

When soldering

- **CLEAN** all parts — copper printed circuit board track, component leads, soldering iron bit — *before* soldering
- **MAKE** a reliable mechanical joint — *before* soldering
- **HEAT** the joint sufficiently — *before* applying solder
- **APPLY** the solder — keeping the soldering iron on the joint while the solder melts
- **REMOVE** the soldering iron and allow the solder to solidify — *before* handling or moving the joint
- **TRIM** the excess component lead from the joint, once the joint has solidified and cooled sufficiently to allow handling.

We should now consider these six aspects in detail.

Cleaning all parts

We already know that flux is used automatically when soldering using cored solder to help clean the joint surfaces, as part of the soldering process. However, flux can only remove so much oxide, grease or dirt. It's best to improve your chances of making a good solder joint by manually cleaning the joint surfaces first. Use an abrasive fibreglass pencil (as shown in Figure 5.7), or an abrasive scrubbing block (as shown in Figure 5.8), rubbing them over both copper track and component leads to minimize dirt and grease.

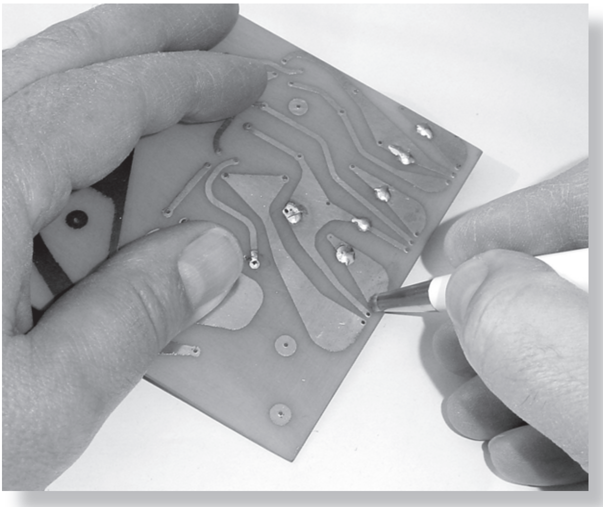


Figure 5.7 Cleaning copper track of a printed circuit board, using an abrasive fibreglass pencil – simply rub the pencil over the track, particularly over the component land areas to clean it. Brush aside the fibreglass residues before commencing soldering.

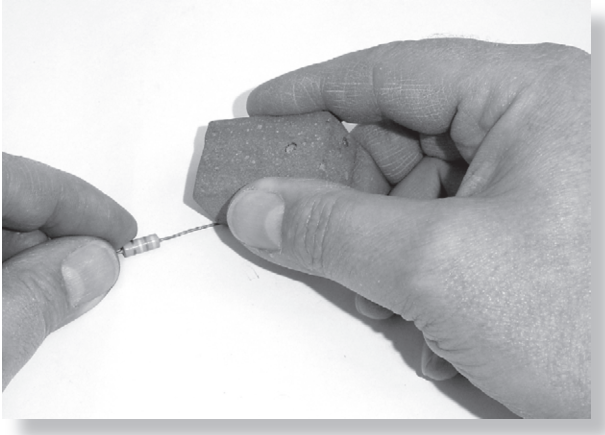

Figure 5.8 Using an abrasive scrubbing block to make sure a component's leads are clean, prior to soldering.

It's vitally important that the soldering iron bit tip be kept clean too, and the best way to do this is to *tin* it. Tinning is a process whereby fresh solder is regularly melted on to the heated bit tip, so that the tip remains coated with fresh solder. As flux-cored solder should be used, just as when soldering the actual joint, the flux within the cores cleans the tip simultaneously.

The process is a two-stage one: first wipe old excess solder off the soldering iron bit tip, then tin the tip by applying fresh solder. Figure 5.9 shows a wet sponge being used to wipe the soldering iron bit tip on. An alternative is shown in Figure 5.10, where a tip cleaning and tinning block is being used.

Hint

If you have bought yourself a new soldering iron and are preparing to tin it, you will find that when you first plug the soldering in to turn it on, smoke will be created and given off from the bit tip: this is because the bit is coated with a grease substance to prevent it oxidizing. This is useful, but also means that as the bit heats and burns off the grease, oxide very quickly forms, making the tip unusable. To prevent this, tin the bit tip as shown in Figure 5.11 immediately as it heats.

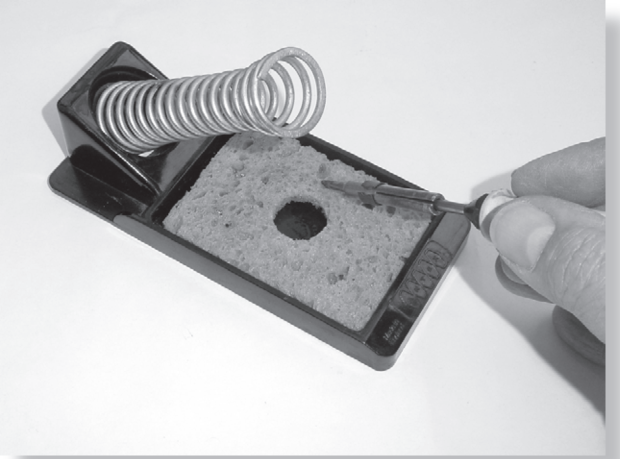

FIGURE 5.9 *Cleaning a soldering iron bit tip using a wet sponge. Simply wipe the tip over the sponge surface.*

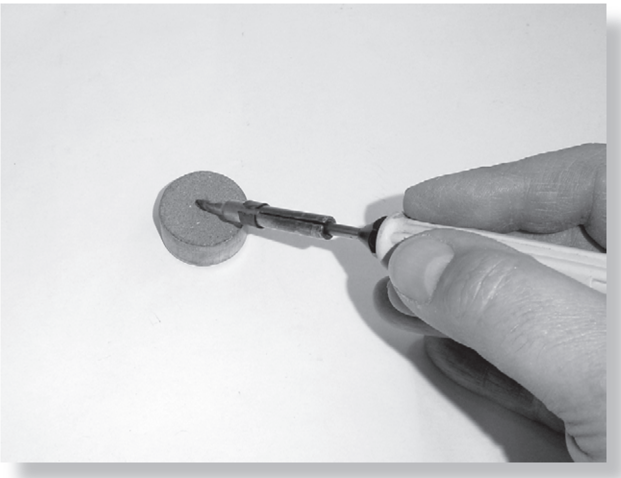

Figure 5.10 Using a tip cleaning and tinning block to clean a soldering iron bit tip – just wipe the tip over the block.

Immediately following removal of old excess solder, apply fresh solder to the soldering iron bit tip, as shown in Figure 5.11. Just a small amount of solder is all that's necessary to keep the tip in err... tip-top condition.

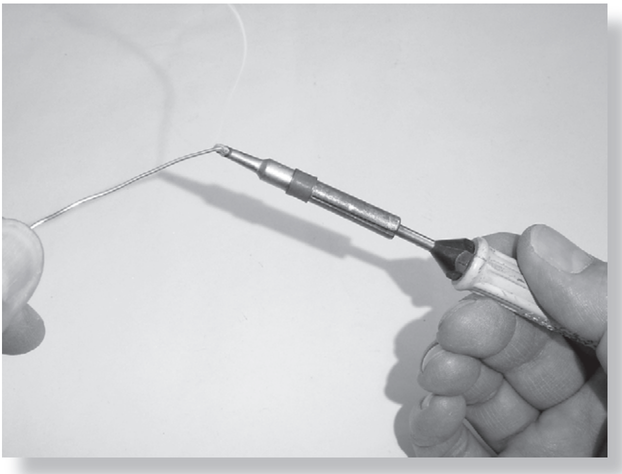

Figure 5.11 Tinning a soldering iron bit tip. Once the soldering iron bit tip has been cleaned as shown in either Figure 5.9 or Figure 5.10, quickly tin it using a small amount of ordinary flux-cored solder. The tip will have a shiny appearance if tinned properly.

Hint

Get into the habit of tinning the soldering iron bit tip every few minutes while it is on, to maintain it in peak condition and ready to solder joints.

Making a reliable joint

Components must not move while you are soldering a joint, otherwise the joint may be faulty. As a general rule, it's best to fix the components in place mechanically somehow before soldering. With axial- or radial-leaded components such as resistors and capacitors, the easiest way to do this is to bend the leads slightly after insertion into the printed circuit board, as shown in Figure 5.12. As a guide, the angle of the bend doesn't need to be (and *shouldn't* be) any more than just a few degrees — bend the leads only as far as necessary to hold the component in place.

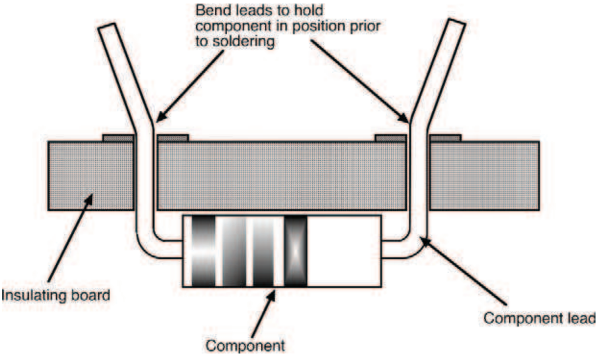

FIGURE 5.12 After inserting a component into the printed circuit board, bend its leads slightly to hold it in place ready for soldering.

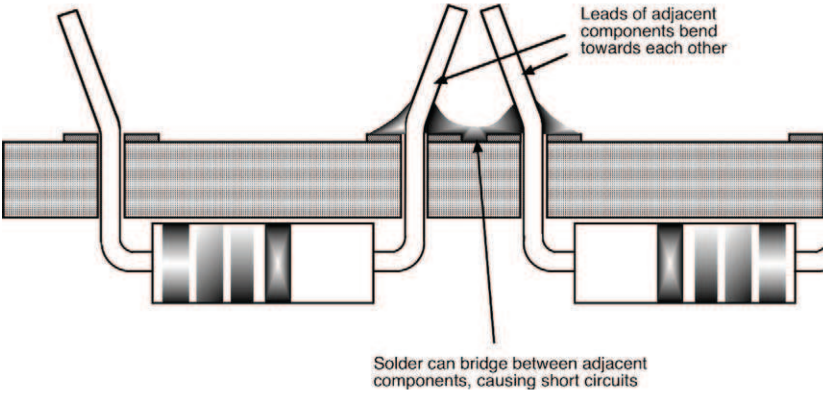
Take Note

If you insert more than one component into a printed circuit board at a time before soldering, and bend their leads outwards to prevent them falling out, be careful that when you solder their joints solder doesn't bridge between them, as shown in Figure 5.13. When angled leads like this are soldered, the joint contains much more solder than a lead which is perpendicular to the printed circuit board.



Leads of adjacent components bend towards each other
Solder can bridge between adjacent components, causing short circuits

FIGURE 5.13 Showing how solder can easily bridge between joints if angled component leads are used to hold components in place prior to soldering – take care when using this method to prevent such short circuits.

Heat the joint

For successful soldering, the metals to form the soldered joint should be pre-heated. Pre-heating is easily accomplished — apply the soldering iron bit tip to the joint — touching both the copper track and the component lead, as shown in Figure 5.14. The time you should pre-heat the joint depends on the size of metal to be heated and the power of the soldering iron, but generally this will be for no more than a few seconds — between about two and eight seconds, say. You will learn to judge the pre-heat time required by joints with practice, but in any case it's not normally *that* crucial.

The factors you should bear in mind are that:

- **IF you don't pre-heat the joint sufficiently, the molten solder cools too quickly and you run the risk of making a defective joint**
- **IF you pre-heat the joint too much, you may damage the component and may even cause the copper track to lift from the printed circuit board.**

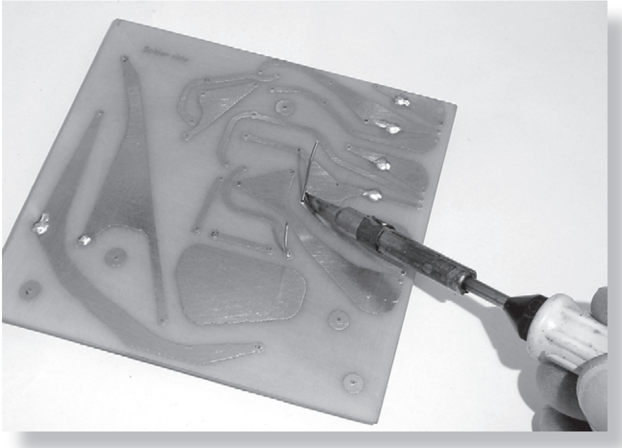


FIGURE 5.14 Pre-heating the joint to be soldered – apply the soldering iron bit tip to the joint's metal surfaces.

Apply the solder

With the soldering iron bit tip in position, apply the end of the flux-cored solder to the joint — touching it to both the joint and the soldering iron bit tip. If everything is as expected, the solder will melt and flow around the joint. Figure 5.15 shows this stage.

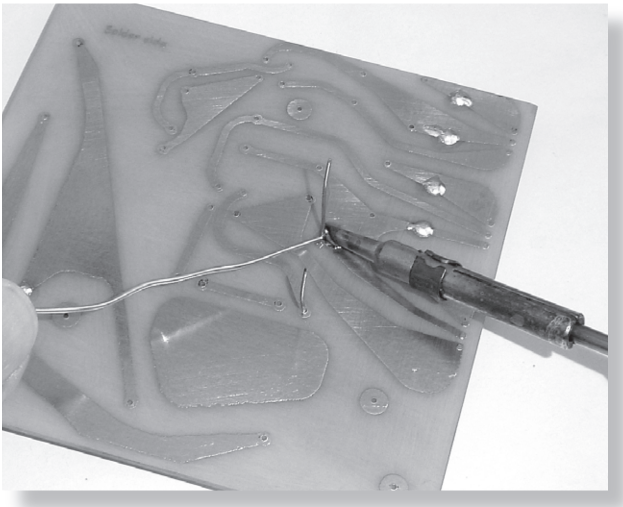

FIGURE 5.15 Solder melting and flowing around the pre-heated joint.

Take Note

Some beginners to soldering melt large amounts of solder on the soldering iron bit tip, then dab the soldering iron bit tip onto the joint they want to make – the soldering equivalent of putting glue onto a spatula then wiping the spatula onto something to spread the glue over it.

DO NOT UNDER ANY CIRCUMSTANCES DO THIS.

While the process might work well for glue, it certainly doesn't work for solder. Soldering is only effective when the joint is pre-heated, and fresh flux is applied at the same time as solder. If you put solder on the soldering iron bit tip, the flux burns away before applying it to the parts of the joint, and the joint is too cool anyway – causing only bad soldered joints.

The moral is: only use the method described earlier to solder joints!

Remove the soldering iron

Once the solder has flowed around the joint (not before), quickly remove the soldering iron. Do not move the printed circuit board, and do not move the component or its leads, until the solder has solidified. If you move anything before the solder solidifies, the joint may be damaged.

▷ FYI ◁

A good soldered joint has a concave, shiny appearance. If the joint is not heated sufficiently, or if you move the joint and damage it, you will probably notice that it is not concave, or that it is a dull, grey colour. Don't worry — just repair the fault by heating the joint again, until the solder flows properly.

Trim excess component leads

If the component leads were left as they are, and more than just a couple of components were inserted into the printed circuit board, you run the imminent risk of component leads touching — effectively forming short circuits. To prevent this you have to trim all excess component leads off immediately above the joint. Figure 5.16 shows this.

After all joints on the printed circuit board have been soldered and excess leads trimmed, it's a good time to check all the joints visually to see if they look 'good' or 'bad', repairing any that are suspect. Also check over all the copper foil track, to see that no solder bridges have formed between tracks or component joints. If you find any solder bridges, use desoldering tools — a solder sucker, or desolder braid — to remove excess solder, and resolder any joints that need it.

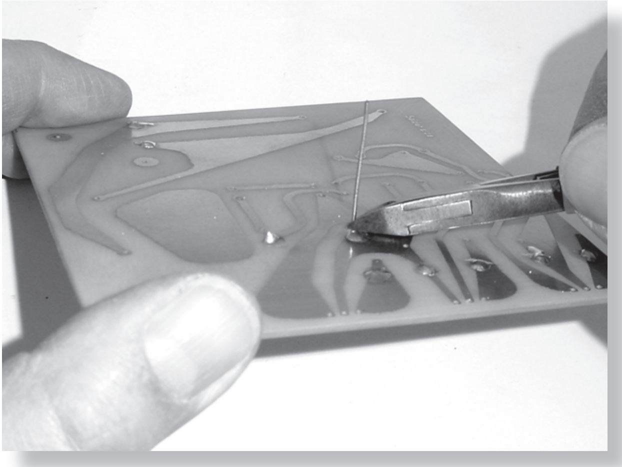

FIGURE 5.16 Trimming excess component leads off, close to the soldered joint, to prevent short circuits.

Connecting leads

Inevitably, any printed circuit board holding its electronic circuit is not isolated from the world around it! It must be connected — to switches, controls, off-board components, input and output sockets, and so on. So, it's common — indeed, normal — to need to solder connecting leads to the printed circuit board copper foil track.

To solder connecting leads to a printed circuit board, use the following procedure:

- **STRIP around 5 mm of insulation from the end of the lead**
- **IF the connecting lead is multi-stranded — twist the loose ends of the stripped lead.** If you solder the lead untwisted to the board, there's a possibility a loose strand may bridge across to another track
- **CLEAN and tin the soldering iron bit tip.** You should ALWAYS do this before any soldering operation

CONTINUED…

...CONTINUED

- **TIN the connecting lead.** This has two purposes: first, it removes any oxides, dirt and grease on the wires making up the leads, and; second, the solder you add in the tinning stage will be used when the joint is made — meaning you won't have to add much solder at that time. The soldering iron bit tip needs to be quite a broad one — around 3 mm — for this job. To tin the lead:

  - hold the flat part of the soldering iron bit tip upwards (as shown in Figure 5.17) and lay the stripped end of the connecting wire on the tip's flat surface
  - apply the end of a length of solder to the wire (not the soldering iron bit tip) — this means you can see when the wire is hot enough, as the solder begins to melt
  - when enough solder has flowed over the lead ends to fully cover the wire, remove the soldering iron and solder
  - allow the lead to cool before touching or moving it.

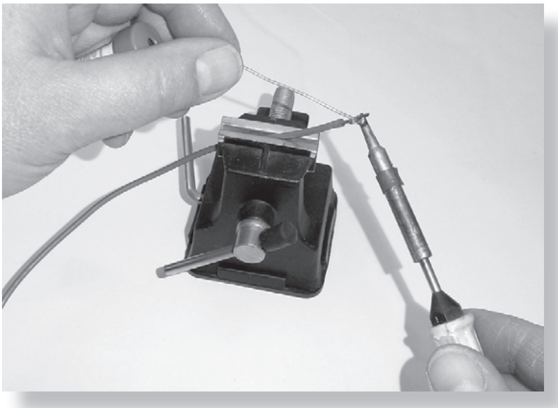

FIGURE 5.17 Tinning a connecting lead – do not heat the lead for too long, as insulation may melt or deteriorate.

CONTINUED...

…CONTINUED

- **TIN the printed circuit board.** At the point where the tinned lead is to be connected to the printed circuit board's copper foil track, the copper must be tinned, to remove oxide, dirt and grease, and to apply solder ready for the joint to be made between board and lead. To tin the printed circuit board track:

  - clean and tin the soldering iron bit tip
  - apply the soldering iron bit tip to the copper track of the printed circuit board, at the point where the lead is to be connected — as shown in Figure 5.18 — and wait for a few seconds

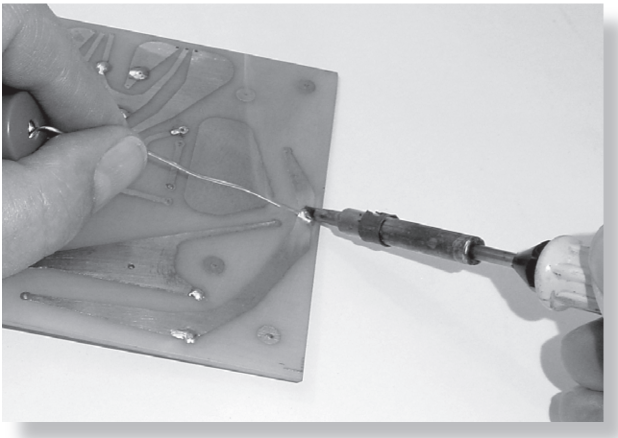

FIGURE 5.18 Tinning the copper foil track of a printed circuit board – apply the soldering iron bit tip first, and wait for a few seconds before applying solder.

  - apply the end of the flux-cored solder to the track, a small distance (about 2–3 mm) away from the soldering iron bit tip — wait for the solder to melt and flow towards the soldering iron bit tip
  - remove the soldering iron bit tip and the solder
  - allow the printed circuit board to cool before moving or touching the solder.

Take Note

While it's correct to tin the printed circuit board copper foil track at the points where connecting leads are to be jointed, this is NOT the procedure where components are to be fitted to the printed circuit board – if the copper foil track is tinned where a component lead is to be inserted, the hole for the lead may be closed with solder.

Once the lead is tinned, it can be soldered to the copper foil track of a printed circuit board. There are three main ways this can be done, soldering the lead:

- **1 directly to the printed circuit board copper foil track**
- **2 to a terminal pin, inserted through a hole in the copper foil track**
- **3 inserting the lead through a hole, purposely designed into the printed circuit board's copper foil track.**

The procedures you should follow for all three ways are detailed below.

1 Soldering a connecting lead directly to copper track

- **TIN the soldering iron bit tip, as described on page 116**
- **TIN the connecting lead, as described on page 124**
- **TIN the printed circuit board copper track, at the point where the lead is to be connected, as described on page 125**
- **HOLD the tinned end of the lead on the tinned copper track, as shown in Figure 5.19**

CONTINUED…

...CONTINUED

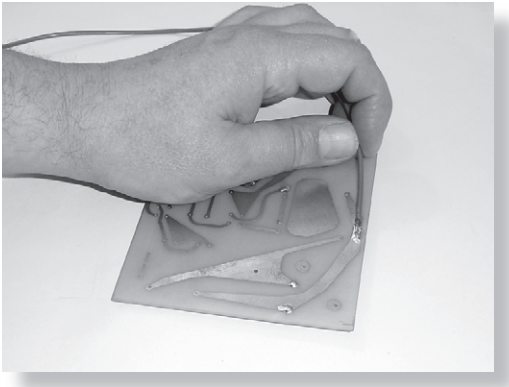

FIGURE 5.19 Position the tinned connecting lead end over the tinned copper track.

- **APPLY** the soldering iron bit tip to the tinned lead end (not the copper track), pressing down on the lead end to hold it in position, and wait for the solder on both the lead end and the copper track to melt, as shown in Figure 5.20

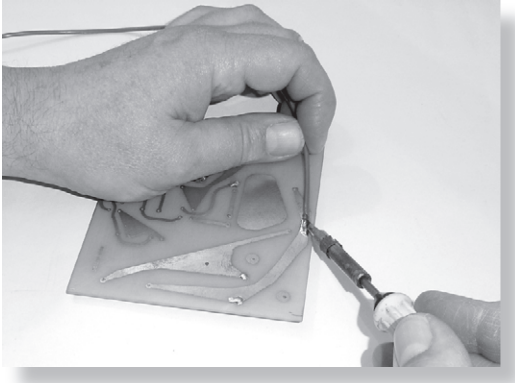

FIGURE 5.20 Heating the connecting lead end and copper track – the solder already present in the tinning on both the lead end and the track will be sufficient to make the soldered joint.

CONTINUED...

…CONTINUED

- **REMOVE** the soldering iron, but hold the lead without moving it

- **WAIT** for the solder to solidify before moving the printed circuit board or letting go the lead.

2 Soldering a connecting lead to a terminal pin

- **INSERT** a terminal pin into the printed circuit board — note that the pin goes through from the copper foil track side of the printed circuit board to the component side of the board ie, the connecting lead will be soldered to the component side NOT the copper track side (see Figure 5.21).

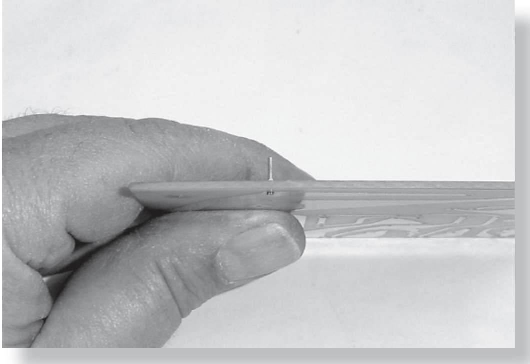

FIGURE 5.21 A terminal pin goes from the copper track side of a printed circuit board, to the component side.

- **CLEAN** and tin the soldering iron bit tip, as described on page 116

- **TIN** the connecting lead, as described on page 124

CONTINUED…

...CONTINUED

- **APPLY** the soldering iron bit tip to the terminal pin and wait for a few seconds (See Figure 5.22)

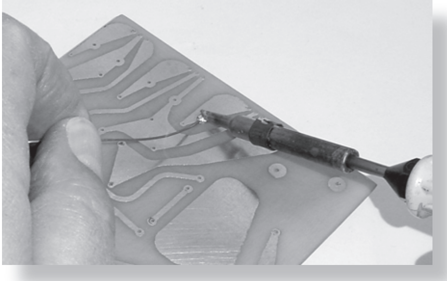

FIGURE 5.22 Soldering a terminal pin to a printed circuit board.

- **APPLY** solder to the terminal pin

- **WHEN** the solder melts and flows over the terminal pin and the copper track, remove the soldering iron and wait for the soldered joint to cool

- **TURN** the printed circuit board over, then tin the terminal pin

- **HOLD** the tinned end of the connecting lead against the tinned terminal pin, as shown in Figure 5.23

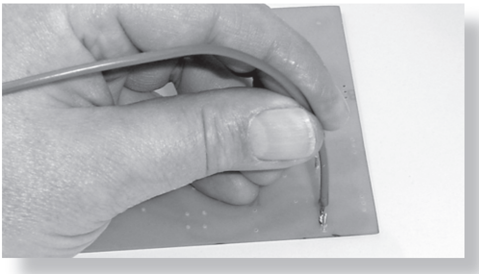

FIGURE 5.23 The connecting lead should be vertically aligned with the terminal pin, and touching it.

CONTINUED...

...CONTINUED

- **APPLY** the soldering iron bit tip to the connecting lead and terminal pin
- **WAIT** for a few seconds for the solder on both the lead and pin to melt, then remove the soldering iron
- **DO** not move either connecting lead or printed circuit board, until the solder has solidified.

Hint

For both these methods of soldering a connecting lead to a printed circuit board, be extra careful not to allow the connecting lead end to move at all once the joint has been soldered and during the cooling phase, or a defective joint may result.

3 Soldering a lead to a hole

- **CLEAN** and tin the soldering iron bit tip, as described on page 116
- **INSERT** the connecting lead through the hole in the printed circuit board — do not tin the connecting lead first, or it will not go through the hole!
- **APPLY** the soldering iron bit tip to the joint, touching both the copper foil track of the printed circuit board and the lead, as shown in Figure 5.24

CONTINUED...

...CONTINUED

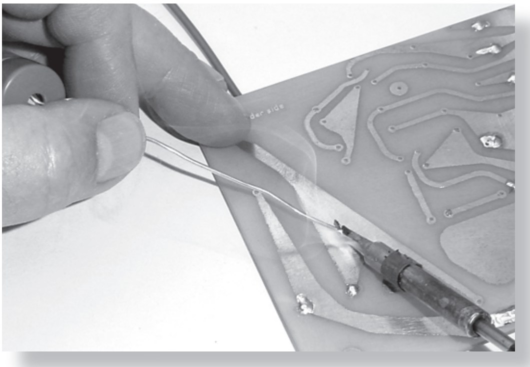

FIGURE 5.24 Soldering a connection lead to a printed circuit board.

- **APPLY** solder to the joint
- **WHEN** the solder melts and flows over the connection lead and the copper track, remove the soldering iron and wait for the soldered joint to cool
- **DO** not move either connecting lead or printed circuit board, until the solder has solidified.

Unsoldering

There are times when it's necessary to unsolder components from a printed circuit board. You may, perhaps, have inserted and soldered a component incorrectly into place, or a particular component may be faulty. In such cases, unsoldering is the only option.

There are two basic methods of unsoldering components (detailed overleaf), and both rely on having extra tools: either solder braid, or a desoldering pump.

Using solder braid

- **TIN** the soldering iron bit tip

- **PLACE** the end of the solder braid over the joint to be desoldered, as shown in Figure 5.25

- **APPLY the soldering iron bit tip onto the solder braid.** Press gently but firmly against the joint. After a few seconds or so, the solder will melt, and some will wick into the solder braid

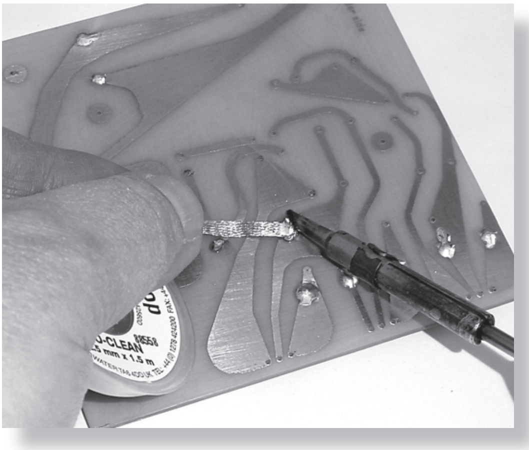

FIGURE 5.25 Desoldering using solder braid – the molten solder wicks into the strands of the solder braid away from the joint.

- **REMOVE the soldering iron bit tip.** Place a fresh portion of solder braid onto the solder joint and repeat the last step until all the solder forming the joint has been removed

- **REPEAT** the process for all component joints

- **REMOVE** the component.

Hint

As you use a portion of solder braid to unsolder a joint, it will become loaded with solder so cease to be usable. Using a pair of side-cutters, trim off the used portion to maintain a fresh solder braid end.

Hint

Sometimes not all solder can be removed from a joint (very often a small amount which cannot be removed will still hold the component lead to the copper track). If this occurs, you will find that you have to heat the joint with the soldering iron bit tip one last time, before quickly – before the solder solidifies – releasing the component.

Using a desoldering pump

- **TIN** the soldering iron bit tip
- **PRIME** the desoldering pump, by pressing the charger down, as shown in Figure 5.26

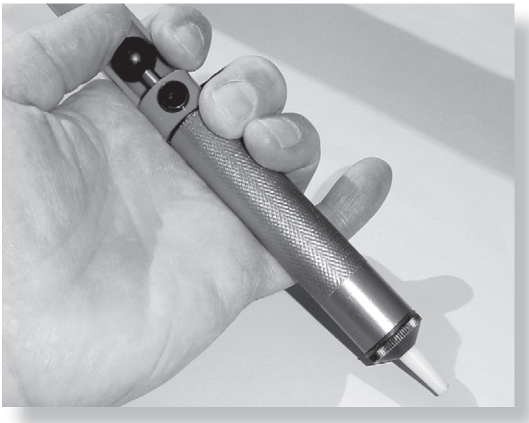

FIGURE 5.26 Priming the desolder pump by pressing down the charger.

- **APPLY** the soldering iron bit tip to the soldered joint and wait for the solder to melt

CONTINUED...

...CONTINUED

- **APPLY the nozzle of the desoldering pump to the molten solder, as shown in Figure 5.27**

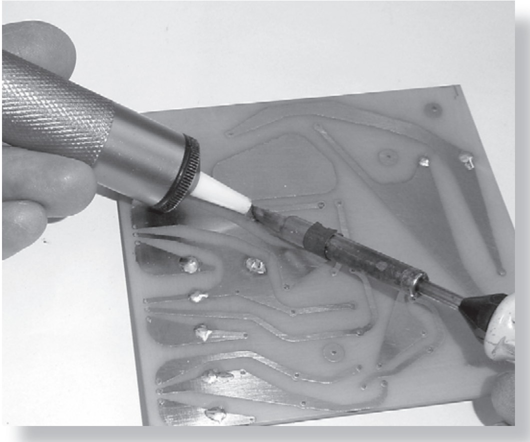

FIGURE 5.27 With the soldering iron bit tip heating the solder, apply the desoldering pump nozzle.

- **PUSH the pump's release button.** The vacuum will suck the molten solder away from the joint and into the desoldering pump chamber, where it will solidify

- **REPEAT the previous four steps as required, until all the solder has been removed from the joint.**

Take Note

Every now and again, the desoldering pump chamber will fill with solidified solder to the point that it doesn't work efficiently. Empty it by repeatedly priming and discharging the pump, so that the solder is forced out of the nozzle.

Take Note

Unsoldering usually requires considerably more application of heat than soldering – the soldering iron bit tip is applied to the joint more times and for longer periods than when soldering.

Remember that components may be damaged by excessive heat, so space the desoldering operations out to allow the components to cool down in between.

Care of your soldering iron

Your soldering iron is a tool — a vital one when it comes to building electronic circuits, of course — and like any tool needs looking after, to keep it in good working order throughout its potentially long life. Things are made a little complicated in that the soldering iron is — I'll state the obvious here — very hot, so you also need to take certain safety precautions while using it. But, fortunately, on the other hand it's a fairly simple tool, so the things you need to do to look after it and the precautions you need to take while you're using it aren't excessive.

Looking after your soldering iron

- **USE a stand.** When at rest, a soldering iron can be easily knocked or moved — it may fall off the work surface or simply touch against something else. Use a stand (as shown in Figure 5.28) when you are not actually soldering with it

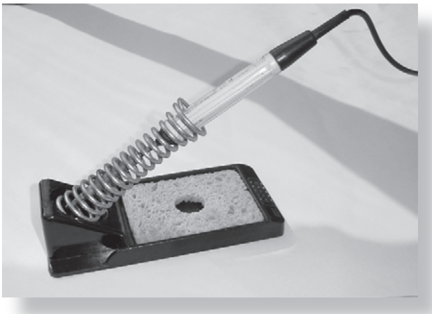

FIGURE 5.28 Use a soldering iron stand when not actually using your soldering iron. Keep the safety risks to a minimum.

CONTINUED...

...CONTINUED

- **TIN the soldering iron bit tip regularly — even at rest.** When you solder with a soldering iron it is regularly in contact with fresh flux-cored solder, so the bit tip is maintained in good condition. On the other hand, when you are not actually soldering and a soldering iron is standing unused but still turned on, the bit tip can become depleted of solder and flux due to the heat, so it oxidizes and become unusable. If you are not going to solder with the soldering iron for a while, remember still to tin it every few minutes

- **TURN the soldering iron off when unused.** To reduce safety risks to an absolute minimum, and to help prevent the soldering iron bit tip from becoming unusable, turn the soldering iron off if you are not going to use it in the next ten minutes or so

- **CLEAN the soldering iron bit tip when cold by lightly rubbing with a nylon pad.** This may help a soldering iron bit tip that will not wet — but do not use wire wool or emery paper to clean the soldering iron bit tip, as this will remove protective plating and shorten the bit life

- **NEVER put a soldering iron — hot or cold — into liquid**

- **CHECK the soldering iron's cable regularly for burns.** A soldering iron when on is, of course, very hot, and accidental burning on the mains cable is a possibility.

Printed circuit board links

If a circuit is complex, it's probable that the printed board copper foil track layout will be complicated too. Under these circumstances, it's often the case that it's simply not possible to design a copper foil layout in a single layer. One trick to get around this problem is to use the component side of the board as well as the copper track side to complete the circuit connections. This is done with the use of simple links of wire, which connect from one point on the copper foil track, go over the track on the component side, then connect to another point on the copper foil track. Figure 5.29 shows an example of a printed circuit board which uses links.

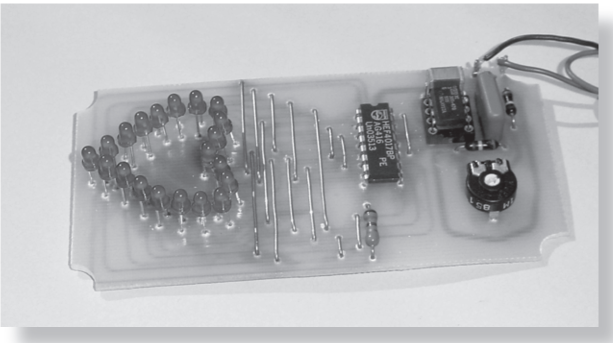

FIGURE 5.29 A printed circuit board that uses links to aid in copper foil track circuit layout. Note that many copper foil connections can take place under links, thereby easing a layout considerably. This particular printed circuit board is the Heart Flasher project, in Chapter 8.

Making a link:

- **CUT a short length of single-strand wire.** This should be a little longer than the distance the link needs to span between holes on the printed circuit board
- **BEND one end of the link around the nose of a pair of long-nosed pliers — see Figure 5.30.** The bend should be at 90°, and there should be sufficient wire to go through the board and be soldered to a copper track

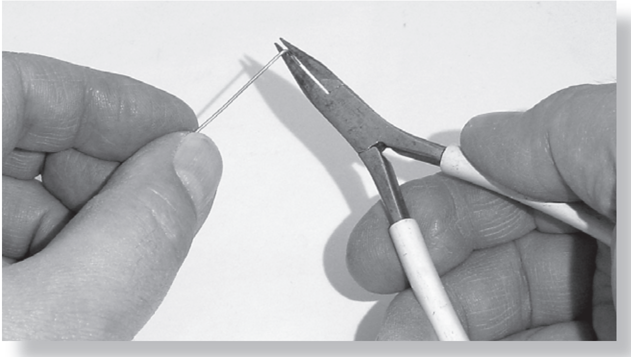

FIGURE 5.30 Bend one end of the link, using long-nosed pliers.

CONTINUED...

...CONTINUED

- **MEASURE the link length required**

- **BEND the other end of the link around the long-nosed pliers — see Figure 5.31.** The length of link between bends should be the same as that you've just measured

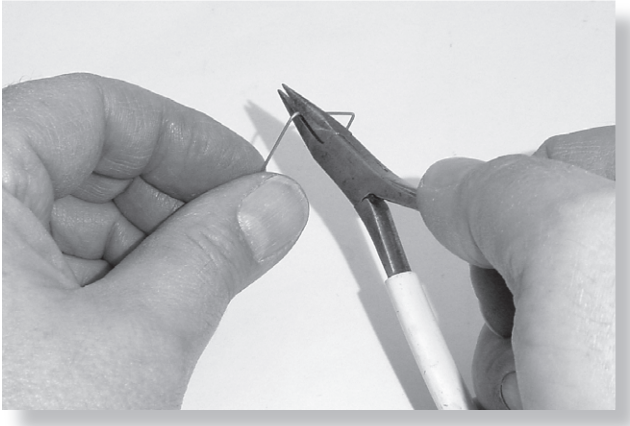

FIGURE 5.31 Bend the other end of the link.

- **INSERT and solder the link**

- **TRIM excess link wire off the soldered joints.**

6

Housings

After the printed circuit board, the next most important part of an electronic project is the *housing* (sometimes called an *enclosure* or *case*). OK, yes, while it's perfectly possible to use an electronic circuit just at its printed circuit board stage (complete with controls and connections hanging off…), it's certainly not the best method of ensuring your circuit has a long working life. Only the housing can 'finish' an electronic circuit off, and turn it into a complete design.

More than just the practical aspect of ensuring the internal electronic circuit is securely and safely held, however, in many respects the housing forms the main (if not the only) interface between the electronic circuit and the user. Yes, the electronic circuit may have connectors for inputs and outputs, and have controls that the user adjusts, but the housing is the means whereby all the controls and connectors are presented for use. How effectively this occurs depends very much on the housing, and how it has been designed. And there's a world of difference between a good housing and an acceptable one.

In fact, to emphasize how important an electronic circuit's housing is, we should look at a complete electronic circuit and see how it breaks down into a total of six levels of interconnection — as shown in Figure 6.1. In this look at the electronic circuit, we have to consider an integrated circuit as being a major component within the circuit itself, in order to understand the various levels and how they interact. Normally, of course, we would most likely use an integrated circuit, without understanding — or even caring — how it is constructed internally. This example, though, shows just how important each particular level is, with regard to the whole electronic circuit design.

The six levels are:

- **LEVEL 1 — on-the-device.** Where individual connections between the semiconductive component parts of integrated circuits are made as minute etched wires — shown in Figure 6.1(a)
- **LEVEL 2 — device-to-package.** Where the semiconductor die is permanently attached, with thin aluminium or gold wires, to the terminals of its package — shown in Figure 6.1(b)
- **LEVEL 3 — package-to-board.** Where flat, round or square package terminals are connected to printed circuit boards, as permanent (ie, soldered) or separable connections — shown in Figure 6.1(c)
- **LEVEL 4 — board-to-board and on-board.** Where components are interconnected with the conductive track of the printed circuit board, and where printed circuit boards are connected to each other by permanent or seperable connectors and cables — shown in Figure 6.1(d). The housing itself is directly involved at this level, simply because the types of connectors you use, and the printed circuit board positioning with respect to these connectors, may well be defined by the housing
- **LEVEL 5 — board-to-housing.** Where connections between a printed circuit board and its housing are made with permanent or separable connectors — shown in Figure 6.1(e). Sometimes, a distinct chassis may be involved between printed circuit board and housing
- **LEVEL 6 — housing-to-housing.** Where separable connections between housings are made with connecting cables — shown in Figure 6.1(f).

Figure 6.1 shows quite graphically what levels of an electronic circuit design the housing affects. Levels 1 to 3 (Figure 6.1(a) to (c)) have no involvement with the housing at all. They are merely concerned with connections between the individual components' innards and the printed circuit board. On the other hand, levels 4 to 6 (Figure 6.1(d) to (f)) are all indeed affected by the housing or housings you might choose for your electronic design.

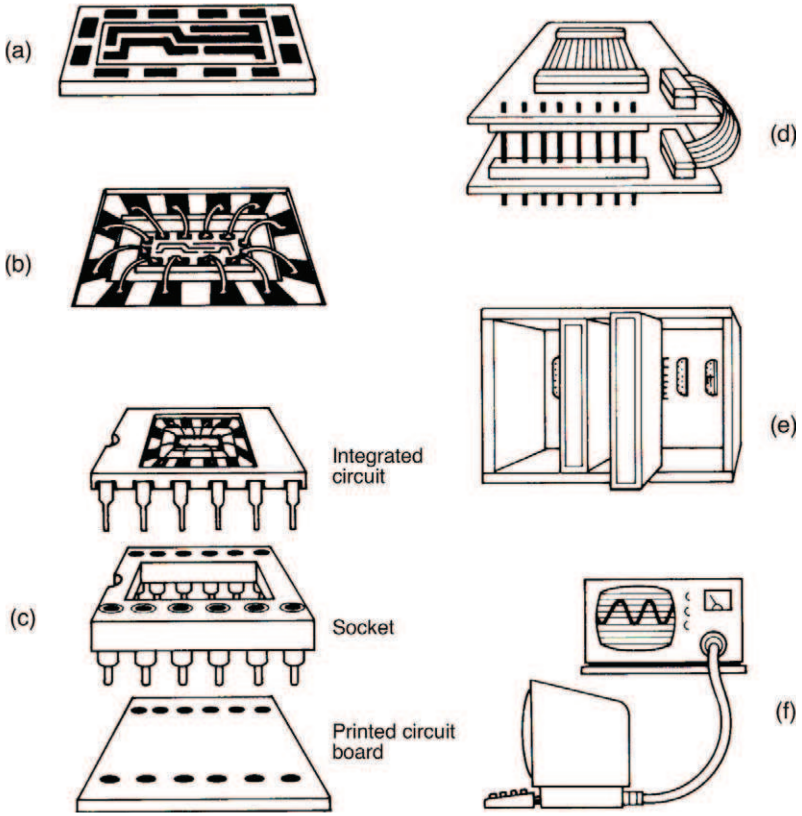

FIGURE 6.1 Six levels of interconnection between parts of an electronic design: (a) semiconductor die; (b) from the die to the terminals of the integrated circuit package; (c) from the integrated circuit to the printed circuit board; (d) between printed circuit boards; (e) between printed circuit boards and the housing; (f) between housings.

Yet, despite this fact that the housing affects or is affected by no less than half of the total electronic design, most magazines and books in general pay little attention to the housing, other than a few spartan words about putting the printed circuit board in to some sort of box. Indeed, only rarely is the actual housing design taken into consideration at all.

This chapter aims to put that right. Hopefully, by the end of reading it, you will see that the housing is as important a part of the total electronic device as the circuit design itself.

What's your housing made of?

There are three main types of housing available to the beginner in electronic construction:

- **PLASTIC**
- **METAL** diecast
- **METAL** folded chassis-type.

FYI

Actually there are more housing types, but these three types (and their derivatives) form the largest bulk of housings you will come across to begin with. As you progress in electronics you will undoubtedly meet other types.

Figure 6.2 shows examples of these housing types.

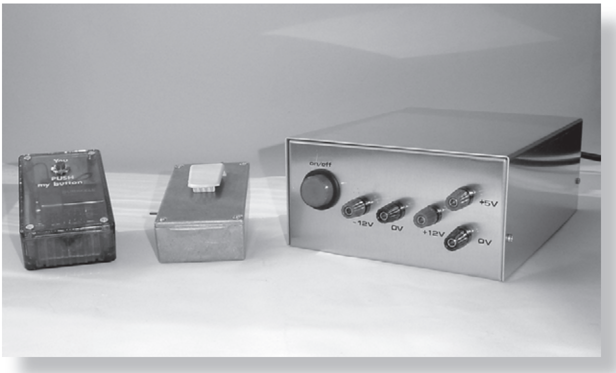

FIGURE 6.2 Housings – from left to right – plastic, metal diecast, metal folded chassis-type.

Plastic

Plastic housings come in several forms. They are relatively cheap to make in bulk, very easy to use, and provide a neat method of housing electronic circuits. Being usually moulded or extruded, some quite intricate and novel plastic housing shapes are available, which means that it's often possible to find a plastic housing that is a good match for an electronic circuit's function — for example, a plastic housing is shown in Figure 6.3 that is provided with a belt clip, and internal battery space, which would make an ideal housing for something like a music player or a pocket game.

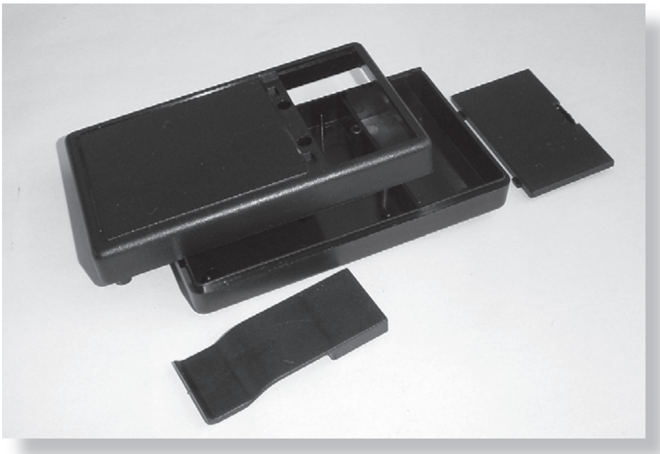

FIGURE 6.3 A small plastic housing, complete with belt clip and battery compartment.

Metal diecast

Made from cast aluminium, diecast housings are extremely tough, yet quite easy to work with. They are not, on the other hand, the most attractive of housings, so probably wouldn't be your first choice to house an electronic circuit that you wanted to use, say, on display in your living room, but a diecast box would be great for, say, a small pre-amplifier for use between an old record deck and a modern hi-fi amplifier.

Metal folded chassis-type

Usually made from just two thin sheets of aluminium, each folded to complement, metal folded chassis-type housings make very effective enclosures for many electronic circuits. The bottom half of a housing is where a printed circuit board and controls are fitted, while the top half of the housing forms a neat lid, allowing full access when removed, and protection when fitted. Often, the top half of such housings are plastic coated, or painted, which gives quite an attractive appearance to the finished electronic device.

Other housings

There are some other housing types that you should be aware off too, notably those made from extruded aluminium. Such housings are very tough, and have internal slots which are useful for the mounting of printed circuit boards — boards just slide into position from one end of the housing.

IP rating

In certain environments such as the great outdoors, it's necessary to use a housing that protects the electronic circuit inside from the elements to some degree or other. While all housings will protect their innards to some small measure, the problem is obviously magnified where the electronic device is to be used in such possibly detrimental environments as outside in the rain. For many years, there has existed a method of determining whether an enclosure is suitably protected against the environments in which it's expected to be used. This is a standard method, called the *ingress protection* (*IP*) rating system. It comprises two or three digits, and each digit refers to a particular level of protection, for a particular type of protection requirement. Thus, an enclosure might be given an IP rating of, say, IP63, or another might have an IP rating of IP485. Table 6.1 gives the IP ratings and numbers.

Where only two digits are given in an enclosure's IP rating, the third of these requirements (impact damage) is not relevant so should be ignored.

TABLE 6.1 Ingress Protection (IP) ratings by number, and their equivalent protection levels.

Value	1st digit	2nd digit	3rd digit
	Protection against ingress of solids	**Protection against ingress of liquids**	**Protection against mechanical impact damage**
0	No protection	No protection	No protection
1	Protected against solid objects over 50 mm eg, hands, large tools	Protected against vertically falling drops of water	Protected against 0.225 joule impact (150 g @ 15 cm)
2	Protected against solid objects over 12 mm eg, hands, large tools	Protected against direct sprays of water up to 15° from vertical	Protected against 0.375 joule impact (250 g @ 15 cm)
3	Protected against solid objects over 2.5 mm eg, wire, small tools	Protected against direct sprays of water up to 60° from vertical	Protected against 0.5 joule impact (250 g @ 20 cm)
4	Protected against solid objects over 1.0 mm eg, wires	Protected against water sprayed from any direction. Limited ingress permitted	
5	Limited protection against dust ingress (no harmful deposit)	Protected against low pressure water jets from any direction. Limited ingress permitted	Protected against 2.0 joule impact (500 g @ 40 cm)
6	Totally protected against dust ingress	Protected against high pressure water jets from any direction. Limited ingress permitted	
7		Protected against immersion between 15 cm and 1M	Protected against 6.0 joule impact (1.5 Kg @ 40 cm)
8		Protected against long periods of immersion under pressure	
9			Protected against 20 joule impact (5 Kg @ 40 cm)

Housings and their use

There are several tasks you will have to carry out which are common, whatever housing you opt to use for your electronic device.

The main tasks are:

- **MOUNTING the printed circuit board**
- **FITTING controls and switches**
- **FITTING connections between the printed circuit board and the outside world**
- **MOUNTING other internal components besides the printed circuit board**
- **WIRING of all internal parts**
- **LABELLING the front and rear panels of the housing.**

Mounting printed circuit boards

One of the primary purposes of a housing is to hold its internal electronic circuit's printed circuit board. It's not just a case of throwing the printed circuit board in, and closing the lid though. A printed circuit board should never be left loose inside any housing. Instead it should be properly and securely fixed, using one or more of a number of methods.

Often, the method you might choose to mount your printed circuit board inside your housing will depend on the type of housing you have opted to use *and* the size and shape of the printed circuit board. If you have a small printed circuit board and a plastic housing, it's perfectly possible to mount the printed circuit board to the inside of the housing using one or two pieces of double-sided adhesive sponge fixing pads, as shown in Figure 6.4.

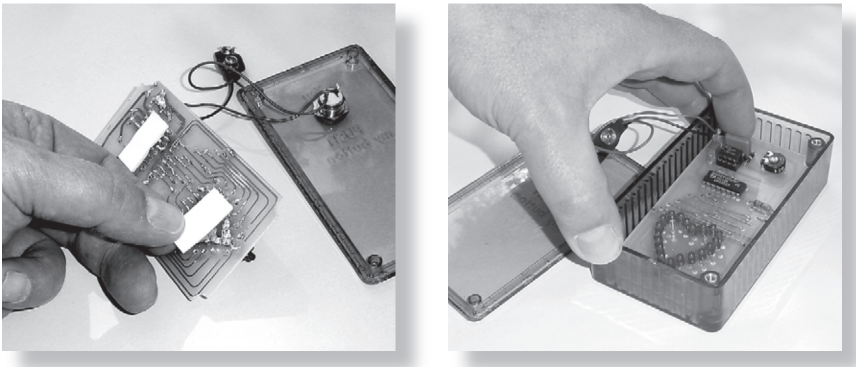

FIGURE 6.4 **Using double-sided adhesive sponge fixers to mount a printed circuit board inside a plastic housing: (left) applying the sponge fixing pads to the bottom of the printed circuit board; (right) applying the printed circuit board with sponge fixing pads to the inside of the plastic housing.**

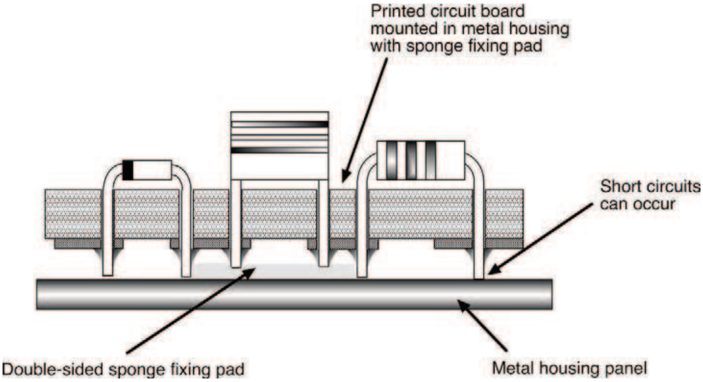
This method should not be used to mount a printed circuit board inside a metal housing though — for the simple reason that sponge fixing pads are thin, and some of the soldered connections on the bottom of the printed circuit board may touch the metal housing base (as shown in Figure 6.5), causing short circuits and possibly damage.



Printed circuit board mounted in metal housing with sponge fixing pad
Short circuits can occur
Double-sided sponge fixing pad
Metal housing panel

FIGURE 6.5 **A printed circuit board should not be mounted inside a metal housing using sponge fixing pads, or short circuits may result!**

Instead, when using a metal housing (or, indeed, if a larger printed circuit board is to be mounted even in a plastic housing) something more substantial must be used.

One of the best methods of mounting a printed circuit board in a housing is to use spacers. These are available in several formats. Some spacers use small bolts to hold them in place to the inside of a housing, as shown in Figure 6.6. Once the spacers are bolted to the housing, the printed circuit board is then bolted to the spacers. Obviously, the housing and the printed circuit board need to be drilled to accept the bolts prior to use.

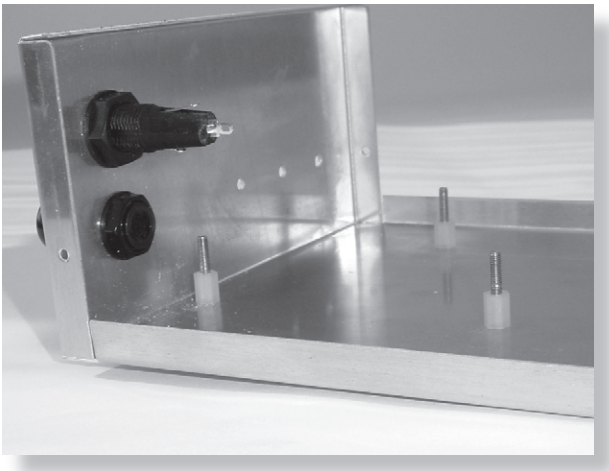


FIGURE 6.6 **Bolted spacers, showing the spacers and the bolts.**

Take Note

If you intend to use spacers to mount a printed circuit board to a housing, you must take into account where the spacers will be positioned on the printed circuit board. Component positions and the copper foil track may have to be adjusted to provide room – not just for the spacers themselves, but to allow access with tools to allow you to tighten the spacer bolts. You need to plan ahead, and decide which printed circuit board mounting method or methods you intend to use, as all the calculations regarding component positions and copper foil track layout need to be done in the very early stages of printed circuit board design – not at the last minute!

Other spacers are preformed, sprung-loaded plastic clips, which push into holes in the housing and the printed circuit board.

There are several variations of printed circuit board guides available. In use, these are fastened to the inside of the housing, and the printed printed circuit board is slid into position along them.

A particular variation of housing — extruded aluminium types — features in-built slots in internal surfaces. Conveniently, these are printed circuit board-sized, so provide an extremely easy method of mounting.

Take Note

In the printed circuit board design stages, make sure no components are positioned close to the edges of the printed circuit board if you plan to use guides of any sort. Further, if you plan to use an extruded aluminium housing, not only must there be no components fitted on the guide edge areas of the printed circuit board, but there must be no copper foil track in those areas.

If your printed circuit board has controls and connections (such as certain printed circuit board mounted potentiometers, switches and connectors) then you can use the controls and connectors to mount the printed circuit board inside the housing, with careful design. This is particularly so for small printed circuit boards.

Mounting the printed circuit board this way depends on using printed circuit board mounted controls and connectors. For example, Figure 6.7 shows a printed circuit board that has an on-board potentiometer and on-board connectors. These effectively hold the printed circuit board in place, as they are held to the housing sides.

Note though, that the actual printed circuit design is highly dependent on the actual controls or connectors. In other words, the housing you intend to use, the exact size and shape of the printed circuit board, *and* the actual controls or connectors all need to be taken fully into account during the very earliest printed circuit board design stages. Literally *everything* is dependent on each other. This method allows a highly integrated, a very professional looking, and often a much reduced size of device, so is often worth the extra time you might need to invest in the early design stages.

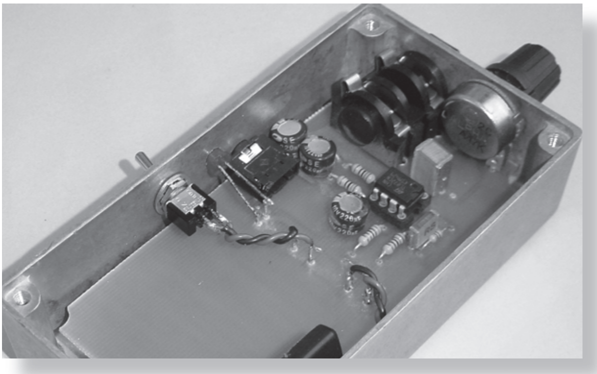

FIGURE 6.7 Using a printed circuit board mounted potentiometer and connectors to mount a printed circuit board inside its housing. This is the Guitar Headphone Amplifier project, in Chapter 8.

A common method of mounting small printed circuit boards inside housings is to make use of a particular type of connector known as an *edge connector*. Edge connectors are multi-pinned devices, comprising a row of contacts into which the edge of a printed circuit board fits tightly. A row of copper foil tracks on the edge of the printed circuit board mates with the edge connector contacts, as shown in Figure 6.8. The edge connector is bolted to the housing or to another — usually larger — printed circuit board. Thus, connections can be made to and from the printed circuit board, but just as importantly, the printed circuit board is held in position. A small printed circuit board mounted this way may need no other support.

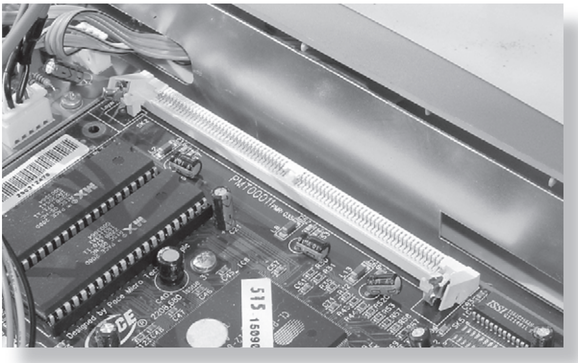

FIGURE 6.8 Using an edge connector to hold a printed circuit board in position. This particular connector (in white) is a RAM-card holder, common to computer and associated equipment.

Fitting controls and switches

While on the subject of controls and switches, we should include details on how they should be mounted to a housing. The methods of doing this are similar, whether they are special printed circuit board mounted controls and connectors, or ordinary, more usual, controls and connectors. The methods are also similar, whatever type of housing is used — metal or plastic, or even wood.

Controls are required in most electronic circuits. They can range from volume and tone controls in an audio amplifier, through time settings for a digital clock, simple on/off switches, or dials to tune in radio stations. The important point is that controls are used to provide an interface between an electronic circuit (in printed circuit board form, inside a housing) and the user of the electronic circuit (in human form — normally — outside the housing).

Potentiometers

Most potentiometers have a threaded stem, that allows them to be mounted to a housing using a supplied nut and washer. Figure 6.9 shows a typical potentiometer, complete with washer and nut. A hole — the diameter of the threaded stem — is required in the housing to insert the stem. Also visible in Figure 6.9 is a location stub that extends beyond the mounting point on the threaded stem. The purpose of the location stub is to fix the potentiometer in position and prevent its rotation — as might happen if the nut becomes loose, over time, say. The problem with the location stub is that a second small hole (the diameter of the location stub) is required in the housing alongside the hole for the threaded stem — the correct distance from the centre of the threaded stem's hole.

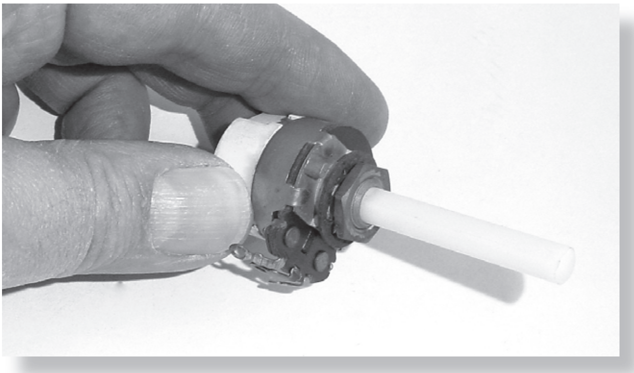

Figure 6.9 A potentiometer, showing its threaded stem, washer and nut, and the location stub.

Now, I should point out here that not all potentiometers have this location stub, and in which case the second hole is not required. And, indeed, I have been guilty myself of removing the location stub from a potentiometer in cases where I felt the nut wasn't likely to become loose, so didn't need the second hole.

Notwithstanding, the job to mount a potentiometer with such a stub is simple enough.

Mounting a potentiometer

- **MARK the centre of the hole where the potentiometer's threaded stem is to be, and mark the centre of the location stub's hole, as shown in Figure 6.10.** The distance between centres depends on the particular potentiometer, as does the angle at which you need to position the two holes relative to horizontal along the line of the housings panel.

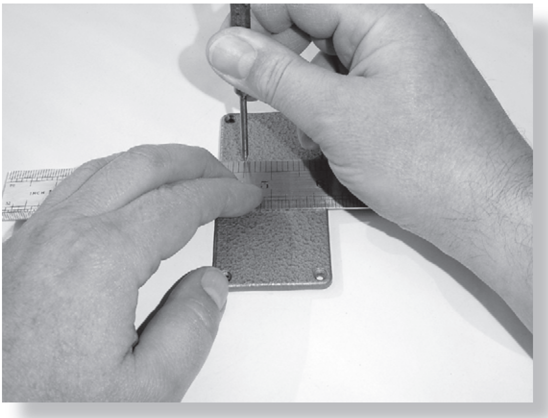

FIGURE 6.10 Marking the position of the two holes required for the potentiometer of Figure 6.9.

- **MARK both holes using a centre punch**
- **DRILL the holes using a pilot drill (no more than 2.5 mm).** Position the housing over a block of wood, so that the drill bit doesn't grab the metal and distort it as the drill bit's cutting edge exits the hole.

CONTINUED...

…CONTINUED

- **DRILL** both holes using a drill the correct size for the location stub
- **DRILL** the threaded stem's hole using the correct sized drill
- **POSITION** the potentiometer in place
- **PLACE** the washer, followed by the nut over the threaded stem.
  Tighten the nut to a finger tightness
- **TIGHTEN** the nut, using pliers.

Take Note

When you tighten a potentiometer nut (indeed, any nut which is located on a housing's panel like this), you should take extra care to make sure the pliers don't slip off the nut and scratch the panel. Figure 6.11 shows how to tighten the nut. Note how the washer underneath the nut protects the panel from the pliers.

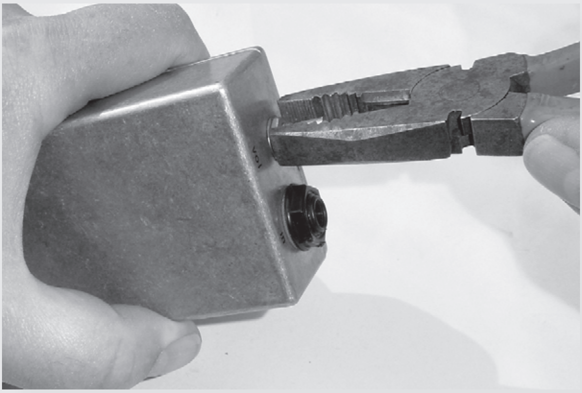

FIGURE 6.11 Tighten the potentiometer nut using pliers. Push the pliers against the washer under the nut to help prevent the pliers from slipping off, thereby protecting the housing panel.

Take Note

New potentiometers have long control stems, in order that you can cut them to the length you want. The final cut length is fixed however, by the type of control knob you want to use. In order that you can cut the stem to the required length, you therefore need to have the control knob to hand. Follow the instructions below to cut the stem to size.

Cutting a potentiometer stem to fit a control knob

- **PUSH** the control knob on the stem till it seats fully against the top of the stem
- **MARK** the stem directly in line with the bottom of the control knob (Figure 6.12)

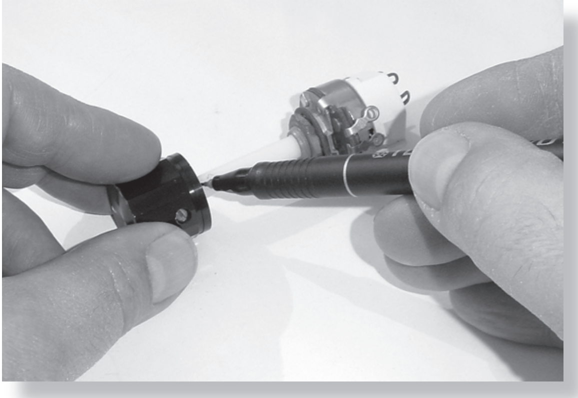

FIGURE 6.12 Push the knob on the potentiometer stem, and mark the stem.

- **REMOVE** the control knob, and measure the distance from the end of the stem to the mark (Figure 6.13)

CONTINUED…

...CONTINUED

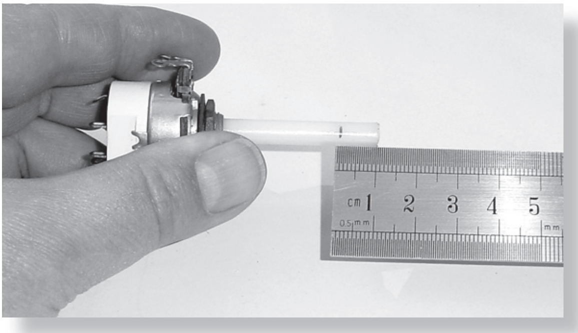

FIGURE 6.13 Measure from the stem end to the mark.

- **NOW make a second mark on the stem the same distance from the top of the potentiometer's threaded stem.** Actually, some knobs have an overhang specifically intended to cover the threaded stem, so this second mark can be a millimetre or two closer to the stem end if your knob features such an overhang

- **CUT the stem on this mark.** To do this, hold the end of the stem in a vice, with the stem horizontal. Hold the potentiometer body in one hand, while cutting the stem with a junior hacksaw in the other hand, as shown in Figure 6.14

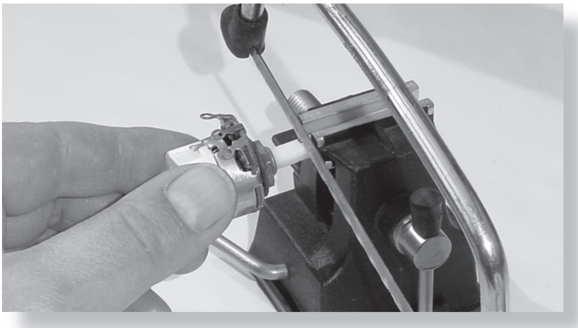

FIGURE 6.14 Cutting the stem of a potentiometer.

- **DEBURR the cut end of the stem with a fine file.** Your potentiometer is now ready to be fitted with its knob.

Take Note

Potentiometers are actually quite fragile. Do not hold the potentiometer body in a vice to cut off excess stem. Make sure you put the stem end in the vice!

Knobs

Many, many types of knobs are available, in all sorts of sizes and styles. Figure 6.15 shows a selection. Most are fitted to a potentiometer either with a push-fit, or (usually) with a small grub-screw through the side, which clamps onto the potentiometer stem.

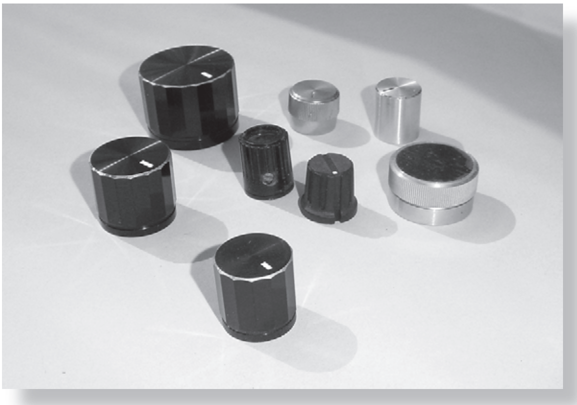

FIGURE 6.15 A selection of common control knobs.

Switches

Several variations exist in switches, with slide, toggle, push, and rotary being the most common (see Chapter 3). Within these variations, however, there are also variations in body shapes and sizes. As a result, it's not possible to include details of how to mount all switches here. Instead, I'm going to generalize, and show how the main variations should be mounted. These main variations are determined by body shape, not internal mechanics. Main body shapes are circular and rectangular, which narrows the field down somewhat.

Circular switches are rather like potentiometers in their fitting, and most of the details in the potentiometer section already covered are relevant here. Some circular switch types even have a location stub, usually in the form of a shaped washer, which requires a second hole (just as with potentiometers) to correctly mount the switch. Figure 6.16 shows a switch which mounts using this method. The method of mounting closely follows that of mounting potentiometers, earlier. Both holes should be marked out and drilled, then the switch is fitted using the location tab washer and a nut which fastens over the switch's threaded stem. As when tightening a potentiometer's mounting nut, take great care when tightening a switch's mounting nut, in case the pliers slip off and scratch the housing's panel.

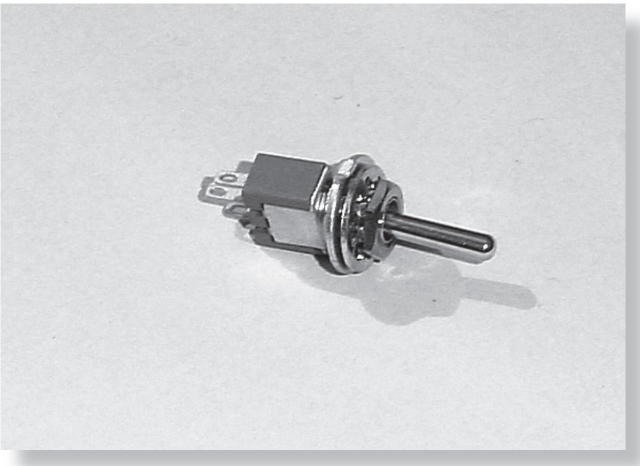

FIGURE 6.16 **A miniature circular toggle switch, complete with location washer having a location tab.**

Some circular switches are provided with two mounting nuts (you can see one on the switch shown in Figure 6.16). These have the purpose of allowing the switch to be adjusted in terms of position, sticking far out from the housing's panel, or closer to the panel. A benefit of this second nut is that the outside nut needn't be tightened with pliers (thus avoiding any risk of damage to the panel outside), and all tightening is done to the inside nut, using pliers.

Rectangular switches are rather harder to mount, simply because rectangular holes are very much more difficult to err… drill. Of course, in general, it's a question of drilling a hole in the panel that is no larger than (but only slightly smaller than) the switch itself, then carefully filing out the hole till it is big enough for the switch to fit. The process is actually easy enough, just somewhat laborious, and follows now.

Fitting a rectangular switch

- **MARK** out the rectangular hole to be made
- **MARK** the centre, using a centre punch
- **DRILL** out a hole (using a pilot drill, and subsequent larger drills), just slightly smaller than the required finished hole
- **FILE** the hole, using fine files to the exact size required.

Hint

When you file a hole in your housing's panel, you'll need to clamp the housing in a vice. To protect the housing from the vice jaws, you should get two small blocks of wood and clamp the housing between the blocks. Make sure the blocks are positioned close to the edge of the hole you are filing – this prevents the panel from flexing too much and being damaged while you file. This is particularly important with thin aluminium folded-metal chassis-type housings. Also, file from the outside in – this means that any burring you naturally get while filing forms on the inside of the housing, so is not visible from the outside when finished.

Some rectangular switches have particular hole requirements. For example, slide switches (other than needing a rectangular hole for the switch tab itself to protrude through) also require holes to suit screws which hold the switch body in place. There's nothing for it but to carefully mark out the holes to drill and file, and get on with it!

▷ FYI ◁

Holes for some common rectangular switch shapes (and some circular ones, for that matter) can be cut out using hole punches, purpose-designed for the task. A hole punch comprises three main parts — a cutting tool, a socket receptacle, and a bolt arrangement. Using them is easy: you drill a hole the size of the bolt diameter, then fit the punch together, with the cutting tool on the front of the housing panel, the socket on the back, and the bolt going through the panel. As the bolt is tightened, the cutting tool punches out the hole in the panel, leaving a very clean hole. Such hole punches are quite expensive, but possibly worth the cost if you intend to make many identical holes.

Hint:

There are so many switch variations that it's usually possible to choose a switch type that is easy to fit. In other words, unless you want to use a rectangular switch for a particular purpose (although personally, I can't think of any!), my advice is to use circular switches always. Remember that every operation you perform to your housing's panel is just another opportunity to scratch the panel.

Fitting connections

Many electronic circuits require some form of electrical signal as an input, or an output. An audio amplifer, say, has outputs to loudpseakers, or a multimeter has inputs from its probes. The connectors used for such connections varely widely, depending on what sort of signals are being connected. Figure 6.17 shows a selection.

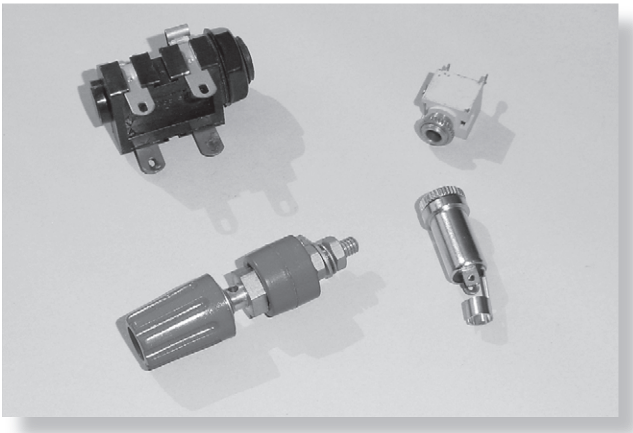

FIGURE 6.17 A variety of connectors used with electronic circuits and their housings.

The mounting of connectors to housings follows the same principles as that of mounting controls such as potentiometers and switches, with only a few minor additions or variations.

Often, circular connectors have a locating key of moulded plastic, which must mate with a notch cut in the panel as the connector is fitted to the housing. The purpose of the key and notch arrangement is simply to prevent the connector rotating. Figure 6.18 shows a connector with this sort of rotation prevention device. It all sounds good, but it does make fitting such connectors a little more tricky. After drilling a hole in the housing's panel to fit the connector, you then have to file out a notch in the panel to fit the key. A set of jewellers' files is best to do that.

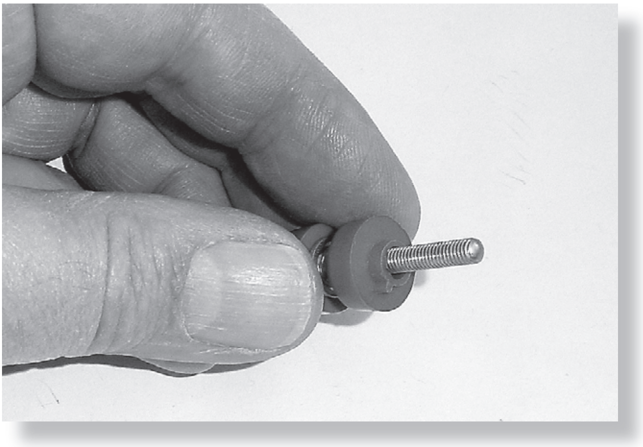

FIGURE 6.18 A connector with a location key – a corresponding notch in the housing panel must be filed (using jewellers' files).

Connectors need to be connected internally — usually to the printed circuit board, with a length of connecting lead. Some connectors may be multi-pole (ie, have two or more individual connections inside the one connector) while others will be single-pole (ie, only one individual connection). The type of connector defines what sort of connecting lead you need to use.

Often multi-pole connectors are audio in nature (microphone, earphones and so on) and they will usually require a special type of connecting lead known as screened cable. Screened cable is formed with a central insulated lead (some screened cable has more than one central insulated lead), wrapped with uninsulated wire, and the whole construction is insulated. Figure 6.19 shows some screened cable, in which you can see the central insulated lead and the uninsulated wire. The uninsulated wire around the central lead is intended to be earthed, so offering a measure of protection (or *screening* — hence the name) for the relatively small signals carried by the cable against electro-magnetic interference.

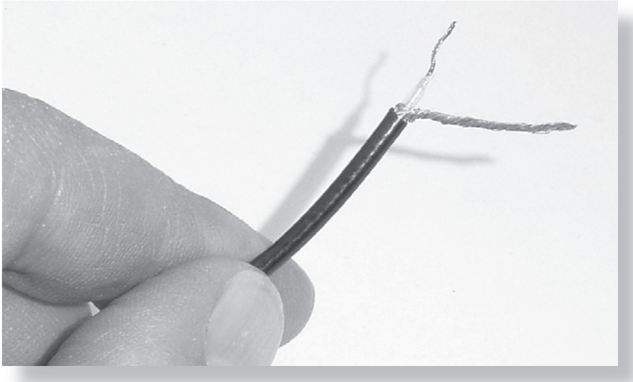

FIGURE 6.19 Screened cable, showing a central insulated lead, and the wire screening, all encased in insulation.

A variant of screened cable, for use with high frequency signals, is coaxial cable. Like screened cable, coaxial cable has a central signal lead, with an external screening. However, the screening is usually in a braided form.

Usually, connecting leads between the connectors and the printed circuit board are made by soldering the lead at each end. However, some connectors (notably power connectors) require some other joining method. The connector of Figure 6.18, for example, features a bolt forming the internal connection. Such a connector requires that solder tags be soldered to the ends of the connecting leads (Figure 6.20 shows a connecting lead with a solder tag connected to it). The solder tag can then be bolted to the connector.

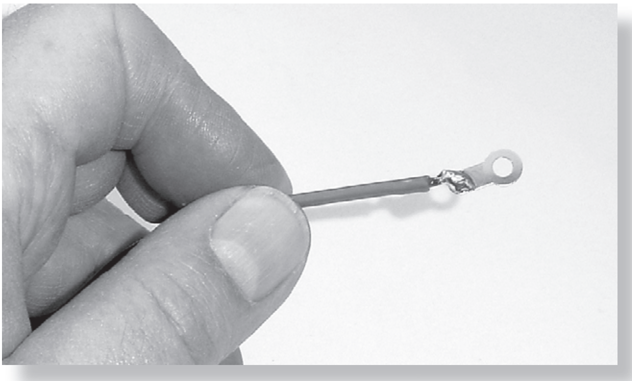

FIGURE 6.20 A solder tag, soldered to connecting lead, for use with bolted connectors.

Other power connectors — usually mains connectors, although the connection method is popular in car electrical circuits too — feature a spade male lug, as shown in Figure 6.21. A mating spade female connector must be crimped to the connecting lead, using a crimping tool. The result is a solid and secure connection.

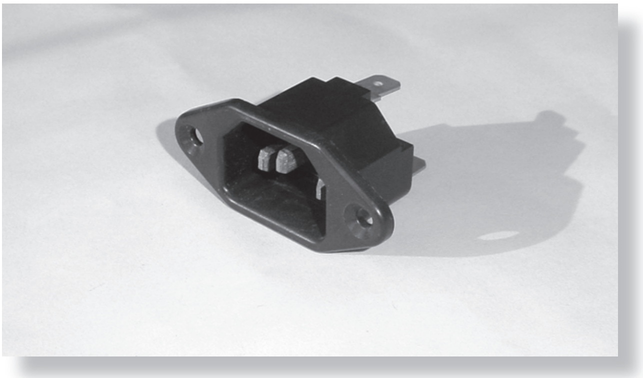

FIGURE 6.21 *Connector featuring spade lugs.*

Some connectors mount directly on to the printed circuit board, which negates the need for leads between the connector mounted on the front panel and the printed circuit board. As a benefit such connectors can be used, as shown on page 148, to aid when mounting the printed circuit board itself in the housing.

Mounting other internal components

A few other internal components that need to be mounted on a housing exist. The most common group is that of indicators — LEDs, bulbs and so on. Generally speaking, they have the same mounting conditions that connectors and switches have, with the exception of LEDs.

Several varieties of LEDs exist. Simplest to mount are the basic, round common LEDs, as shown in Figure 6.22. These *can* be mounted just by drilling a hole in the housing panel the exact diameter of the LED and pushing the LED in.

The problem with this method is that it's just as easy to push the LED back out, from the outside of the panel. The solution is a simple clip, shown in situ on a LED in Figure 6.23. In use, it's a simple matter of drilling a hole in the housing panel the correct size for the clip, inserting the clip into the hole from the panel front, then pushing the LED into the back of the clip, until it seats correctly with a click. Clips come in the same range of sizes that LEDs do — it's just a matter of making sure you have a clip the same size as the LED.

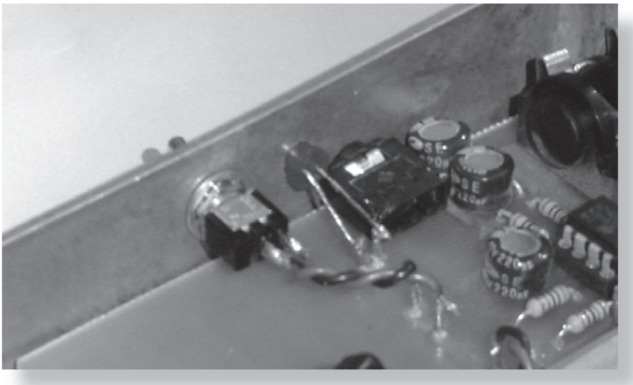

FIGURE 6.22 Simple mounting of a LED to a panel.

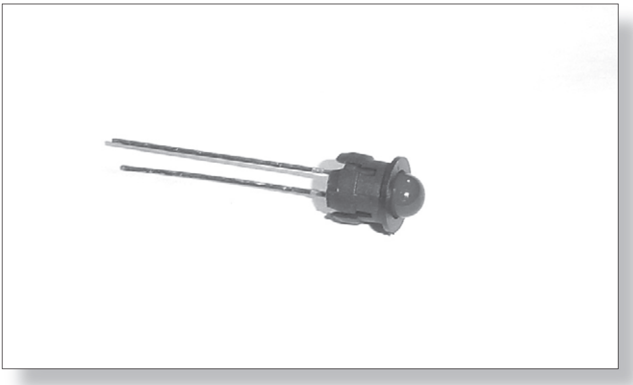

FIGURE 6.23 A LED, complete with panel clip.

Fuse holders

Mains-powered circuits usually require a fuse for safety purposes, and the most common type of fuse holder is chassis-mounted. These are fitted to a housing panel, so that the fuse is accessible from the outside of the housing, while all mains connections are made on the inside (see Figure 6.24). There are no particular considerations in the actual mounting requirements, but there may be wiring precautions (to make sure live terminals cannot be touched when removing or installing a fuse).

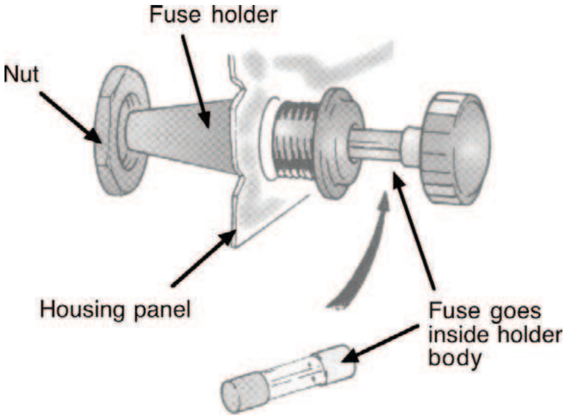

FIGURE 6.24 Mounting a fuse holder into a panel.

Heatsinks

All electronic components generate heat as electric current flows through them. Generally this is not a problem, as they naturally dissipate the heat so that the temperature doesn't get too high to damage them. However, large current flow through certain components such as certain transistors, generates heat to the point that such a component *could* be damaged if the heat was left to dissipate naturally, and some method of removing heat is required to maintain a component core temperature lower than that which would cause the damage.

The method of removing heat — known as *heatsinking* — usually relies on mechanically connecting the component to a large mass of metal. As metal is a heat conductor, heat from the component core is thus shunted away, preventing damage.

Inside an electronic device's housing, components which may heat up to the point of damage can be protected with readily available push-, clip-, or bolt-on heatsinks; a selection is shown in Figure 6.25. Typically, the larger metal surface of the heatsinks allows a degree of cooling just because of increased natural convection. To increase the surface area and air flow around heatsinks, they are often finned.

Most heatsinks of this type are simply fitted to the component in question and then forgotten about, so they provide quite an easy way of providing component cooling. They do, however, only have a limited ability to aid component cooling.

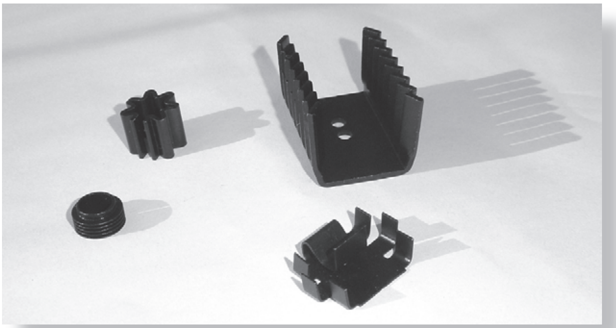

FIGURE 6.25 A selection of small heatsinks.

Where components are likely to get hotter than such heatsinks can cope with, a common trick is to mount the components on a panel of the housing (assuming the housing is metal, of course).

All these heatsinking methods rely on the fact that the medium directly in contact with the hot component will dissipate heat sufficiently to maintain an acceptably low temperature. When deciding which heatsink is required for which component, there are five main variables which need to be considered.

Five variables of heatsinks

- **TEMPERATURE of the component's surface.** What is the maximum temperature the component can reach when operating under circuit conditions?
- **TEMPERATURE of the surroundings.** What is the maximum ambient temperature?
- **THERMAL resistance of the junction between the component and the heatsink medium.** How easily does heat flow from one to the other?
- **ABILITY of the heatsink to dissipate heat**
- **ELECTRICAL conductance.** Components are metal, heatsinks are metal, metal conducts electricity — so is there likelihood of short circuits?

If you are designing an electronic circuit from scratch, then you need to know or at least be able to calculate all the above variables to ensure that a heatsink will do its job properly. If you are simply building a circuit from a magazine or book such as this one, then you don't need to do any calculatons — simply use the heatsink that is recommended.

Whether you design a circuit yourself, or follow one, there is a particular method when using a heatsink to make sure the best performance is obtained.

The problem is that the surface of a component, and the surface of a heatsink are not always perfectly flat. Small air pockets always exist which restrict heat flow from the component to the heatsink — known as the *thermal conductivity*.

Thermal conductivity can be improved by coating both surfaces with *thermal compound* (sometimes known as *thermal joint compound*, or *heatsink compound*, or *thermal grease*). This is a silicone oil based grease, impregnated with metal (usually zinc or silver) particles, which fills in air pockets and promotes heat flow. It's usually supplied in tubes or syringes (see Figure 6.26) for easy application.

Using it it quite easy: apply a small amount to your finger, then rub your finger and thumb together to thin the compound out, then apply some to each surface.

Finally, mate the surfaces.

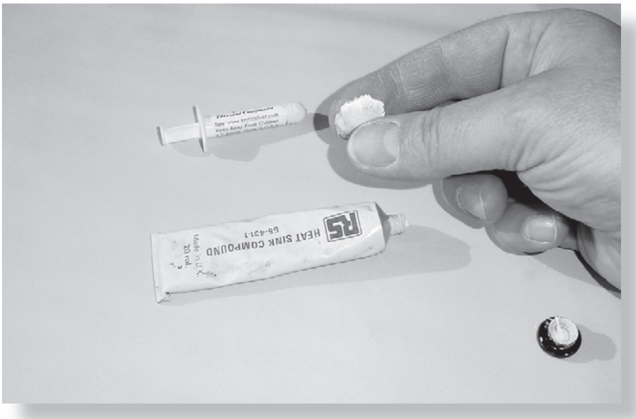

FIGURE 6.26 Thermal compound – supplied in various ways. Put a small amount on your finger and rub between finger and thumb before applying to a component or heatsink surfaces.

Take Note

It is important not to have too thick a layer of thermal compound between component and heatsink! Too much compound restricts heat flow just as much as too little compound.

FYI

Even mounting components on a metal housing's panel may not provide sufficient cooling for some applications. Better cooling methods need then to be adopted — the most common of which is the fan (seen most often in large computers) which helps to ensure that air flows round hot components. Other heatsinking methods exist, including heat exchange, refrigeration and water-cooled systems, but these are generally beyond the scope of the beginner to electronics construction.

To make sure no electrical connection occurs between a component or its heatsink, use an insulating washer and plastic mounting tab or bush. Traditionally, insulating washers are commonly made of the insulator mica, but increasingly popular are silcon rubber washers. Both are shown in Figure 6.27 along with an insulating mounting tab. Note that the size and shape of the insulating washer depends totally on the size and shape of component it is for. The washers shown in Figure 6.27 are meant to fit a TO220-type transistor shape component. Insulating washers — obviously — fit between the component and the heatsink, so introduce another two surfaces into the equation, so when applying thermal compound prior to fitting a heatsink, put thermal compound on all four surfaces.

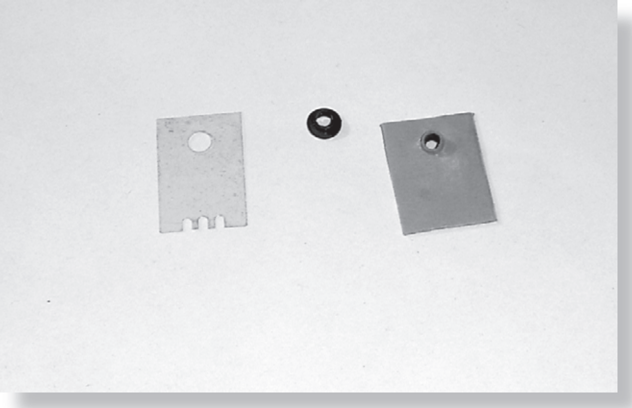

FIGURE 6.27 Insulating washers: left is a mica washer, right is a silcon rubber washer. In the middle is an insulating mounting tab.

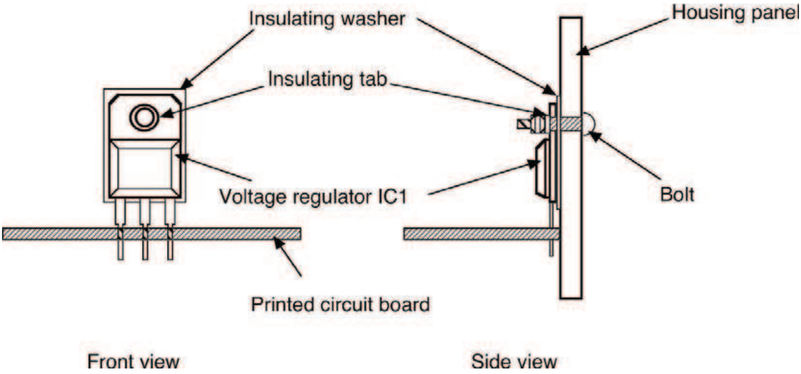
The component needs to be fastened mechanically to the heatsink in some way. When fastening a component to a housing panel the usual method is with a small nut and bolt. The plastic insulating mounting tab ensures that the nut and bolt used do not cause a short circuit between the component and the housing panel. The way the arrangement should be fitted together is shown in Figure 6.28.



Insulating washer

FIGURE 6.28 Bolting a component – in this case a voltage regulator integrated circuit – complete with insulating washer and mounting bush, to a heatsink.

Figure 6.29 shows an actual application of heatsinking components, in the Bench Power Supply project of Chapter 8. Here you can see the three voltage regulators that are heatsinked to the rear panel of the project housing.

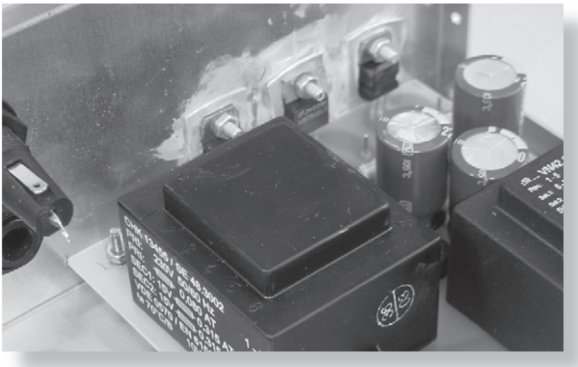

FIGURE 6.29 Showing three components, heatsinked to a metal housing rear panel.

Take Note

Electrical conductance does not need usually to be taken into consideration where a heatsink is a simple push-, clip-, or bolt-on type, that is fastened directly to an individual component on a printed circuit board. After all, as long as the heatsink touches nothing else metallic, there can be no danger of short circuits.

However, electrical conductance for a component mounted onto a metal housing's back panel for heatsinking purposes is of prime importance – several components of circuit parts (the printed circuit board, connectors, controls, power supply parts and so on) may also be mounted on the housing. Here, problems of possible short circuits need to be taken seriously. Some form of insulating washer should be used to prevent electrical connection between the component and the housing.

Wiring of all parts

In some instances, once a printed circuit board is mounted in its housing, the electronic device is complete, and it only requires the housing lid to be fastened on for final completion. In most instances though, there will remain some wiring of internal parts together.

If you are building an electronic device from a magazine or book design any internal wiring will usually be shown as a wiring diagram, although this is normally topographic — ie, like a railway map, it shows theoretical connections but not the actual routes. More often than not, how the wires themselves are connected between parts is left to you, the constructor to determine. With this in mind, there are some basic guidelines, but the rest is up to you.

Generally, use multi-stranded insulated wire for connections.

Multi-stranded wire types and uses

- **FOR low voltage, low power connections a suitable choice is known as 7/0.2 equipment wire (which means it has seven strands of wire, each one being 0.2 mm in diameter).** This is flexible and easy to route inside housings.

CONTINUED…

...CONTINUED

- **AN alternative to individual wires is ribbon cable (ie, several strands of insulated 7/0.2 wires, moulded together side-by-side).** Ribbon cable has an advantage over single equipment wire in that where multiple connection are made between internal parts, connections are grouped. Ribbon cable is available with each strand a different colour, which makes checking connections an easy job, too. Ribbon cable is available in 10-, 20-, and 30-way strips, but strips can be easily separated just by pulling, into the number of connected strands you want for each connection

- **MAINS or higher power connections must be made with thicker multi-stranded wire (eg, 16/0.2, 24/0.2, or 32/0.2).** Often the magazine or book will specify the exact type to use

As construction of the circuit and wiring goes on there may be instances where several lengths of wires follow the same route. As a matter of neatness, and to prevent wire movement (which could cause soldered joints to come apart) it's a good idea to tie the lengths together. Plastic cable ties are ideal for this job. An alternative is the cable clip, which comes with a double-sided adhesive pad to stick the clip onto a housing panel. Use ties or clips at least every 100 mm or so along panels, and at corners where the grouped wires go round.

▶ FYI ◀

In the 'good old days' tying of cables was done with special continuous cable tie cord, and was more a work of art than a technique. Fortunately, 'good old plastic' cable ties do an equally good job these days.

Where wires are grouped and tied or clipped together into cables, it can become tricky working out which wire is which. If you have a selection of coloured wires this can help, as can using coloured ribbon cable. But where you have more than just a few of these, you still might find it awkward. If this is the case, use cable markers. These are small plastic rings, placed over each end of wires before soldering. They can be coloured, and also numbered.

Mains wiring

The wiring of electronic circuits which use mains power bears particular mention. Mains power is, of course, dangerous — potentially lethal — and precautions must be taken when you intend to build a circuit which uses it.

General guidelines for mains wiring

- **IN general, use a metal housing for any electronic circuit you construct that has a mains power supply.** Use three-core mains cable (ie, with live, neutral, and earth wires), and make sure the cable enters the housing using a good quality cable entry clamp, properly tightened so that connections are not strained. A selection of cable entry clamps is shown in Figure 6.30. You must ensure the clamp is the correct size for the cable used.

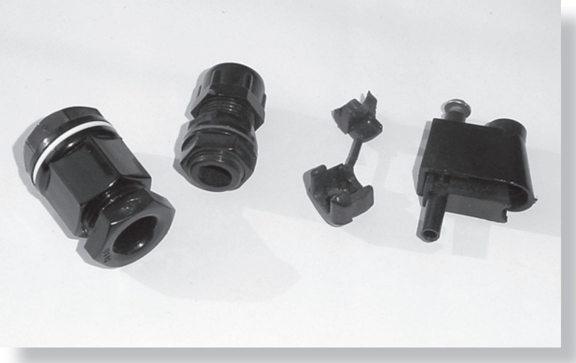

FIGURE 6.30 Cable entry clamps for use when mains cable enters a housing.

- **AN alternative to a cable entry clamp is a good quality plug and socket connector — such as that shown in Figure 6.21.**

- **USE insulating sleeving over all soldered connections, to ensure that no mains electrical parts are exposed.** Push the sleeving onto a wire prior to soldering it to a connection. After soldering push the sleeving back along the wire, and over the soldered joint, as in Figure 6.31.

CONTINUED…

...CONTINUED

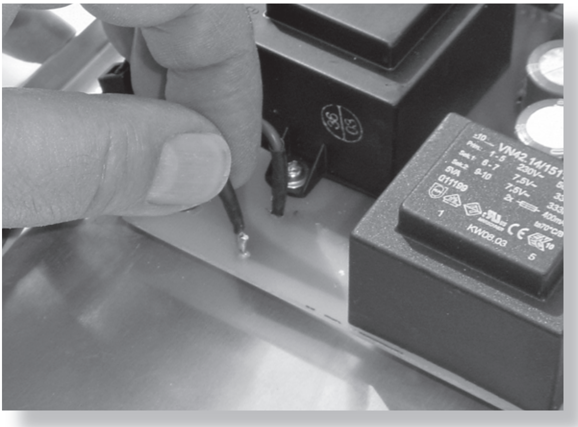

FIGURE 6.31 Using insulating sleeving over a mains circuit soldered joint. Here the joint has been made, and the sleeving is being pushed into position to cover the joint.

- **ALL soldered connections must be made good mechanically, prior to soldering.** Thus, if the soldered conection comes loose, the wire is still held in place.

- **MAINS live and neutral wires should go straight to an on/off switch.** Use a double-pole on-off switch for this purpose, and connect the live connection to one pole, and the neutral connection to the other. Such a switch ensures that the following circuitry is completely disconnected from mains when the switch is switched off.

- **TO protect the electronics circuit (and you, for that matter) from damage in case of an internal fault, use a panel-mounted fuse holder, with a fuse rating no greater than that specified in the magazine or book the electronic circuit comes from.** Mains live is taken directly from the other contact of the live pole of the on/off switch to the central connection of the fuse holder (thus, if the fuse is removed when the device is connected to mains, no contact can be made to a live part).

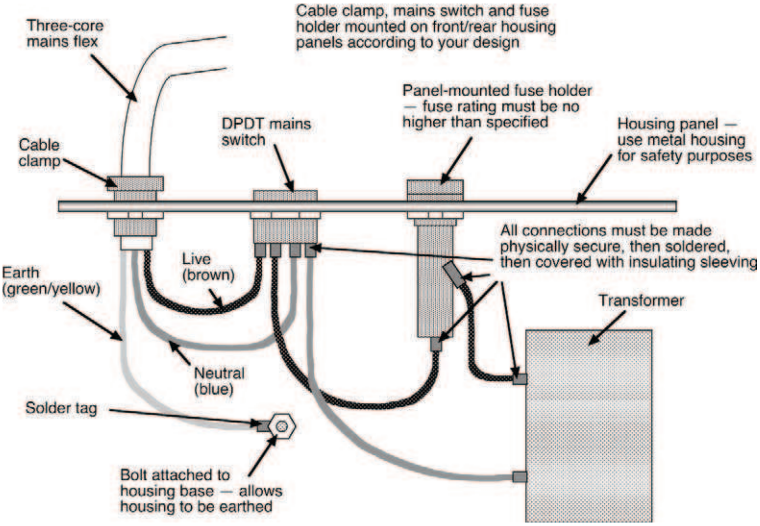
CONTINUED...

...CONTINUED

- **THE earth wire in the mains cable must go directly to a bolted connection on the housing chassis.** Use a solder tag on the earth wire, and shakeproof washers on the bolt, to ensure the bolted connection is reliable over the long term.

- **CHECK, double-check, and triple-check all connections and the circuit prior to connecting to mains power.**

Figure 6.32 shows a general wiring diagram for mains powered electronic circuits which follows these guidelines.



Three-core mains flex
Cable clamp, mains switch and fuse holder mounted on front/rear housing panels according to your design
Panel-mounted fuse holder — fuse rating must be no higher than specified
DPDT mains switch
Cable clamp
Housing panel — use metal housing for safety purposes
All connections must be made physically secure, then soldered, then covered with insulating sleeving
Live (brown)
Earth (green/yellow)
Transformer
Neutral (blue)
Solder tag
Bolt attached to housing base — allows housing to be earthed

FIGURE 6.32 A general wiring diagram for mains powered circuits.

Take Note

If a single-pole switch is used, even if it is in the live circuit on construction, at some stage somebody may rewire the mains plug incorrectly, at which point the switch is then in the neutral circuit and the remaining circuit will be live even if the switch is turned off! A double-pole switch prevents this situation.

Front and rear panel labelling

When an electronic circuit is mounted in a housing, and all connectors and controls are fitted, then the device is ready for use. Well, not quite!

The main interface between you and the electronic circuit you've just made is the housing's front panel and all its controls and connections. With maybe just a couple of these, you probably remember what each is, or does. But if there are more than just a couple, it becomes increasingly difficult to remember. And if anyone else needs to use the device, how will they even know at all?

The answer is that your front panel (and possibly the rear panel if there are controls and connections round the back) should be labelled.

Labelling is all part of the process which is often called *finishing off*. The point is though, that far from being a process you undertake at the finish of building a circuit, you need to be considering the front and rear panel and its layout right at the very earliest design stages.

For a start, labelling can't possibly be the last thing you do — to put labels on, all controls and connections need to be removed so that you can work on a clean, flat panel. So, when you think about it, Labelling is not actually a finishing off process, it has to be done quite a bit earlier on in the whole build.

Panel labelling

Once you know the layout of the panels, and have drilled holes for all control and connectors you can start labelling. There are several methods for this. The simplest would be merely writing the labels on with a permanent ink marker pen, but of course that would not make a particularly good-looking end result.

A much better method however is to use rub-down transfer letters. These are available in hundreds of typefaces (more commonly called fonts and sizes), and it is quite simple to create a good effect with a bit of practice.

Transfers such as these are available in sheets, and any good stationers will stock them or order them for you. Ask to see their catalogues to see the range of typefaces available.

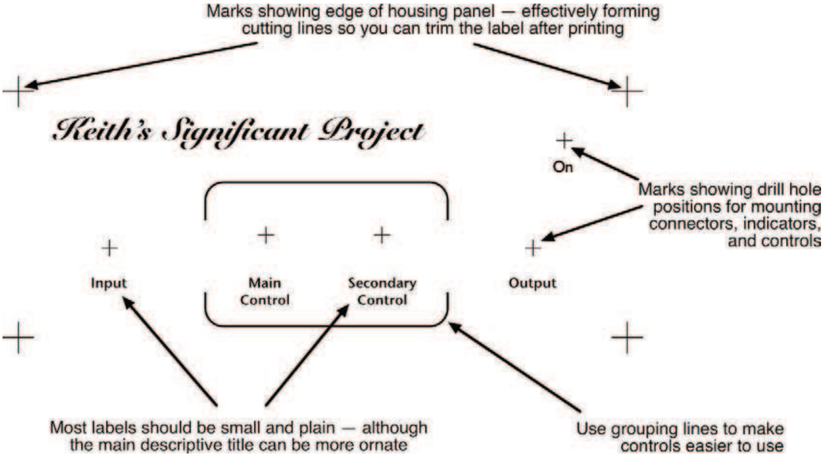
Key points when labelling with rub-down transfers:

- **USE guidelines to ensure labels are level.** Rule faint lines in pencil, or stick lengths of tape along the length of the panel
- **TAKE care when centring labels around controls or connections — if they go too far to one side or the other they will look odd**
- **GROUP controls and connectors where you can.** Perhaps ring them using some rub-down transfer lines, so that they appear cohesive in one part of the panel
- **USE a typeface of only a few millimetres high for most labels.** This equates to a publishing measurement (in points), of around 12 to 16 points
- **USE a plain typeface for most labels.** In publishing-speak, this could be a sans serif font
- **USE a more ornate typeface if you want for the main descriptive label — eg, Audio Amplifier.**

Using a computer

If you have access to a computer, you can use it to aid when labelling a housing. First you can design the panel layout on screen, simply to give yourself a good idea of what looks good — even if you opt to use rub-down transfer lettering to actually do the labelling in the end. All you need is a fairly basic illustration application of some description on your computer. There are several such applications available, and even a fairly basic image manipulation application (such as you probably have bundled with your printer, for working with photographs, say) can often produce good results. All it needs to be able to do is to use the range of fonts and sizes your computer already has installed, and perhaps draw a few lines. Of course, a proper illustration application is best.

Designing a good-looking label is not rocket science — the key points above can help. The advantage of designing the panel on a computer screen, though, is that you can make adjustments until you get it just right. Figure 6.33 shows the sort of label you can hope to create using a computer. Note the outside marks, which act as registration marks to make sure the label will fit the panel exactly.



Marks showing edge of housing panel — effectively forming cutting lines so you can trim the label after printing

Input
Main Control
Secondary Control
Output
Most labels should be small and plain — although the main descriptive title can be more ornate
Use grouping lines to make controls easier to use

FIGURE 6.33 A computer-generated front panel.

Better than this though, after you have designed the panel label on screen, you can print it out using a printer, then attach the whole label to the housing panel in one step. You don't even need a particularly expensive printer to do this — most modern inkjet printers produced over the last few years would work. As you are printing the label, you are not restricted to just monochrome, and judicial use of colours can be used to make the housing more attractive.

Simplest way here is to print the design onto photographic paper (glossy or matt, whichever you prefer). The paper can be trimmed to size, then stuck to the housing panel using adhesive (a spray adhesive is ideal for this task).

Alternatively, if your printer is capable, you can print the design onto acetate transparency. Print the design in mirror-image format on the back of the acetate sheet, then trim the acetate to fit. Stick the acetate onto paper (white or coloured, for the desired effect), then stick the whole thing onto the housing panel.

One of the best methods of labelling using a computer is with the Quick-Laser system, shown in Figure 6.34. In this process, special coloured polyester sheets with optional, die-cut and peel-off sections (similar in principle to address labels for envelopes) are used together with a laser printer to produce very high-quality self-adhesive labels.

House!

Finally, after you've labelled the housing, you can refit the controls and connectors, and your electronic device is complete. Congratulate yourself!

7

Fault-finding

At some time or another, anyone and everyone who has more than a passing interest in electronics has built a circuit up, perhaps spending a great deal of time not to mention money in doing so, only to find that it doesn't work. Even the professionals encounter this, so what chance have people like you or I got in producing a working and reliable circuit?

Well, fortunately, we have a remarkably good chance of doing so, particularly if we follow a fairly logical and straightforward approach to *building* electronic circuits in the first place. Fortunately also, in the vast majority of cases the reasons why circuits don't work is that there is some form of easily identifiable mechanical fault.

So, by a combined strategy of building electronics circuits properly in the first place (so that they *do* work first time usually), and being able to identify and correct the cause or causes of them *not* working in the second place, then we all stand an extremely good chance of being able to produce working circuits.

That is what this chapter, indeed, what this whole *book*, is all about — producing a combined strategy of proper building techniques so that (hopefully) circuits *will* work first time, together with the means of identifying the problems and faults in those circuits that do not work first time.

Hint

Remember: fault-finding is not just about locating what you've done wrong after you think you've finished – it's about locating what you did wrong BEFORE you think you'd finished...

A strategy of building electronic circuits

With all this in mind, it's obvious that to prevent faults in a circuit which you will have to spend time fault-finding later, it's better to take care when building your circuit in the first place so that the faults simply don't occur. Remember the old saying: a stitch in time saves nine.

As such, I'm going to give you, first, a fairly straightforward list of things that you should do when building an electronic circuit which, if you *do* follow will help to largely negate the need for fault-finding afterwards. This list is based on a knowledge of what faults typically do occur in electronic circuits, and what's more, why those faults occur. At the end of the chapter, I'll then give you a method of fault-finding which will see you in good stead for the rest of your electronics constructional life.

A Strategy To Follow

KEEP CLEAN — every part of the electronic circuit. Printed circuit board track, component leads and so on can all be affected by dirt and grease to the extent that soldered joints are not properly made. Worse, dirt or grease in a joint can affect its performance over time — it might work initially but stop working after a short while. Often, just cleaning the parts is enough to ensure a good joint.

CLOSELY INSPECT — the printed circuit board. Your complete electronic device depends totally on the printed circuit board. A minor imperfection (such as a crack in the copper foil track), or a hairline short circuit of copper between tracks which are not intended to be connected will prevent a circuit from working.

DOUBLE-CHECK — component values. Check once when you choose a component that it is the correct value, then check it again after it's been inserted in the board immediately prior to soldering.

DOUBLE-CHECK — polarized components. Electrolytic capacitors, semiconductors and so on must be inserted into a circuit the right way round (this is called *correct polarization*). Check their polarity is correct once when you insert the component in the board, then once more immediately prior to soldering.

TRIPLE-CHECK — component positioning. As you select a component for insertion into a printed circuit board, check its value on the circuit diagram. Next, check that the position on the printed circuit board is correct according to the layout diagram. Finally, after insertion, recheck both value and position again immediately prior to soldering.

DO NOT — insert more than a handful of components in at a time. If you insert too many components in to a printed circuit board before soldering them in, they may slip partially out of the circuit board. This may create short circuits that affect the circuit's operation. Only insert a few components before soldering them in, then moving on to the next batch.

WHEN SOLDERING — make sure each and every joint is properly made. Check each joint visually immediately after making the joint. Do not make hundreds of joints one after another without checking. Read Chapter 5 thoroughly, and practise making soldered joints until you can make a good joint *every* time.

AFTER SOLDERING — but before testing. Check for shorts between joints, and check for dry joints.

BUILD STAGES — and test as you go along. Divide the complete circuit into complete functional units (most — if not all — circuits can be thought of this way) and build each stage up in turn. As you finish one stage you can test it, before moving on to build up and test the next stage. In this way, if you *do* have a fault, you have isolated it in the production stage, and so can repair it more easily than if the complete circuit is built.

POWER ON — as a last resort only. Inevitably, when you have finished your printed circuit board you want to connect power and see if it works. The problem is — if you do and there is a fault such as a short circuit, or if polarized components have been inserted the wrong way round, or if components of the wrong value have been inserted, or for any number of other reasons — you could easily cause irreperable damage to components. Take time out for a few minutes, then inspect the printed circuit board carefully — use a magnifying glass if you have one, to see if you can find any possible faults. Remember: once you've connected the printed circuit board to its power supply it might be too late — a simple fault becomes a big-time problem…

Types of faults

If I was to be pinned down on this issue, I would have to say that in 99.9999999999999999 (OK, that's enough!) per cent of cases, the reason (or reasons) why a circuit does not work is due to a mechanical fault introduced by the person making the circuit. Very rarely — and I do mean *very* rarely — the reason why a circuit does not work properly first time is due to a faulty component. This is, quite simply, because electronic components are made to a pretty high standard, and are quality controlled so that you may rarely expect one to not work. Even more rare are those faults which occur due to a circuit (an incorrectly specified component, say, or an error in circuit design).

As a result, when a circuit you have built does not work, the first and most important thing to do is assume *you* are at fault — not the components. The second thing to do is look closely at what you have done — to find out where you have gone wrong.

With this in mind, you can now try to isolate the reason why the electronic circuit you've built doesn't work. Check things in the following order:

Finding faults? Walk this way:

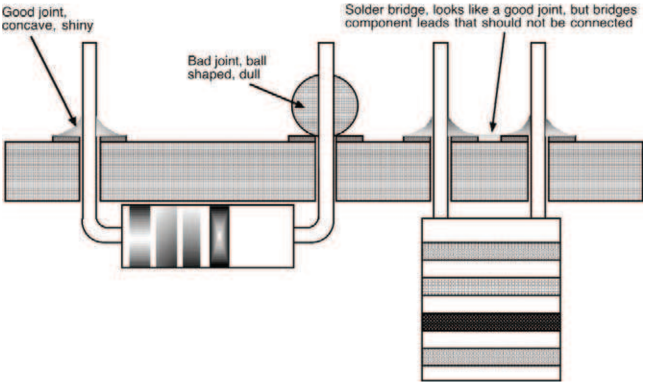
- **SOLDERED joint faults**
- **PCB faults**
- **WIRING faults**

Once you've thoroughly checked, and are happy that your soldering, your pcb and your wiring is not at fault, then — and only then — you should begin to consider the remaining potential causes of faults:

- **CONNECTORS**
- **COMPONENTS.**

Soldered joint faults

Basically, there are two types of faults that can occur when soldering. The first is just a bad, or dry joint. The second is a solder bridge. Figure 7.1 compares a good joint with a bad joint and a solder bridge. Good joints tend to be concave and shiny in appearance. Bad joints tend to be blobby (to the point of being ball-shaped) and may be dull in appearance. Solder bridges form between copper tracks on the printed circuit board. In many cases of bad or bridged joints you can isolate each merely with a close visual inspection. It helps, though, if you have a magnifying glass and good lighting.



Good joint, concave, shiny
Bad joint, ball shaped, dull
Solder bridge, looks like a good joint, but bridges component leads that should not be connected

FIGURE 7.1 A good joint, a bad joint, and a solder bridge.

If you spot bad joints, they will need to be resoldered. Note that one of the main causes of a bad joint is that the joint was not hot enough before solder was applied, so when resoldering a bad joint, make sure it gets sufficiently hot first.

If you spot bridged joints, you need to reheat the joint and remove the excess solder. Use either desoldering braid or a desoldering pump for this task, but remember that once the solder has been removed you will need to reapply fresh solder to make the joint again.

PCB faults

Particularly if you make your own printed circuit boards — although even if you buy them ready-made — you should be aware that they can have faults. So, no matter how good your soldering or circuit building techniques are, they will never be able to produce a working electronic circuit. A good procedure would therefore be to check the printed circuit board, before you even start to solder components into it.

Look for three things:

- **1 Bridges between adjacent copper tracks.** Sometimes, if the etching process hasn't fully completed before the printed circuit board is removed from the etchant, or if small areas of etch-resist have not been developed fully, small bridges of copper remain between tracks. Sometimes these bridges can be extremely thin, but even a hairline bridge forms a short circuit. Thoroughly check all copper tracks of the printed circuit board — a magnifying glass and good lighting helps. If you spot what you think is a bridge, you can confirm it using a multimeter set to resistance measurement. Bear in mind that if you find one copper bridge, there is a good chance there will be more at other places on the printed circuit board

- **2 Broken tracks.** In the etching process, a small (even minute) break in the resist allows the etchant to remove the copper underneath. If the break in the resist cuts across a track, there will be a complete break in that track. The circuit built on that printed circuit board will not work correctly. Again, there is nothing for it but to first check the copper track visually. If you spot a broken track, clean the area to either side of the break with an abrasive scrubbing block or abrasive fibreglass pencil, then solder a joint which bridges the two sections of copper track

- **3 Incorrect or missing track.** The copper track on your printed circuit board is intended to represent and make all connections between components in the circuit diagram. If you have designed your own printed circuit board from a circuit diagram then made it yourself, there is the potential that somewhere in the copper foil track layout design process you have made an error. If the completed electronic circuit does not work, then as part of the fault-finding process you need to double-check your printed circuit board's copper foil track layout. Make sure that all connections on the circuit diagram have a corresponding connection on the copper foil track — if any connections are missing, then the circuit parts are effectively open circuit. If you find any connections missing, make them using a small length of 7/0.2 wire. Strip a very short amount of insulation from each end of the wire, then tin each end before soldering it into place to make the missing connection. Also make sure there are no *extra* connections (possibly forming what amounts to short circuits between circuit parts) that should not be in the copper foil track. If you find a connection present that should not be, cut through the copper track using a craft knife or similar to break it.

Wiring faults

When constructing any electronic device, mounting the printed circuit board in a housing, then connecting the printed circuit board to controls and connectors, wiring is always an issue and a potential area for faults to arise. If you suspect wiring to be the problem (or, at least, you have gone through the processes above and the circuit *still* does not work), check the wiring against the wiring diagram. Isolate each connection in turn between the printed circuit board and housing-mounted control and connectors, and make sure each end of it connects to its correct places. Look out for bad soldered joints at each end. Note that some connection terminals on connectors are relatively large metal terminals (at least in comparison with copper foil track connections), and soldering a connection to them requires significantly more heat than it does to printed circuit board joints. As a result, it’s easy to make a bad joint to such terminals. Resolder any joints that look in any way suspect.

Connectors

After soldering errors, printed circuit board faults, and wiring errors, the next most important cause of faults in electronic devices is that due to connector faults. Most of these occur after time and use, but you still must consider connectors as a potential cause for faults if you have worked through all the processes covered already in this chapter.

It is often easy to check that a connector is doing its job by using a multimeter set to resistance measurement mode. If resistance is infinite between one end of the connector and the other, the connection is open circuit. If two or more terminals on one side of the connector have zero resistance between them, the connections are short circuited.

Components

Finally, once you have gone through all the processes above to check soldered joints, printed circuit board copper foil tracks, wiring, and connectors, you can begin to suspect that one or more of the components is faulty.

Bear in mind though, that it may even be that one of the faults you have already found as you work through the processes in this chapter has actually caused one or more of the components on the printed circuit board to be damaged. A short circuit due to a solder bridge or copper track bridge, say, might cause sufficient current to pass through a component not designed to cope with the current to be damaged. So, even though you might have found one fault (or more) in your soldering or the printed circuit board, or the wiring, others may have been created by this.

Down with fault-finding

It's not the intention of this book to cover all fault-finding processes when all the processes have been followed and we are finally down to component level. There are, though, many other books on this topic. Just remember that fault-finding at component level must be the very last resort.

Instead, my intention in this book is to help the beginner to the construction of electronic circuits and devices see that fault-finding is not a process distinct and separate from the construction processes. Fault-finding should be, in fact, completely integral with the constructional processes.

Indeed, it should be *so* integral that checking for faults and correcting them as they occur should be natural to the constructor. So integral that you shouldn't even *think* of fault-finding as a distinct and separate process at all.

With this in mind, shown opposite is a method of fault-finding which comprises a general list of things to do and bear in mind as you construct any electronic circuit or device. As you become more experienced in electronics construction, the list should begin to become second nature to you.

Picture this!

So far, we've only looked at the theory behind fault-finding, trying to isolate the areas where faults can arise, what sorts of faults there may be, and what causes them. For the rest of this chapter we can take a look at what these faults actually look like.

Fortunately, several mechanical printed circuit board faults can be fairly readily identified with a close visual inspection. However, for the beginner to electronics construction (and, indeed, for even the not-such-a-beginnner!) it's not always *easy* to identify them, simply because finding something when you don't know what it looks like is like looking for a needle in a haystack when you're blindfolded.

So, for the remainder of this chapter, some photographs of the most common printed circuit board soldering faults are given, in Figures 7.2 to 7.14.

A total method of fault-finding:

- **KNOW the circuit, and how it works.** Break it up into logical *black box* sections. Often, the magazine or book giving the circuit will do this for you, in a separate 'How it Works' section, but if not, try to do it yourself. The more you understand how a circuit works, the easier it becomes to construct and get working!

- **CHECK the plain printed circuit board.** Check it for any short circuits. Check it for any broken tracks. Check that it follows the circuit, with copper foil track for every connection within the circuit, and with no extra connections

- **BUILD one section of the circuit at a time.** Insert and solder only those components within that section, then check the section works fully before you start the next section. If one section does not work, find and correct the fault before you start the next section. This way, any faults should lie only in the last section you built

- **ONCE the printed circuit board is complete, with all components 'stuffed', check that it works.** If not, as long as you have been following this method, the fault should again lie in the last section you built

- **HOUSE the printed circuit board, together with controls and connectors**

- **CHECK the complete and housed device.**

Blistering or lifting — where copper track lifts from the board surface, usually due to excessive soldering heat.

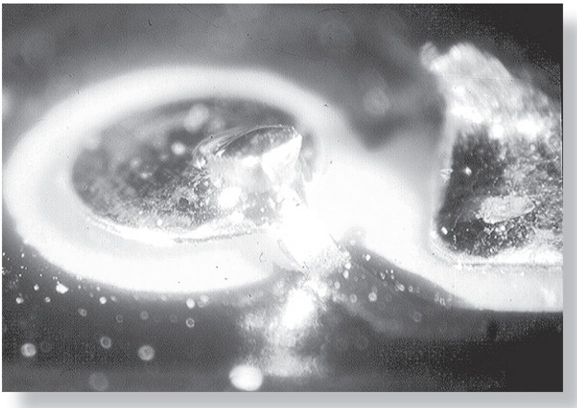


FIGURE 7.2 Lifted pads on a printed circuit board.

Bridging or shorts — where solder joins two or more conductive parts which are not meant to be connected.

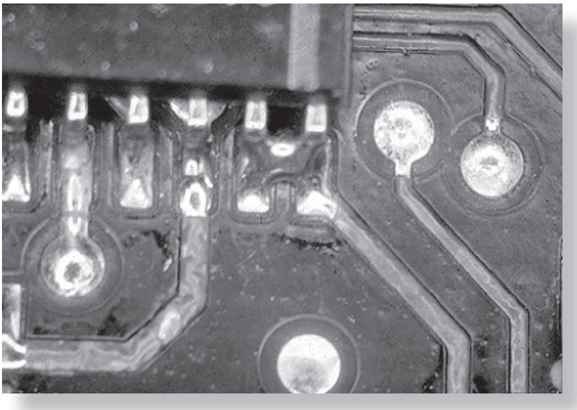

FIGURE 7.3 Solder bridging between connection pins of an integrated circuit.

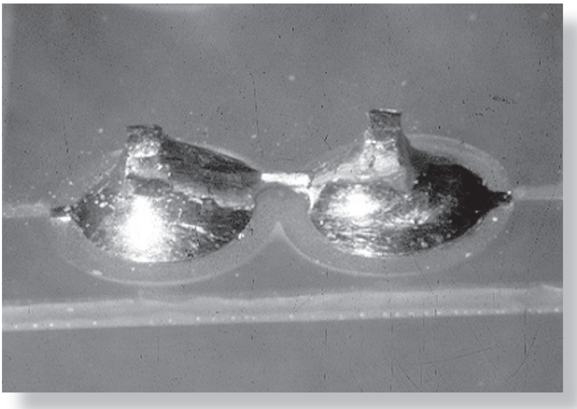

FIGURE 7.4 A minute solder bridge between two component pads.

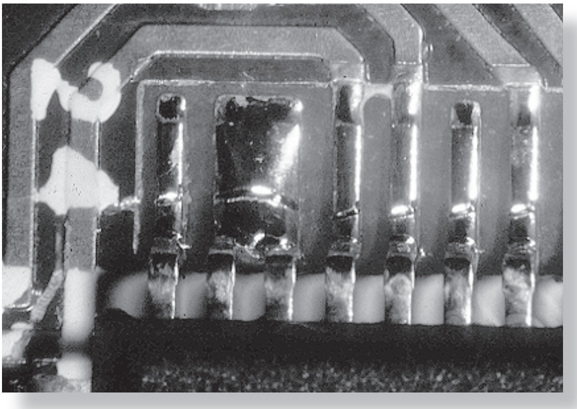

FIGURE 7.5 Solder bridging between adjacent printed circuit board tracks.

Components lifting — where components become displaced between stuffing and soldering. Faults like these don't necessarily cause the circuit to malfunction by themselves, but components that do lift may short to adjacent components.

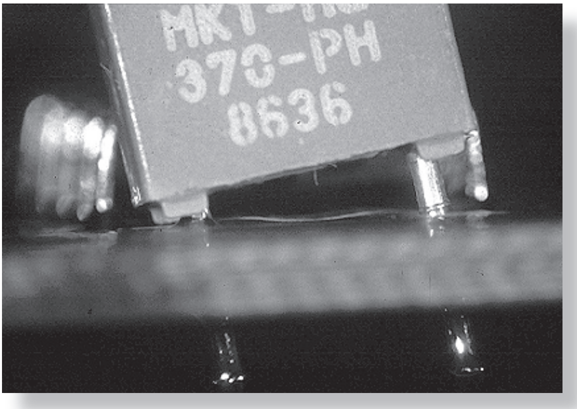

FIGURE 7.6 A capacitor that has lifted.

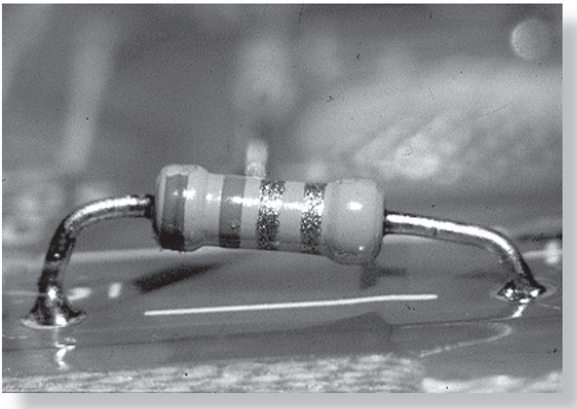

FIGURE 7.7 A lifted resistor.

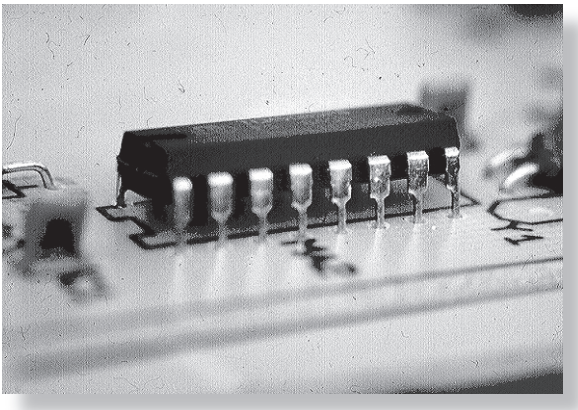

FIGURE 7.8 An integrated circuit that has lifted.

Cracked joint — if a printed circuit board is not adequately fixed in position in a housing, occasionally soldered joints that come under mechanical stress can crack, thereby creating a broken connection. The hairline cracks so caused are very easy to miss under normal visual inspection — a magnifying glass is usually required to see them.

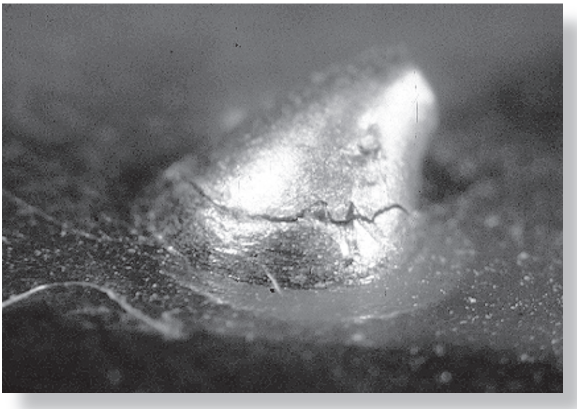

FIGURE 7.9 A cracked joint.

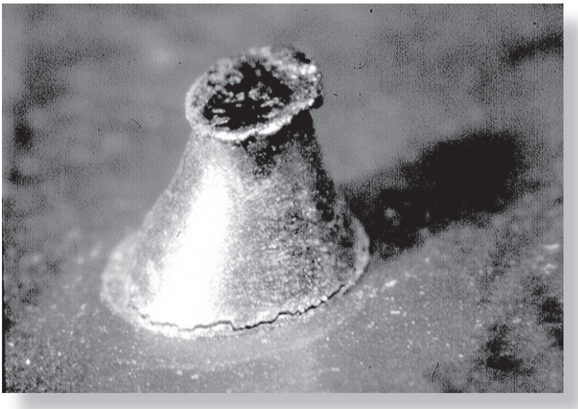

Figure 7.10 Another cracked joint.

Dewetting — where an initial bond is formed when soldering, followed by a withdrawal of solder from the joint, leaving irregular shaped mounds of solder separated by areas covered only with a thin solder film.

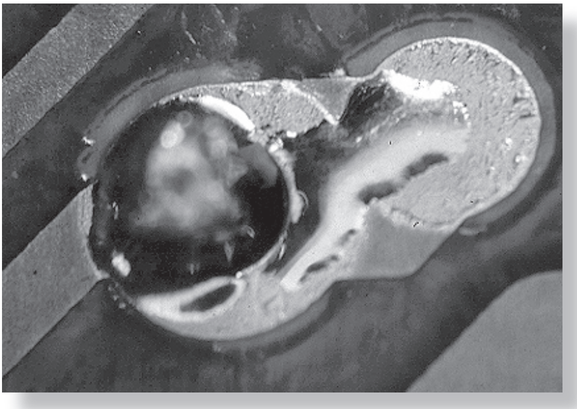

Figure 7.11 Dewetting between two connected component lands.

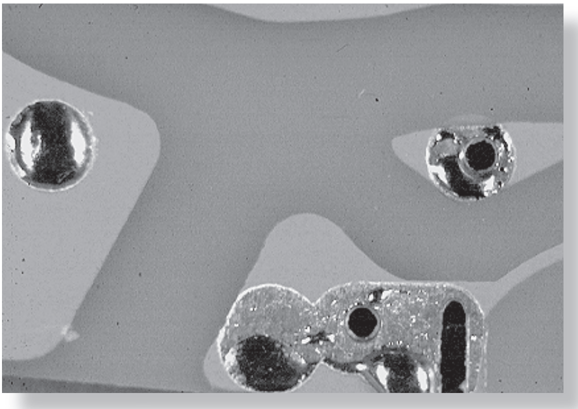

Figure 7.12 Dewetting of component lands.

Excessive solder — too much solder on a joint — this may also cause bridging with local lands.

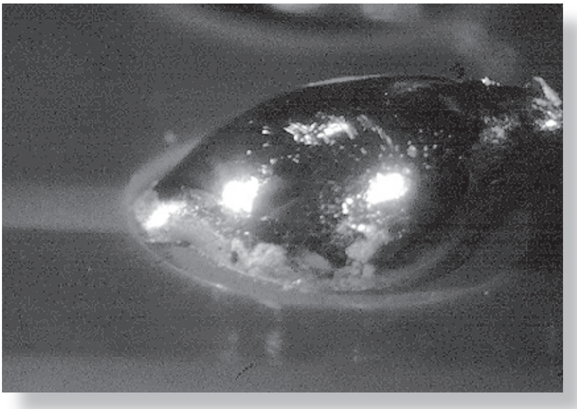

Figure 7.13 Excessive solder looks like a blob on the printed circuit board.

Solder voids — too little solder on a joint creates a potential weakness.

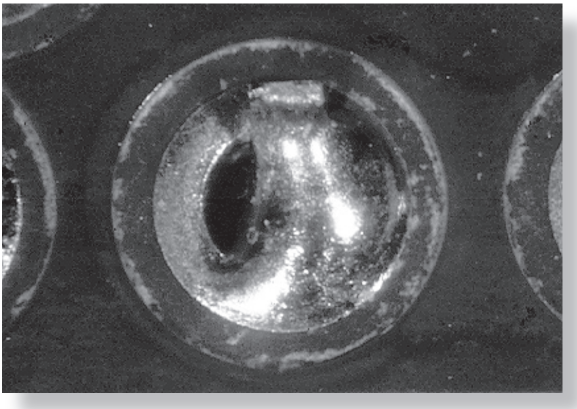

FIGURE 7.14 A solder void on a component land.

8

Projects

While this book so far has been quite theoretical in parts, I hope I haven’t lost you all to sleep…

To wake you up again if you did succumb to the effects of boredom while I’ve waffled on, I’ve included some projects in this chapter that you can choose to construct if you want.

Even if you choose *not* to construct them, the projects are still highly useful, in that they illustrate many of the processes that I have covered throughout the book. They are graded to a limited extent — the first ones being easiest to build and the later ones being harder. That’s not to say that if you want to construct one of the later circuits first you shouldn’t be put off by its greater practical requirements — with the exception of the last project — the mains-powered Bench Power Supply. The principles, after all, of contructing any electronics circuit are the same whatever the complexity, and are covered in detail throughout this book. So, if you decide to build any of the projects, hopefully all the information you need to do so is somewhere in these pages for you to read.

Take Note

The last project – a mains-powered power supply – should not be attempted unless you are confident of your skills. Mains voltages are dangerous – potentially lethal – and extreme care must be exercised when constructing the project to prevent a situation arising where a user comes into contact with those voltages.

In short, if you are not confident of your skills, and do not take requisite care – do not construct this project!

The projects

I thought long and hard about these projects, trying to weigh up complexity, ease-of-construction, and usefulness, aiming to get a balance between all three. What I decided early on was to promote what I feel is the *best* way of constructing projects, not necessarily the easiest. For instance, I have eschewed the use of stripboard construction, instead giving only printed circuit board descriptions and layouts. My reason in doing that is because stripboard is, in essence, merely a prototyping method of construction, not the sort of method I want to promote to my readers in the final projects in my book.

My feeling is though, that in a modern electronic circuit, the printed circuit board is as much a component of the final device as any other part. It is not merely a method of making connections between parts of a device — it is a part of the device in its own right! Indeed, in many circuits, how the printed circuit board is made, how it is designed, where all the components are physically placed in relation to each other, and in fact what it is made of, can all define how the circuit works, or even *whether* the circuit works.

Likewise, though not so important to the working of an electronic circuit, the housing used for a circuit is worth bearing in mind. A good housing can help to make a good electronic device; a poor housing inevitably makes a poor device. You can't make a silk purse from a sow's ear, and if your project is housed in a sow's ear of a housing, then no matter how well the circuit works, no matter how much hard graft you've put into it, your project simply can't be a silk purse.

So, on to the projects themselves. There are four, listed with brief details and grading for complexity below.

The four projects:

1. **Car-to-USB Power Supply.** Allows certain devices (digital audio players, mobile phones and so on) to be powered and recharged in your car. *Easy*.
2. **Heart Flasher.** Fun device to show your love. *Moderate*.
3. **Guitar Headphone Amplifier.** Don't wake the neighbours while fingering your frets. *Moderate*.
4. **Bench Power Supply.** Useful test-bench equipment you can use to power other circuits you build. *Hard*.

Note that even though I class them as being between easy and hard to build, none of them is beyond the scope of most competent DIY-ers and, with the exception of the Bench Power Pupply (which is mains-powered), you shouldn't worry too much about things going wrong, as the only damage you're likely to do even if you bodge up totally is to ruin a couple of cheap electronic components.

Furthermore, if you read this book first, and follow constructional details given here, things shouldn't go wrong at all.

Car-to-USB Power Supply

These days, rechargeable battery-powered consumer devices are becoming increasingly more complex. As many of them are now often linked with computers, they can often be recharged via the computer connection. *Digital audio players* (sometimes called *mp3 players* — a misnomer, as most play music files in other formats than just mp3) are the commonest such device, although some mobile phones and other devices seem to be going the same way.

A computer connection most commonly relies on a *universal serial bus* (*USB*) connection, from which the device can obtain its recharging power, as the USB interface allows a certain level of power (5 V, at up to 500 mA) through the connector. Away from a computer, however, users have to rely on another source or recharging power if the battery runs low on their devices. Typically, this is in the form of a mains-powered recharger. This is fine if you are within reach of a mains power socket. Not so fine though if you are further afield than that — in the car, say. A useful project if you have a USB-rechargeable device is therefore the Car-to-USB Power Supply — shown in Figure 8.1, and detailed first.

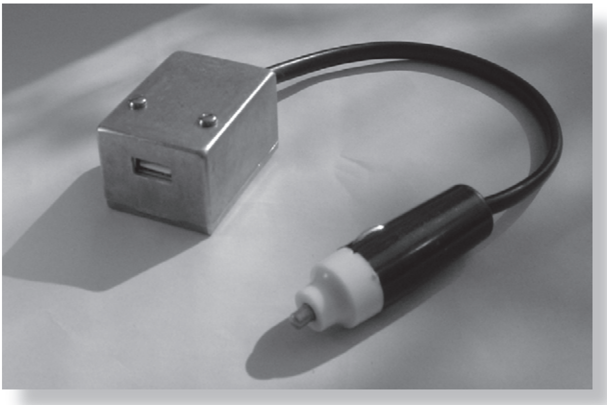

FIGURE 8.1 The Car-to-USB Power Supply.

Principle

The Car-to-USB Power Supply project here uses a car's internal low voltage electrical circuit to allow a USB-rechargeable device to be recharged. It does this by connecting to the car's electrical circuit using a cigar lighter plug that plugs into the car's cigar lighter socket. The low voltage (between about 11 V and 14 V DC) is regulated within the Car-to-USB Power Supply down to exactly 5 V DC, and supplied to a standard USB A-type socket (the same sort that's on any modern personal computer).

The principle of the Car-to-USB Power Supply is shown in Figure 8.2, where these three main stages are identified.

Take Note

The output from the Car-to-USB Power Supply project is not suitable for direct connection to rechargeable batteries, so you shouldn't use it to connect straight to, say, a battery pack. Such packs require some form of control circuitry to ensure only the correct recharge voltage and current is applied. The output of the Car-to-USB Power Supply is a basic 5 V DC regulated supply at up to 1 A, and control circuitry (always present within a rechargeable battery-powered consumer device) is still required.

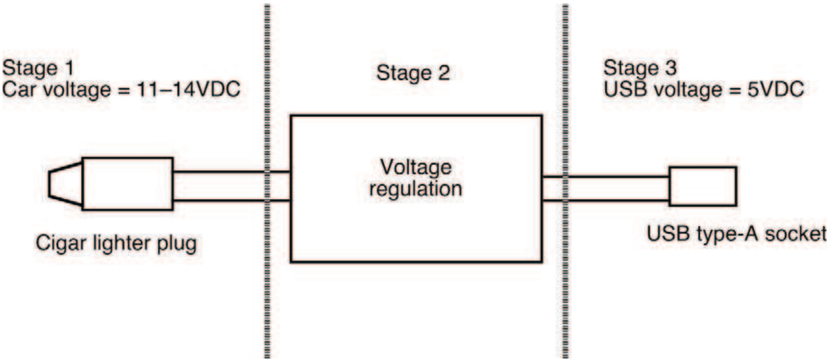

FIGURE 8.2 The Car-to-USB Power Supply principle.

Circuit

The Car-to-USB Power Supply circuit is shown in Figure 8.3. It's not the world's most complicated circuit as you'll appreciate, with the grand total of only five components. It does however, introduce an important principle — that of the integrated circuit voltage regulator (IC1). Voltage regulation is a process whereby an unregulated or varying DC voltage is changed to a regulated or fixed one. In this project a car's main voltage is around 12 V DC, but can vary between about 11 V and 14 V, depending on the state of the car battery and whether the engine is running, so is effectively unregulated. The USB specification, on the other hand, calls for a regulated 5 V DC supply. So what is required is a voltage regulator that takes the unregulated input of 11 to 14 V DC, and gives a regulated output of the required 5 V DC. Integrated circuit IC1 does just that.

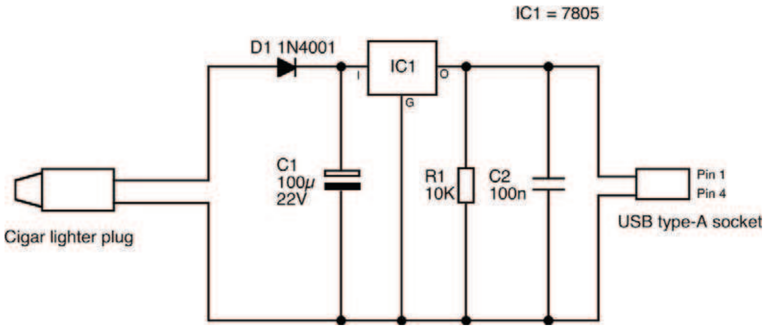

FIGURE 8.3 **The Car-to-USB Power Supply circuit.**

The remainder of the circuit merely aids this. Diode D1 protects the remainder of the circuit against reverse polarity connection (say, if you wired the project incorrectly so the input voltage was reversed). Capacitor C1 acts as a current reservoir, ensuring that sharp voltage peaks and troughs don't pass through the circuit to the output. Resistor R1 and capacitor C2 aid this.

Construction

Voltage regulator IC1 has a maximum voltage dropped across it of about 9 V (the maximum 14 V car voltage, minus the 5 V output voltage). At the USB specification of a maximum of 500 mA, the maximum power it dissipates is:

$$P = IV = 500 \text{ mA} \times 9 \text{ V} = 4.5 \text{ watts}$$

As a result, there is a potential heat problem if the voltage regulator is free-standing while operating in worst-case conditions, and it requires some form of heatsinking to aid heat dissipation and keep it cooler. The easiest way to provide heatsinking is — and that's the method used here — to bolt it to a metal housing. The metal housing conducts heat away from the voltage regulator quite efficiently.

FYI

Actually, voltage regulators like IC1 are protected from overheating by their internal circuitry. If such a voltage regulator gets too hot, an internal thermal cutout control turns the output supply off until it cools down again. Heatsinking merely aids in preventing the cutout situation happening.

None of the components are critical. Any of the 7805 variety of 1 A voltage regulators is usable, and neither the resistor nor the capacitors need to be closely matched. Capacitor C1 should have a voltage specification of at least the car's voltage, so 16 V is the next highest standard limit. The only component which needs matching in any way is the USB socket — as it's a board-mounting variety you should make sure you obtain the correct fitment. Alternatively, you could just adapt the printed circuit board copper foil track layout to suit the one you buy.

The printed circuit board layout is shown in Figure 8.4. Start construction by fitting and soldering the terminal pins, diode D1, resistor R1 and capacitors C1 and C2 into the printed circuit board, checking polarity of the electrolytic capacitor C1 prior to soldering.

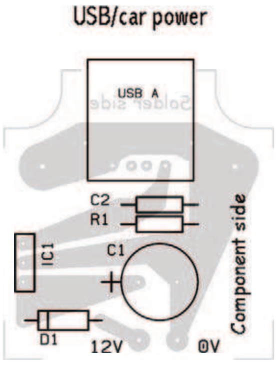

FIGURE 8.4 Printed circuit board layout of the Car-to-USB Power Supply (actual size).

Next up, fit the USB connector to the board. Note that it has four connection terminals, while two extra tabs are used to hold the whole socket in place. The tabs require larger holes (about 2 mm) to be drilled prior to mounting. Bend the lugs of the extra tabs over once the socket is in place on the printed circuit board, to provide extra strength. Solder the tabs to the printed circuit board along with the four terminals.

Take Note

The four connection terminals of a USB type-A socket are numbered as shown in Figure 8.5.

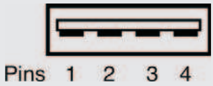

FIGURE 8.5 USB type-A socket, as viewed from the outside.

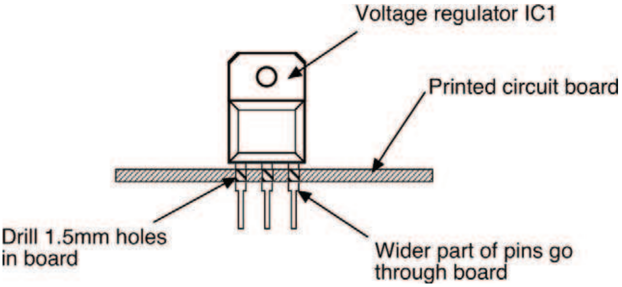
Now fit the voltage regulator IC1 — note though that if you intend using a small diecast metal housing like the one used in the project here, the regulator must be fitted very close to the printed circuit board, with only 1 or 2 mm clearance, in order that there is enough room for the completed printed circuit board to fit inside the housing. To allow the regulator to fit this closely to the printed circuit board, the component holes need to be larger than 1 mm to allow the wide top end of the regulator pins to go through the board — as shown in Figure 8.6. Use a 1.5 mm drill for these holes.



Voltage regulator IC1
Printed circuit board
Drill 1.5mm holes in board
Wider part of pins go through board

FIGURE 8.6 Fit the voltage regulator close to the board to reduce its height – this way, a smaller housing can be used.

Now solder the ends of the connection lead to the terminal pins. This completes the printed circuit board construction.

Drill the housing to take the cable clamp, the bolt to hold the voltage regulator, and two bolts for spacers. File a slot to take the USB connector. When complete, the housing should look something like that in Figure 8.7.

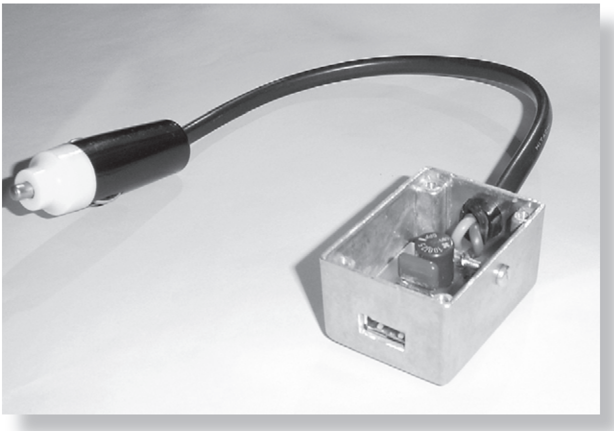


FIGURE 8.7 Showing holes and slot in the Car-to-USB Power Supply housing.

Fit the two printed circuit board mounting bolts to the inside of the housing, using washers and nuts to act as spacers (to prevent the soldered connections on the underside of the printed circuit from touching the metal housing). Next, feed the free end of the connection lead through the cable clamp hole. Rub some heatsink compound on the voltage regulator tab and on the inside of the housing where the regulator is to be bolted. Offer the complete printed circuit into place inside the housing onto the mounting bolts. Insert the voltage regulator bolt through from the outside, fitting a washer and nut on the inside. Fit washers and nuts to the mounting bolts to hold the printed circuit board in place. Tighten all bolts to hold the printed circuit board firmly.

Take Note

Note that no insulating washer is needed between the voltage regulator and the housing. The metal tab of the voltage regulator is at 0 V, so there is no risk of short circuiting between the voltage regulator and other components, or the housing and other parts within the car.

Finally, connect the cigar lighter plug to the free end of the connection lead. Make sure that polarity is correct — that is, the positive connection is the inner terminal of the plug.

Figure 8.8 shows the printed circuit board copper foil track layout.

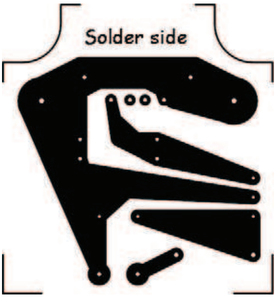

FIGURE 8.8 Printed circuit board copper foil track layout of the Car-to-USB Power Supply (actual size).

Parts list

Semiconductors

IC1	7805 voltage regulator
D1	IN4001 diode

Resistors

R1	10k 0.125 watt

Capacitors

C1	220µ, 16 V radial electrolytic
C2	100n polypropylene

Miscellaneous

Printed circuit board
Housing, diecast aluminium (approximate dimensions 52 by 38 by 32 mm)
USB type-A, printed circuit board-mounting socket
Car cigar lighter plug
Two-core insulated wire — to take at least 0.5 A
Cable clamp

Heart Flasher

OK, I admit it! This is just a fun thing. It's not a practical project at all really — scoring zero on a usefulness rating, it's just meant for a bit of a laugh. Nevertheless, the project does have some purpose, introducing readers to some solid electronic circuit concepts and providing a handy basis from which to practise some circuit building techniques.

The heart of the project — excuse the pun — is an array of light emitting diodes (LEDs), that flash on then off in an ordered and sequential manner, such that the physical shape of the array forms a heart appearance. Persistance of vision as the LEDs flash on and off means that to the observer the heart shape appears vibrant and pulsing (Figure 8.9). Just the thing to build and give to your loved one as, say a soppy Valentine's Day present, or just for fun.

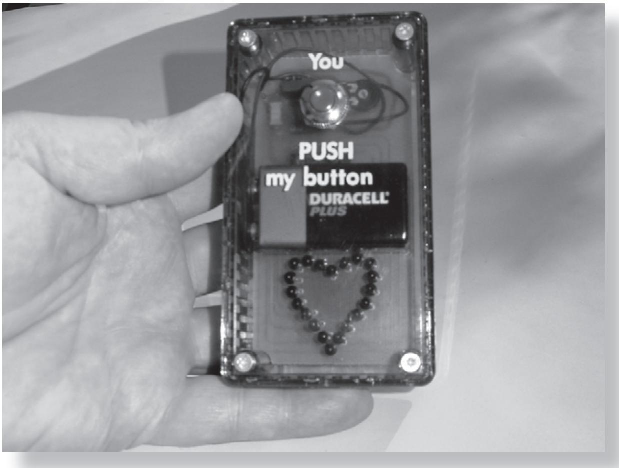

FIGURE 8.9 Wear your heart on your sleeve with the Heart Flasher.

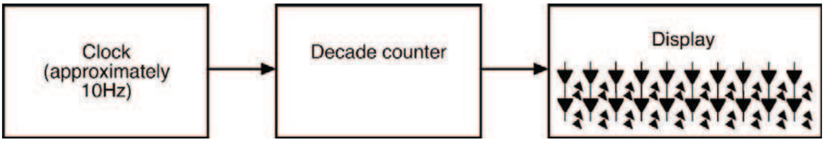
Principle

The Heart Flasher project has three main sections, shown in Figure 8.10. Section one is formed around a clock circuit that provides a constant electrical pulsing at a rate of approximately 10 cycles a second (10 Hz).



Clock
(approximately
10Hz)
Decade counter
Display

FIGURE 8.10 The principle of the Heart Flasher project.

The next section is a decade counter — a type of circuit that counts the incoming pulses from the clock, and issues output signals to each of ten outputs sequentially. Once the decade counter has counted ten input pulses from the clock, it cycles round to start at the first output again.

The final section of the circuit is an LED array. Some 20 LEDs are used, two per sequential output from the decade counter. The LEDs are formed into the shape of a heart, so that as they are cycled on and off, the visual impact is of a pulsing heart.

Circuit

The circuit of the Heart Flasher is given in Figure 8.11. Integrated circuit IC1 is a 555 timer, connected as an astable multivibrator, to provide a clock signal. Frequency of the astable multivibrator is given by the expression:

$$f = 1.44/C(R1 + 2[RV1 + R2])$$

which means that the frequency can be adjusted between about 50 Hz and 6 Hz.

FIGURE 8.11 Circuit of the Heart Flasher project.

The output (from pin 3 of integrated circuit IC1) is taken to the input of integrated circuit IC2, which is a 4017, divide-by-10 Johnson counter with decoded outputs. Integrated circuit IC2 presents a high logic level at each of its decoded outputs sequentially. While the outputs are shown in the circuit as from pins 1–7 and 9–11 of the integrated circuit, the outputs are not sequentially in this order. Figure 8.12 shows how the actual integrated circuit pin numbers correlate to the decade counter outputs.

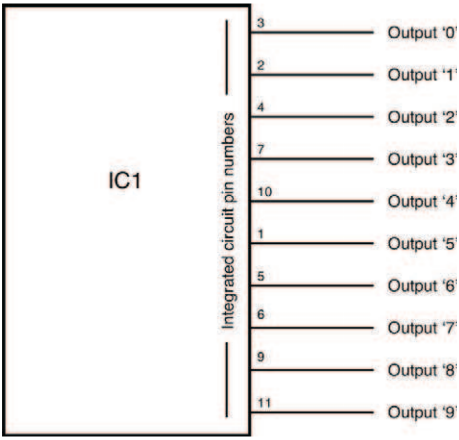

FIGURE 8.12 **Showing how the actual pin numbers of integrated circuit IC1 relate to the decade counter outputs.**

Light emitting diodes LEDs 1–20 form the heart-shaped array, driven directly by the decade counter outputs. Two LEDs are driven by each output, which means that the heart shape is actually made from ten pairs of LEDs, rather than twenty individual ones.

Construction

While construction of the project is not too complex, care must still be taken — particularly with the printed circuit board as it features many thin copper tracks and resultant small component pads. Soldering must therefore only be undertaken with a pretty fine soldering iron bit tip, and preferably only using no higher than a 15–20 watt soldering iron. Figure 8.13 shows the printed circuit layout and wiring connection details.

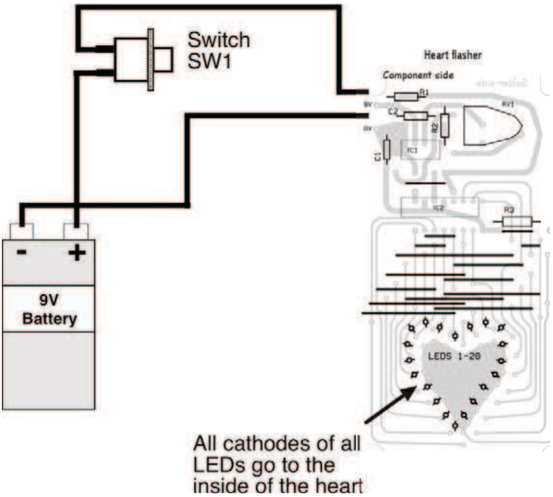

FIGURE 8.13 Printed circuit board layout and wiring connection details of the Heart Flasher.

First, make sure the printed circuit board fits snugly into the housing, filling out the corners to fit the housing corner posts. Insert and solder two terminal pins into the printed circuit board.

There are some fifteen wire links to be made on the printed circuit board, and these should be inserted and soldered next.

Insert and solder the remainder of the components in the following order: resistors, capacitors, integrated circuits, and finally the twenty LEDs. You can use an integrated circuit holder for integrated circuit IC1, but (if you use the same sized housing as used here) you should not use a holder for integrated circuit IC2 — the 9 V battery lies above this, and if IC2 is in a holder there will not be enough room. Make sure that all polarized components (ie, integrated circuits and LEDs) are the correct way round prior to soldering. Note that the cathodes of all LEDs go to the inside of the heart shape. Also, for visual purposes, make sure that all twenty LEDs are mounted at the same height above the board — approximately 10 mm.

Next, solder the battery connector and switch SW1 onto the printed circuit board.

Finally, mark and drill the housing to mount switch SW1, label the housing to suit, and complete the project.

Press switch SW1 to operate the Heart Flasher, and adjust the flash speed to suit by adjusting preset potentiometer RV1. While the flash speed is calculated to give a reasonable flash rate, you can adjust the overall speed by replacing resistors R1 and R2 with lower values to increase the flash rate, or higher values to slow it down.

Figure 8.14 shows the printed circuit board copper foil track layout.

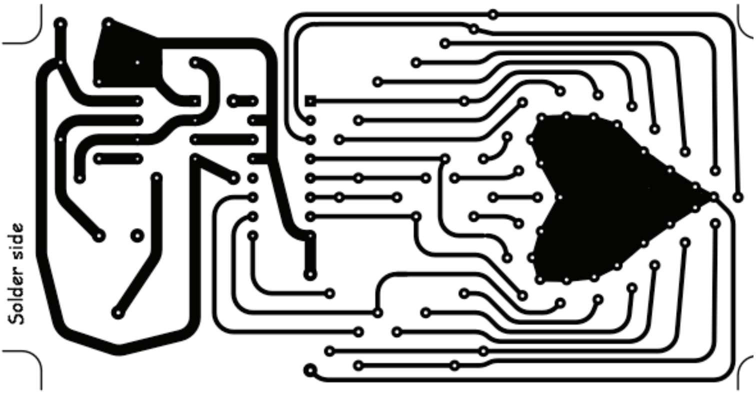

FIGURE 8.14 Printed circuit board copper foil track layout of the Heart Flasher (actual size).

Terminal pins

Guitar Headphone Amplifier

Are the neighbours giving you grief? Are you fed up with the complaints over your racket? Do you wish they'd all go away and leave you to practise alone? Well, with this Guitar Headphone Amplifier your problems could all be solved. You could slash your axe at the volume you want, without disturbing anyone else's peace.

The Guitar Headphone Amplifier here is a neat project that amplifies your electric guitar's output to a suitably loud level for even the most headstrong head basher, but with ordinary earphones. So no one else hears your playing. The grief disappears, and everyone's happy.

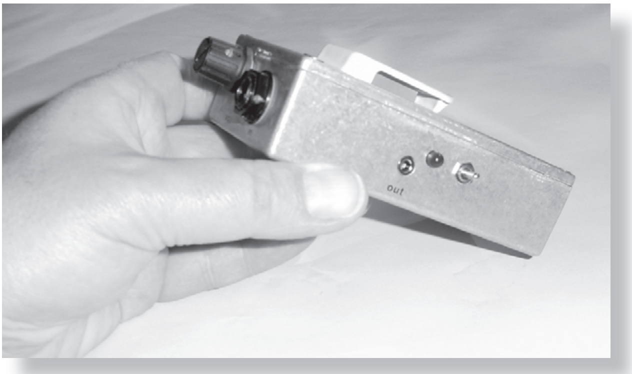

FIGURE 8.15 The Guitar Headphone Amplifier.

Principle

The Guitar Headphone Amplifier is based around two operational amplifiers, which together increase the signal created by an electric guitar when being played in two stages, up to the levels required by a pair of ordinary earphones.

Circuit

The circuit of the Guitar Headphone Amplifier is shown in Figure 8.16, where you can see the two operational amplifiers, which operate in series to amplify the small level signal at the circuit's input up to the levels necessary to drive earphones. The particular operational amplifiers used, while separate electrically, are not actually physically separate devices, and instead are combined in a single integrated circuit IC1. This reduces the size of the circuit, hence allowing a smaller printed circuit board to be used, in turn keeping the physical size of the completed project down to a pocket-sized format.

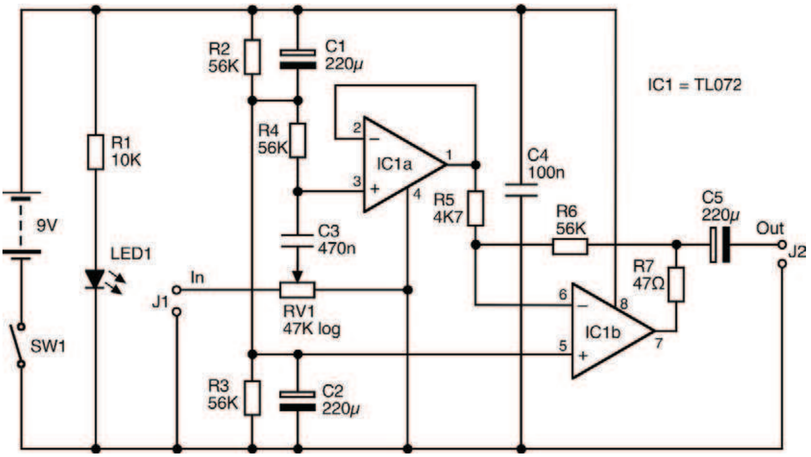

Figure 8.16 *Circuit of the Guitar Headphone Amplifier.*

Potentiometer RV1 allows control of the overall output volume, which in combination with the electric guitar's own volume control, can be configured to give clear sound levels, right up to severe distortion levels. The Guitar Headphone Amplifier should therefore suit most if not all kinds of electric guitar players from folk through to rock, from jazz through to heavy metal.

Operational amplifiers usually require a split-rail or three-level power supply (ie, a power supply with positive, negative, and ground voltages). Operating an operational amplifier from a single supply voltage requires that the voltage (9 V, provided by a PP3-sized battery) be split to give a mid-rail of around 4.5 V, thus emulating a split-rail supply. Capacitors C1 and C2, together with resistors R2 and R3 form a potential divider which does just that.

Construction

While the majority of component holes in the printed circuit board are of the standard 1 mm size, some component holes (for potentiometer RV1, and jack socket J1) should be drilled with a 1.5 mm diameter drill.

Also, if you use the same size of diecast housing as used here, you'll need to file the corner of the printed circuit board for the housing corner post. Also, cut the stem of potentiometer RV1 to the correct length to take its knob (see page 153). These jobs should be carried out before any components are soldered into the printed circuit board.

The printed circuit board layout for the Guitar Headphone Amplifier is shown in Figure 8.17, together with wiring details. Begin construction by inserting and soldering components in the following order: the six terminal pins, resistors R1–7, capacitors C1–5, followed by the larger components jack sockets J1 and J2, and potentiometer RV1.

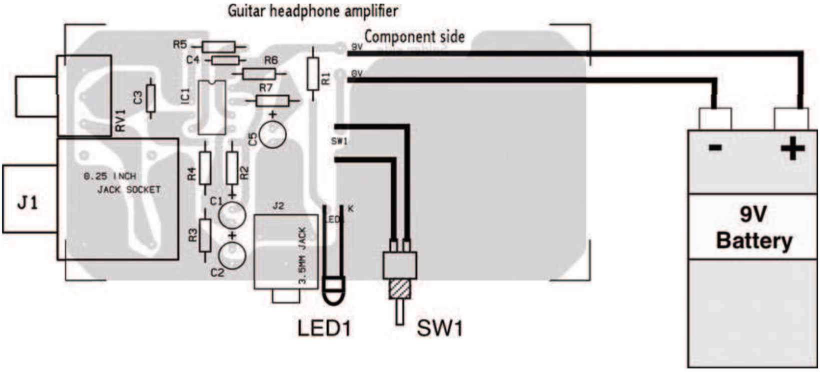

FIGURE 8.17 Guitar Headphone Amplifier printed circuit board layout and wiring diagram.

At this stage you can test the circuit by temporarily soldering the battery clip and switch SW1 to the circuit board. Plug in a guitar (using a standard guitar-style 0.25 inch jack lead) to jack socket J1, and plug in a pair of earphones to jack socket J2.

Once tested, it's time to fit the completed printed circuit board into a housing. Mark and drill holes in the housing for the two jack sockets, the potentiometer, light emitting diode LED1, and switch SW1. Make the holes for jack socket J1 and potentiometer RV1 slightly larger than their actual diameters (by a millimetre or so) then you will be able to wiggle the board into position as the tab of jack socket J2 pushes tightly into its hole in the housing. Using the washers and nuts provided with jack socket J1 and potentiometer RV1, clamp the components to the housing. The printed circuit board should now be held tight within the housing.

Making sure that light emitting diode LED1 is the right way round, push-fit it into the hole you've drilled, and solder its leads to the terminal pins on the printed circuit board. Mount switch SW1 into the housing, and solder its leads to the printed circuit board. Resolder the battery clip to the printed circuit board, and connect the battery.

Finally, mark and drill the holes on the housing lid to mount the belt clip, then bolt the clip to the lid.

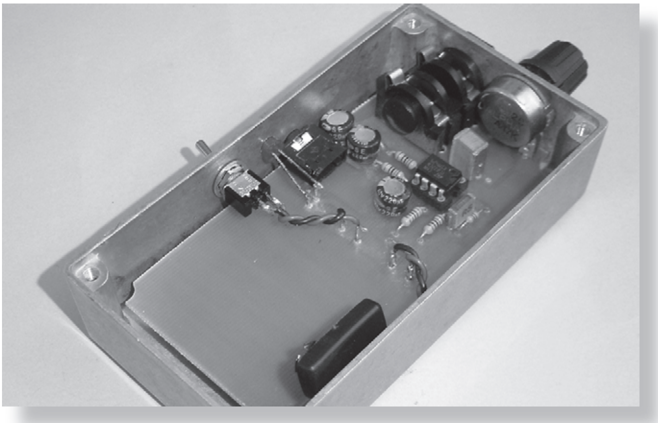

FIGURE 8.18 Showing how the printed circuit board fits inside the diecast housing.

Belt clip, for housing
Knob (for potentiometer RV1)

Bench Power Supply

If you want to build electronics projects, work with electronic components, experiment with electronic circuits, and do any of the things covered in this book, you'll need some source of electric power. In many cases batteries can be used, of course, and they're fine for low-power circuit requirements, but batteries have several drawbacks. First, they can provide only limited current before their output voltage drops, so any circuit you work with that requires lots of current can't be powered from them. Second, batteries don't last forever and run down (usually when you least want them to!).

A much better source of power is a mains-powered bench power supply (Figure 8.20). These can give significantly greater current and, while connected to mains electricity, always provide the power needed.

To keep the project as simple as possible, the design used here gives a number of fixed voltages, rather than being variable. The voltages directly available are from a dual-rail (ie, positive and negative values) +12 V/0 V/–12 V supply at a maximum output current of about 0.3 A, together with a single-rail +5 V supply up to a maximum output current of about 0.5 A.

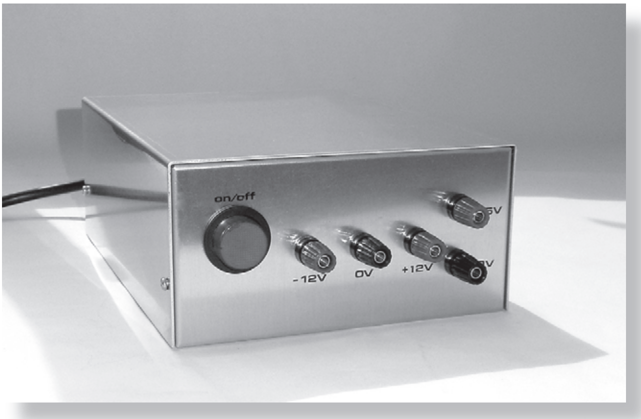

Figure 8.20 The Bench Power Supply.

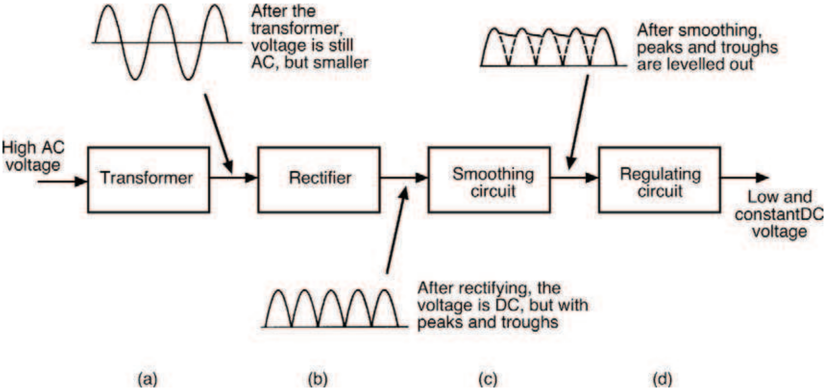
These two separate power supplies are internally unconnected though it's possible to connect them externally as you wish, to add to or subtract from each other, this way providing a range of supply voltages.

As most circuits you'll build are powered by only a small number of voltage options anyway, the voltages provided by this power supply should be more than adequate. For example, most operational amplifier circuits require a dual-rail power supply of between about +/– 9 V to +/– 15 V, so the output of the power supply here is ideal. Likewise, much logic circuitry needs a single-rail power supply of between about 5 V and 10 V, so the single-rail power supply here is also ideal.

These standard voltages aside, it's also possible to combine the two separate internal supplies to create a variety of other voltages. For example, by connecting the 0 V terminal of the 5 V circuit to the +12 V of the other circuit, and using the –12 V connection as ground, a 29 V supply can be formed (ie, 12+12+5). Likewise, connecting the 5 V terminal to the +12 V terminal, then using the two 0 V terminals a 7 V supply can be formed (ie, 12–5). Other voltages can be formed similarly.

Principle

A mains power supply has the job of reducing and converting a high mains AC voltage into a low DC voltage. In a standard power supply this is undertaken in four main stages, illustrated in Figure 8.21 together with the waveforms at the various stages.



After the transformer, voltage is still AC, but smaller
After smoothing, peaks and troughs are levelled out
High AC voltage
Transformer
Rectifier
Smoothing circuit
Regulating circuit
Low and constantDC voltage
After rectifying, the voltage is DC, but with peaks and troughs
(a)
(b)
(c)
(d)

FIGURE 8.21 The four main stage waveforms in the mains-powered bench power supply.

First, the high mains AC voltage is transformed to a lower AC voltage, as shown at Figure 8.21 (a). After this the AC voltage is converted to a DC one by rectification — Figure 8.21 (b). Next, the voltage is smoothed to reduce the peaks and troughs of the basic rectified voltage — Figure 8.21 (c). Finally, as shown at Figure 8.21 (d), the output voltage is regulated to maintain a constant DC voltage.

The power supply here follows these basic stages, although there are in fact three individual power supply circuits making up the overall design. Two circuits combine together to give positive and negative +12 V/–12 V values, while the third 5 V circuit is unconnected. The main principle of each is the same however.

Circuit

The overall circuit of the power supply is shown in Figure 8.22, where the three individual circuits within the whole circuit can be identified. Transformers T1 and T2 transform 230 V ac mains voltage input to the lower voltages (15 V ac and 9 V ac) required by the rest of the circuit.

Bridge rectifiers BR1 and BR2 rectify the alternating voltages to direct voltages, while capacitors C1–3 smooth these voltages.

Integrated circuits IC1–3 are voltage regulators, which regulate the smoothed voltages into slightly lower, but fixed output voltages.

FIGURE 8.22 Mains-powered bench power supply circuit.

Construction

The printed circuit board contains most of the components for the Bench Power Supply, and is a compact yet easy-to-build design. Some holes on the printed circuit board should be drilled larger than 1 mm — the mounting holes for the housing and the mounting holes for transformer T1 are all 4 mm diameter, while the terminal holes for transformers T1 and T2 are 1.5 mm. Figure 8.23 shows the layout of the printed circuit board to locate the components.

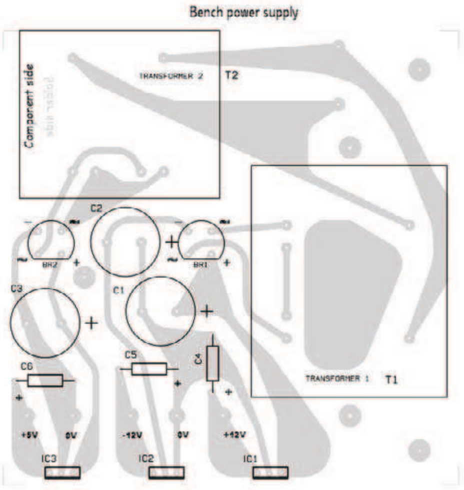

FIGURE 8.23 Layout of the Bench Power Supply printed circuit board.

Now position the printed circuit on the inside base of the housing where it is to be mounted — make sure the positions for the three integrated circuits IC1–3 are against the rear panel of the housing. Mark the holes in the housing base for the three mounting bolts. Remove the printed circuit board, and drill the holes in the housing base, using a 4 mm drill. Insert the 20 mm long M3 bolts and spacers, ready for the printed circuit board.

Insert and solder the seven terminal pins, and integrated circuits IC1–3 into the printed circuit board.

Mount the printed circuit board temporarily onto the three mounting bolts in the housing base. Mark the three integrated circuits IC1–3 mounting holes on the rear panel of the housing. Now remove the printed circuit board again, and drill the holes you just marked, using a 4 mm drill. Make sure the holes have no burrs on their edges, and if burrs exist use a large drill to hand ream the hole edges to remove them.

Now insert and solder all remaining components into the printed circuit board, in the following order: bridge rectifiers BR1 and BR2, capacitors C1–6, transformers T1 and T2. Now, using 6 mm long M3 bolts, bolt transformer T1 to the printed circuit board.

Mark and drill holes in the housing panels for the cable clamp, the panel-mounting fuse holder, and the on/off switch, then mount these components to the housing.

Position the printed circuit board onto its mounting bolts in the housing, but do not fasten it down with nuts and washers yet. Insulating washers must fit between the three integrated circuits IC1–3 and the housing panel, as the three integrated circuit tabs are at different voltages, and bolting them directly to the panel would create short circuits. Each integrated circuit must therefore be bolted to the panel as shown in Figure 8.24, with an insulating washer between the integrated circuit tab and the panel, an insulating bush through the integrated circuit tab hole, and a bolt through the bush. This arrangement ensures that the integrated circuit is electrically isolated from the housing, though rigidly held to it.

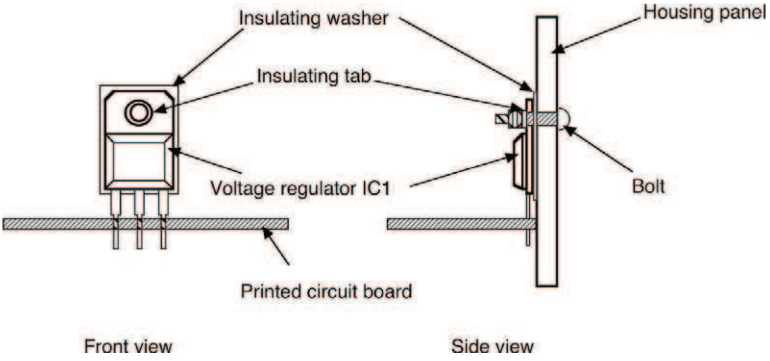

Figure 8.24 Mounting arrangement for integrated circuits IC1–3 to the housing rear panel.

The panel is also used as a heatsink, dissipating heat safely away from the integrated circuits, so heatsink compound must be applied to all mating surfaces prior to assembly. See page 165 for details of applying heatsink compound to surfaces.

Once heatsink compound is applied, the insulating washers and tabs are fitted, and the three integrated circuits are bolted to the housing rear panel. Complete the mechanical assembly by fastening the printed circuit board with nuts and washers onto the three mounting bolts.

Following the wiring diagram of Figure 8.25, wire up the project. For safety, and following the same sort of layout as in Figure 8.26, keep all mains wiring to one side of the housing, running it from the housing panel-mounted components (cable clamp, fuse holder, and on/off switch) down to the housing base, along the base and up the other panel. Take mains connections to the printed circuit board from the panel-mounted components down to the base, along the base with the other mains

wires and directly from the wire group to the printed circuit board. Make doubly sure all mains connections are made tight. Use heatshrink insulated sleeving on all mains connections to make sure that no metal parts remain visible (or more important, make sure they are not touchable).

The five low voltage wires from the printed circuit board to the connectors should be taken to the other edge of the housing to the mains wires, running along the housing base to the front panel, then along the housing base to each connector.

Once wiring is completed, use cable ties or similar to tie the loose wires together into cables, as can be seen in Figure 8.26.

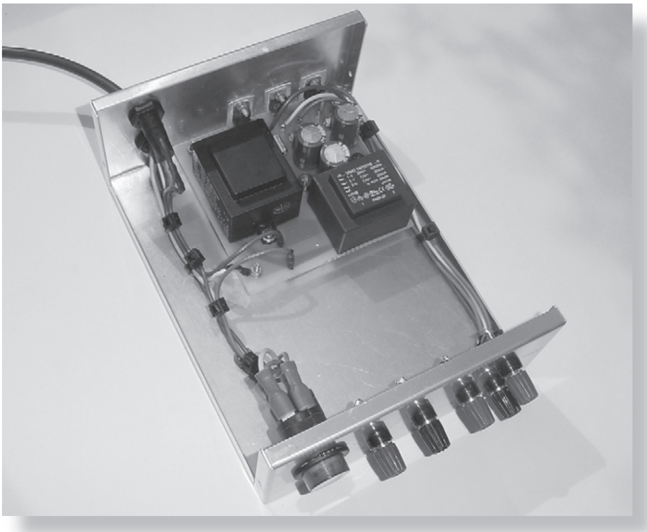

FIGURE 8.26 Showing the Bench Power Supply innards – note the use of cable ties to form the two groups of wires (mains wiring on the left, low voltage wires on the right).

71. Adding the 80 metre band to the Yearling receiver 251
72. How the Yearling works 255
73. A field strength meter 258
74. Preselector for a short-wave receiver 261
75. An audible continuity tester 265
76. An experimental 70 cm rhombic aerial 268
77. Water level alarm 272
78. A delta loop for 20 metres 275
79. A simple desk microphone 279
80. Morse oscillator 284
81. A simple 6 m beam 287
82. An integrated circuit amplifier 291
83. A novice ATU 293
84. CW QRP transmitter for 80 metres 297

85. An audio booster for your hand-held 303
86. A grid dip oscillator 306
87. A CW transmitter for 160 to 20 metres 312
88. Matching the end-fed random-wire aerial 315

Preface

Although we are surrounded by sophisticated computerised gadgets these days, there is still a fascination in putting together a few resistors, capacitors and the odd transistor to make a simple electronic circuit. It is really surprising how a handful of components can perform a useful function, and the satisfaction of having built it yourself is incalcuable.

This book aims to provide a wide variety of radio and electronic projects, from something that will take a few minutes to a more ambitious weekend's worth. Various construction techniques are described, the simplest requiring no more than a small screwdriver, the most complex involving printed circuit boards.

Originally published by the Radio Society of Great Britain, the projects were all chosen to be useful and straightforward, with the emphasis on practicality. In most cases the workings of the circuit are described, and the projects are backed up by small tutorials on the components and concepts employed. In the 21st century it may seem strange that few of the published circuits use integrated circuits (chips). This is intentional as it is much easier to understand how the circuit works when using discrete components.

Anyone buying the *Radio and Electronics Cookbook* will find that it will lead to hours of enjoyment, some very useful and entertaining gadgets, and increased knowledge of how and why electronics circuits work, and a great sense of satisfaction. Beware, electronic construction is addictive!

WARNING: This book contains construction details of transmitters. It is illegal to operate a transmitter without the appropriate licence. Information on how to obtain an Amateur Radio Licence can be obtained from the Radiocommunications Agency, tel. 020 7211 0160.

1 A medium-wave receiver

Introduction

Let us start off with something that is really quite simple and yet is capable of producing a sense of real satisfaction when complete – a real medium-wave (MW) radio receiver! It proves that receivers *can* be simple and, at the same time, be useful and enjoyable to make. To minimise the confusion to absolute beginners, *no* circuit diagram is given, only the constructional details. The circuits will come later, when you have become accustomed to the building process. In the true amateur spirit of ingenuity and inventiveness, the circuit is built on a terminal strip, the coil is wound on a toilet roll tube (as amateur MW coils have been for 100 years!), and the receiver is mounted on a piece of wood.

Putting it together

Start by mounting the components on the terminal strip as shown in **Figure 1**, carefully checking the position and value of each one. The three capacitors are all the same, and so present no problem. They (and the resistors) may be connected either way round, unlike the two semiconductors (see later). The resistors are coded by means of coloured bands. You can refer to Chapter 7 if you have difficulty remembering the colours and their values.

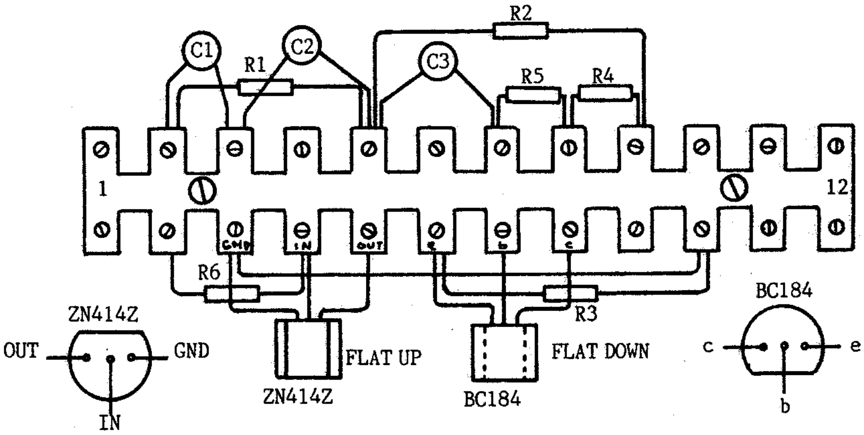

Figure 1 Terminal strip – position of components

1.	Brown, Black, Yellow	100 000 ohms	(R1, R5, R6)
2.	Green, Blue, Brown	560 ohms	(R2)
3.	Red, Violet, Brown	270 ohms	(R3)
4.	Brown, Black, Orange	10 000 ohms	(R4)

The integrated circuit (the ZN414Z) and the transistor (the BC184) *must* be connected correctly. Check Figure 1 carefully before fitting each device.

Now wind the coil. Most tubes are about 42 mm diameter and 110 mm long. Don't worry if your tube is slightly different; it shouldn't matter. Make two holes, about 3 mm apart, about 40 mm from one end, as shown in **Figure 2**. Loop your enamelled wire into one hole and out of the other, and draw about 100 mm through; loop this 100 mm through again, thus anchoring the wire firmly. Now wind on 80 turns, keeping the wire tight and the turns close together but not overlapping. After your 80th turn, make another two holes and anchor the wire in the same way as before. Again, leave about 100 mm free after anchoring. Using another piece of enamelled wire (with 100 mm ends as before), loop one end through the same two holes which contain the end anchor of the last winding, wind two turns and anchor the end of this short winding using another pair of holes. Figure 2 shows the layout.

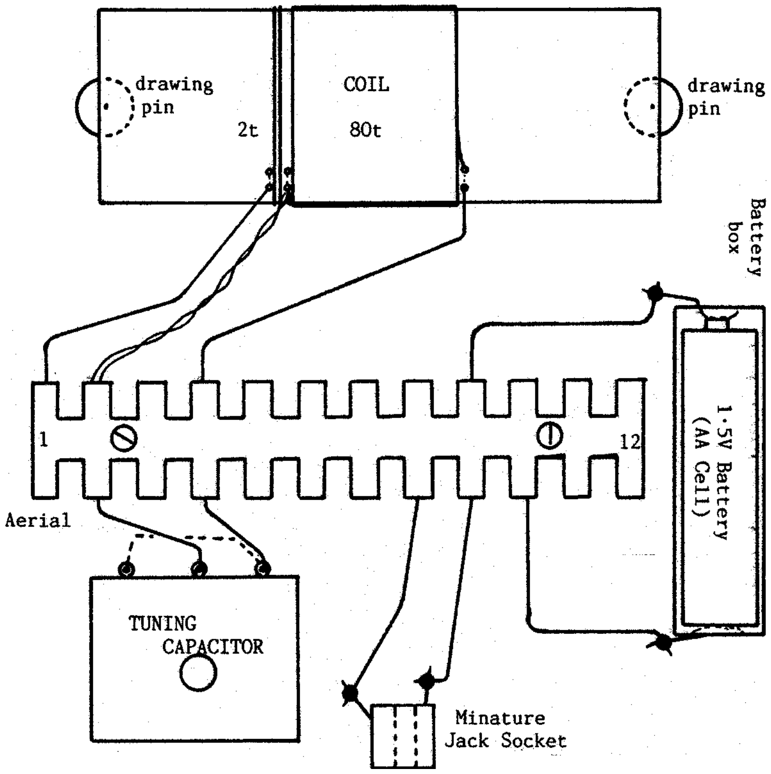

Figure 2 The layout of the parts on the wooden base

With some glass paper, remove the enamel from the ends of both pieces of wire which go through the same holes (i.e. the bottom of the large coil and the top of the small coil), then twist these bare ends together. Remove the enamel from the remaining ends of the coil. The coil is now finished!

The baseboard can be any piece of wood about 150 mm square. Fix the coil near the back edge using drawing pins and connect the wires from the coils to the terminal strip as shown in Figure 2. Using short pieces of PVC-insulated wire (and with assistance if you have never soldered before), solder one piece across the two outer tags of the variable capacitor, shown by the dotted line in Figure 2, and then two longer pieces to the centre tag and one outside tag. Connect these to the terminal strip. Then solder two more insulated wires on to the jack socket (into which you will plug your crystal earpiece), the other ends going to the terminal strip. The last two wires (one must be red) need to be soldered on to the battery box, their other ends going to the terminal strip also. Make sure the red wire goes to the *positive* terminal on the battery, and is connected to terminal 9. The other connection to the battery goes to terminal 10.

Attach the terminal strip to the baseboard with small screws or double-sided sticky tape. The other parts can be mounted the same way.

Listening is done ideally with the recommended crystal earpiece. Don't be tempted to use your Walkman earpieces; they are not the same and will not perform anything like as well. The receiver should work without an extra aerial, but one can be attached to terminal 1 if necessary. A long piece of wire mounted as high as possible is ideal. The *Audio-frequency Amplifier* project will enable you to use a loudspeaker with your receiver, using the signal from the jack socket. No circuit modifications will be needed!

Parts list

Resistors: all 0.25 watt, 5% tolerance

R1, R5, R6	10 kilohms (kΩ)
R2	560 ohms
R3	270 ohms
R4	10 kilohms (kΩ)

Capacitors

C1, C2, C3	100 nanofarads (nF)
	500 picofarads (pF)

Semiconductors

ZN414Z, BC184

Additional items
- 12-way 2 A terminal strip
- 22 metres of 28 SWG enamelled copper wire
- A few short pieces of coloured PVC-insulated wire
- Crystal earpiece
- 3.5 mm jack socket
- 1.5 V AA-size battery and box
- Toilet roll tube
- Double-sided sticky tape or selection of screws

Tools required

Small screwdriver, soldering iron.

2 An audio-frequency amplifier

Introduction

This simple amplifier can be built by anyone who is able to solder reasonably well. It doesn't require any setting up and, provided our instructions are followed exactly, will work very well. The circuit diagram is included for the benefit of our more advanced readers, but it is not needed in the construction process. Please practise your soldering before you start, and don't use a printed circuit board (PCB) until you are confident that your soldering is up to scratch.

The amplifier can be used with other projects; it will provide plenty of sound from the MW Radio or from the Morse Sounder projects. It will usually be built into other pieces of equipment, so a box is not supplied with the kit. There is no reason why it shouldn't be put into a box and used as a general-purpose amplifier to help test other projects.

The components

Before you start, you should check that you have *all* the components to hand. A list and some helpful hints are given below.

1. PCB. The plain side is the *component side* and the soldered side is the *track side*. **Figure 1** shows the track side full size. Make the PCB from the pattern given in Figure 1. Otherwise, build the circuit on a matrix board.
2. Three resistors. Locate the gold or silver band around the resistor, and turn the resistor until this band is to the right. There are three coloured bands at the left-hand end of the resistor. Find the resistor whose colours are YELLOW, VIOLET, RED, and look at the resistor colour code chart which you will find in Chapter 7. From this, you will see that YELLOW indicates the value 4, VIOLET the value 7, and RED the value 2. The first two colours represent real numbers, and the last value is the number of zeros (noughts) which go *after* the two numbers. So, the value is 47 with two zeros, i.e. 4700 ohms. In this way, the resistor coloured BROWN, GREY, BROWN has a value of 180 ohms, and the last one, BROWN, RED, GREEN, has a value of 1 200 000 ohms. The ohm (often written as the Greek letter omega (Ω)) is the unit of resistance. If you do not yet feel confident in identifying resistors by their colours, use the Resistor Colour Codes given in Chapter 7.
3. Four capacitors. The two small 'beads' are tantalum capacitors and will be marked 4.7 μF or 4μ7, with a '+' above one lead. A tubular capacitor with wires coming from each end should be marked 220 μF, with one end marked '+' or '–'. This is called an *axial* capacitor because the wires lie on the axis of the cylinder. This is in contrast to the final capacitor, where both wires emerge from the same end. This is a *radial* capacitor, and will be marked 47 μF. Again, one lead will be marked '+' or '–'. Capacitors marked like this are said to be *polarised*, and it is vital that these are placed on the PCB the right way round, so take notice of those signs!
4. Two diodes. These are tiny glass cylinders with a band around one end, and may be marked 1N4148; this is their type number. Like polarised capacitors, they *must* be put on the PCB the correct way round!

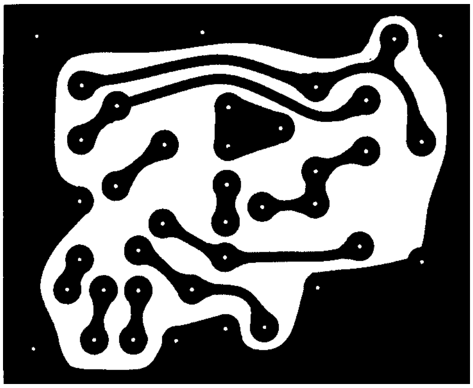

Figure 1 The toil pattern of the PCB – looking from the track side

5. Three transistors. One should be a BC548 (or a BC182), the other two should be BC558 (or BC212).
6. One volume control with internal switch.
7. One loudspeaker. This is quite fragile – don't let anything press against the cone.
8. One PP3 battery clip with red and black leads.

Putting it together

Lay the PCB on a flat, clean surface with the track side downwards. It is always useful to compare the layout with the circuit diagram, given here in **Figure 3**. Although you can't see it, the D-i-Y Radio sign should be at the top. Compare the hole positions with those shown in **Figure 2**. Bend the resistor wires at right angles to their bodies so that they fit cleanly into the holes in the PCB. Push each resistor towards the board so that it lies flat on the board. Then supporting each one, turn the board over and splay out the wires *just* enough to prevent the resistor falling out. Then, solder each wire to its pad on the PCB, and cut off the excess wire. When you have more confidence, you can cut of the excess wire *before* soldering; it often makes a tidier joint.

Figure 3 The amplifier's circuit diagram

Now fit the four capacitors. Each must be connected the right way round, so look at each component, match it up with the diagram of Figure 2, bend its wires carefully and repeat the soldering process you performed with the resistors, making sure that the components are close to the board and not up on stilts! Fit the two diodes the correct way round, and solder then as quickly as you can – they don't like to be fried!

Mount the transistors about 5 mm above the PCB. Make sure the correct transistors are in the correct places, and that the flats on the bodies match up with those shown in Figure 2.

Mount the volume control so that the spindle comes out from the front of the board. Use a piece of red insulated wire to the pad marked + on the PCB, and a black piece to the pad marked –, and solder these to the tags on the back of the control, as shown in **Figure 4**. Connect the two leads from the battery clip to the other tags on the switch; Figure 4 will help you. Finally, use two pieces of insulated wire about 100 mm long, twisted together, to connect the loudspeaker to the PCB.

Box clever!

If you wish to put the amplifier into a box, there is no problem; almost any box that is big enough will do. All that is needed is one hole big enough to accept the bush of the volume control; the PCB will be supported by the volume control. The prototype was not fitted into a box, but mounted on an odd piece of aluminium, bent into an L-shape and screwed on to a wooden base. The loudspeaker was mounted on the aluminium panel by two small pieces of aluminium with 3 mm holes drilled in them, which acted as clips around the edge of the speaker. Drill a few holes in the panel in the position of the speaker to let the sound get out!

Your input signal can be connected to the amplifier with two short pieces of wire, but if the connection needs to be long, use screened cable, with the braid connected as shown in Figure 2.

If you decide to use a different loudspeaker, make sure that its impedance (the resistance value marked on the back of the magnet) is at least 35 ohms. Anything lower may damage TR2 and TR3, and will certainly run down your battery very quickly. You will be surprised at the uses you can find for this little amplifier!

Parts list

Resistors: all 0.25 watt, 5% tolerance

R1	180 ohms (Ω)
R2	4.7 kilohms (kΩ)
R3	1.2 megohms (MΩ)

3 A medium-wave receiver using a ferrite-rod aerial

Introduction

This design came from the Norfolk Amateur Radio Club, and enables you to build a simple Amplitude Modulation (AM) receiver for frequencies between 600 kHz and 1600 kHz. It should take you around 2 hours to build, and can be used with Walkman-type earpieces. **Figure 1** shows the circuit diagram.

Figure 1 Circuit and block diagrams of the radio

Description

The whole circuit is built on a 50 mm by 50 mm printed circuit board (PCB) designed to fit on the inside of the lid of a plastic box, and is stuck there using sticky pads, the shaft of the variable capacitor going through a hole in

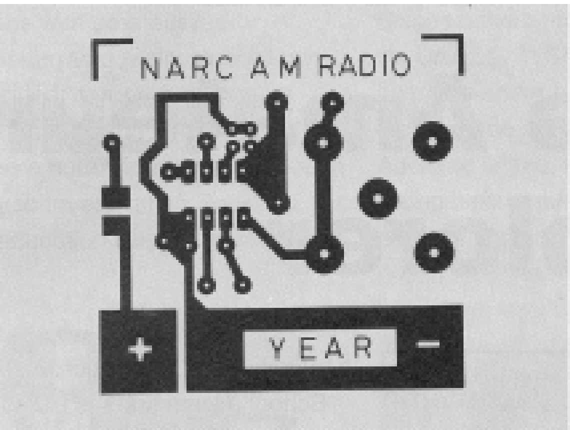

Figure 2a The PCB, solder side

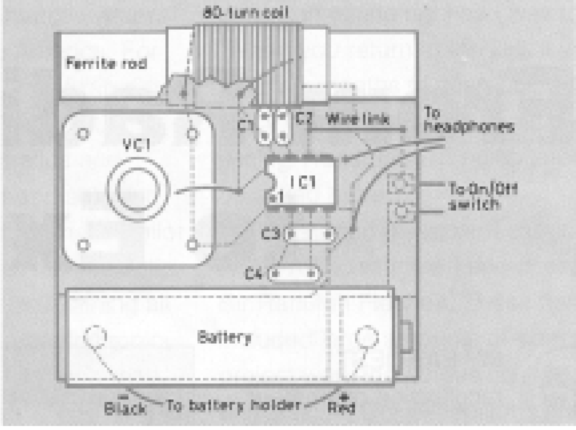

Figure 2b The PCB, component side

the lid. Only two pairs of leads are soldered to the board – one pair goes to the 1.5 V battery in its holder, and the other to the earphone socket. **Figures 2a** and **2b** show the printed circuit and the component layout double size for clarity. You are not obliged to build the circuit on a PCB.

Building it

1. **Check and identify components**. Tick the parts list.
2. **Carefully unwind the wire.** Use paper to make an insulating tube (called a 'former') around the centre of the ferrite rod and secure it with Sellotape. Now, close-wind *all* the wire (leave no gaps between adjacent turns) around the paper former. Secure the winding with more Sellotape, leaving 50 mm of wire free at each end for connection to the circuit. See **Figure 3a.**
3. **Solder in VC1.**
4. **Solder in the integrated circuit holder.** There is a notch in one end of the holder; this should face VC1. Solder also the wire link and the capacitors. Be careful to avoid solder 'bridges' between adjacent tracks on the PCB.
5. **Solder the battery leads.** These must be connected properly – the red battery lead to the + (positive) area and the black lead to the – (negative) area.
6. **Strip bare 1 cm of insulation from the ends of two wires**. Solder them between the PCB and the headphone socket (see **Figure 3b**). Use the end tabs on the socket. Using another pair of insulated wires connect the ON/OFF switch to the PCB tabs shown in Figure 2b.

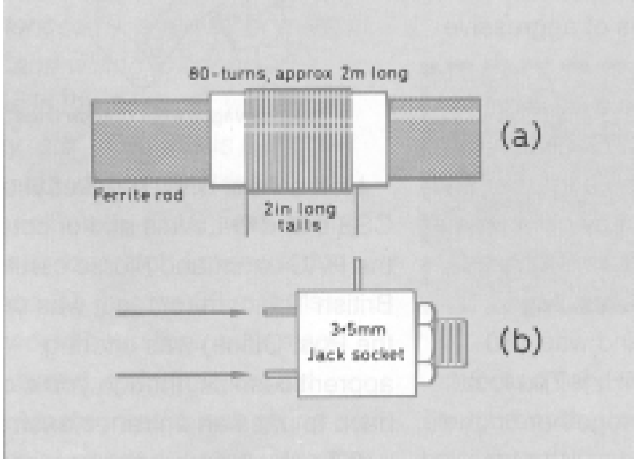

Figure 3 Details of coil and headphone socket

7. **Fix the elastic band.** This goes through the holes at the top of the PCB, with the ferrite rod being slipped through the two end loops. (Note: although the coating on the copper wire is designed to melt away during soldering, it is quite common for difficulty to be experienced in obtaining a good soldered joint; to be on the safe side, remove the coating *before* soldering (with a small piece of sandpaper).) Carefully place the wire ends of the coil through the PCB just above VC1, and solder on the track side.
8. **Fit IC1 into its holder.** This should be done carefully, making sure that *all* the pins are located above their respective clips *before* applying any pressure! Make sure also that the notch on the IC (as shown in Figure 2b) matches the notch in the holder, and faces VC1.
9. **Put battery in its holder.** Listen for some noise in the headphones as VC1 is rotated. Make sure the headphone plug is fully inserted into its socket.
10. **Fix the working board to the lid.** Use the sticky pads and apply *gentle* pressure. Fit the tuning knob, the ON/OFF switch and the earphone socket.
11. **Test again.** If all is still working, fit the lid screws and admire your completed radio!

Parts list

Capacitors

C1, C2	0.01 microfarad (μF)
C3, C4	0.1 microfarad (μF)
VC1	500 picofarads (pF)

Semiconductor

IC1	ZN416E

Additional items
- Plastic box (recommended size 76 × 64 × 50 mm internal)
- 8-pin DIL socket for IC1
- Printed circuit board
- Tuning knob for VC1
- Wire link for PCB
- 2 m of 30 SWG copper wire, self-fluxing
- Piece of paper 25 × 50 mm, to make the coil former
- Ferrite rod 70 mm long by 10 mm diameter, approximately
- Battery, AA size 1.5 V, with holder and attached wires
- Miniature earphone socket (3.5 mm stereo jack)
- ON/OFF switch (push-button SPST latched or slide switch)
- 4 off 100 mm insulated connecting wires, for jack socket and ON/OFF switch
- Pair Walkman-type earphones
- Elastic band, to attach ferrite rod to PCB
- 4 off sticky pads for securing PCB to box lid

Kits

Ready-made PCBs may be available from Alan J. Wright, G0KRU, Hewett School, Cecil Road, Norwich NR1 2PL.

4 A simple electronic organ

Introduction

This project has nothing to do with radio but, let's admit it, *any* electronics project is good experience! Why not build this little organ – it will keep the children amused at least! It uses the popular NE555 integrated circuit, which contains a circuit which will periodically switch the voltage on the output pin between the supply voltage and zero. Just how frequently this switching occurs depends upon the components external to the integrated circuit. If this switching occurs several hundred or thousand times a second, the change in voltage produced will generate a musical note when connected to a small loudspeaker. The circuit is shown in **Figure 1**.

Putting it together

(a) Using a PCB. The job is very simple. The placement of components on the unsoldered side of the board is shown in **Figure 2** and the design on the copper track is illustrated in **Figure 3**. Put each component, in turn, on the board, making sure that it lies flat on the board with its tags or wires going cleanly through the holes provided for it; then, solder the wires to the board, cropping them before or after the soldering,

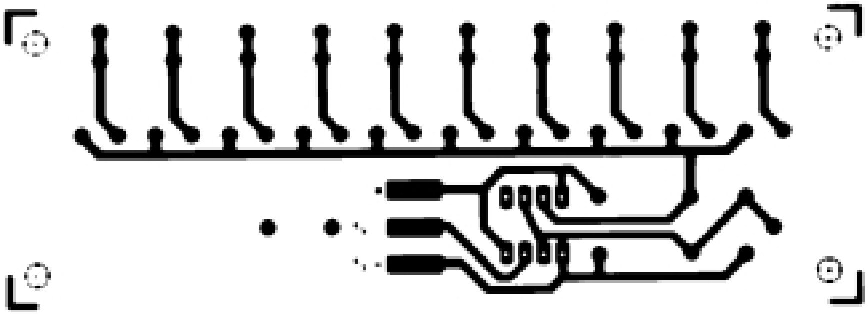

Figure 3 The connections

depending on your preference. If you choose to use a holder for your integrated circuit (highly recommended if your soldering is less than perfect), make sure that the end with a notch in it faces R1 and R2, as shown in Figure 2. Solder the two leads to the speaker to the tabs marked S (either way round), having looped them through the two holes to the right of the tabs in Figure 2. Looping them through the holes acts as a strain relief, ensuring that the soldered joints are not subjected to pulling and bending as you move the wires about. Do the same with the battery leads, the red lead going to the + tab and the negative lead to the – tab (which also has one speaker lead already attached to it). **Figure 4** shows this in detail. Treat the loudspeaker with care – the cone is quite fragile and must not be touched.

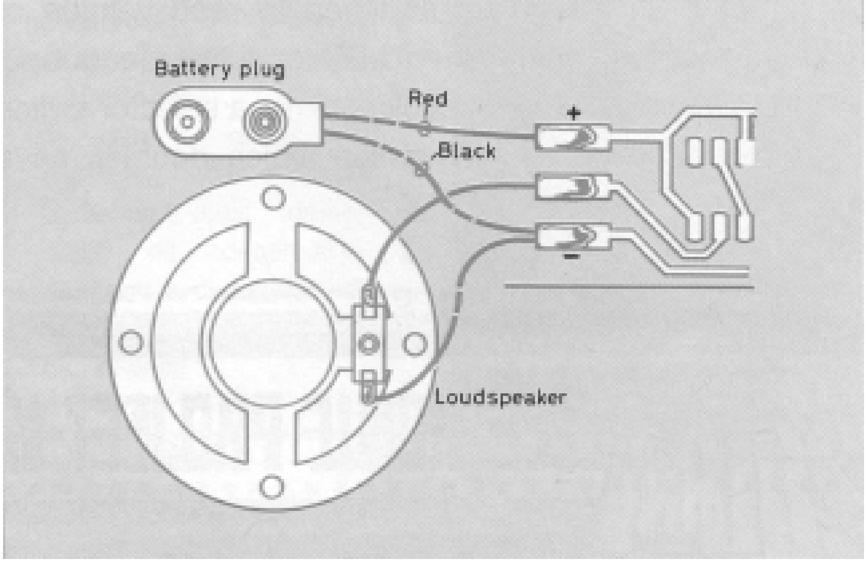

Figure 4 Battery plug and loudspeaker connections

(b) Without a PCB. This is more difficult, and you may need to enlist some help. Using some matrix board (such as Veroboard) is probably the best way of replacing the PCB. You could arrange your circuit in exactly the same way as in the PCB in Figure 3, using wires to replace the copper track.

A simple ‘keyboard’

The keyboard is a row of solder pins along the rear edge of the PCB, one for each note covering the range shown in Figure 2. A flying lead with a small spade on it is provided to touch any of the pins in turn, producing any one of ten different notes.

Testing

Check first that each component is in the correct place. When inserting the NE555 chip, first make sure that the end carrying the notch lies over the end of the holder with the notch; then, make sure each pin of the chip lies directly above the hole into which it fits, before pressing *gently* to insert the chip into the socket. Make sure the battery connections are correct, and insert the battery into the clip. Nothing should happen, except for a click from the loudspeaker; touching the spade on any of the pins should produce a coarse note from the speaker. If nothing happens, check everything again; don’t *assume* that wires go where you think they go!

After you get the first note, all the others should work, too, but they will sound off-tune at first. The organ needs tuning up by adjusting the 10 preset variable resistors P1 to P10. The approximate frequency to which each note should be tuned is given in Figure 2; if you can beg, borrow or steal a frequency counter, setting up is easy. If you have a piano, the organ can be tuned by comparison of the notes with those on the piano. The frequencies are given in Hertz (abbreviation Hz), and represent the number of times the IC switches on and off every second. If the sound coming from the loudspeaker is too loud or very distorted, then try putting an 330 Ω resistor (colour code orange, orange, brown) in series with the loudspeaker. This is done by taking the resistor and cutting its leads to about 5 mm; then, disconnect one speaker lead from the tab on the PCB (it doesn’t matter which). Solder one end of the resistor to the vacated speaker tab, and the free speaker lead to the other end of the resistor. This will limit the volume of sound from the speaker, and lengthen the life of your battery. If it is still too loud, try a resistor of a larger value, or use a smaller resistor to make it louder.

Parts list

Resistors: all 0.25 watt, 5% tolerance

R1	2.7 kilohms (kΩ)
R2	1 Megohm (MΩ)
P1–P5	Preset resistor 100 kilohms (kΩ)

	1 off spade terminal
	12 off solder pins ‘Veropins’
	3 off 10 cm lengths of ‘hook-up’ wire

(This article is based on projects originally designed by Radio Scouting, Netherlands.)

5 Experiments with the NE555 timer

Introduction

Several of the projects in this book use the NE555 timer, an integrated circuit which is at the heart of many circuits whose processes are determined by time intervals. **Figure 1** shows the circuit diagram of an audio oscillator using the 555. The timing voltages (governing the frequency of oscillation) are produced by R1, R2 and C2; a voltage appears at pin 3 which 'switches' at this frequency between zero and a voltage close to the supply voltage, which in this case can be anywhere between 6 V and 14 V. The output current, when applied through R3 to a small loudspeaker, produces an audible tone, provided that there is a DC path between the two test leads.

Figure 1 The circuit diagram

Construction

The simplest way to mount the components is on a piece of matrix board (Veroboard), available from any of the good suppliers. The prototype of this circuit used the type of board with copper strips along the underside; these strips are used like the copper tracks on a PCB, to join components together. Firstly, cut the four strips between the positions of the pins of the IC socket, as shown in **Figure 2**. You can buy a tool for this purpose, but a small twist drill (about 3 mm diameter) is just as good. Turn it between your fingers – if you use a drill you will end up with holes right through the board! Then solder in the IC socket (with the notch in the position shown), followed by the four links made with single-conductor insulated wire. Put in each component as shown, ensuring that C1 (an *electrolytic* or *polarised* capacitor) is connected correctly. When all the components have been soldered in, take the 555 chip and lay it on its socket, with its own notch lying above that of the holder. Then, making sure that each pin lies *directly* above its corresponding socket, press down *gently* on the chip, with the board supported on a flat surface.

Testing

Connect the circuit to a battery or small power supply, ensuring that the positive and negative leads are the right way round. Always use red and black leads here, then you are less likely to get it wrong! Switch on. Nothing

Figure 2 Veroboard layout. If you can read a circuit diagram, the project can be built using other methods

should happen until you short together the two test leads, when there should be a note from the loudspeaker. If this doesn't happen, switch off, disconnect the circuit and check your wiring and soldering. Is it exactly like Figure 2? Are the soldered joints round and shiny? If any are dull, then 'sweat' them briefly with a hot soldering iron until the solder runs, remove the iron, and check that they are as shiny as the rest. Check that there are no solder 'bridges' between adjacent tracks by holding your board up to a strong light. Then, reconnect, switch on and touch the test leads together. All should now work!

Uses of your circuit

1. As a Morse practice oscillator. Simply connect the two test leads to your key and, each time the key is pressed, you should hear a note from the speaker. The frequency of the note may be altered by putting a resistor in series with the key. To do this, remove one test lead from the key and select a resistor; connect one end of the resistor to the free test lead and the other to the empty terminal on your key. Selecting the value of resistor that you need will be a useful experiment in itself.
2. As a continuity tester. You can check fuses and lamp bulbs by connecting them across your test leads. If the speaker remains silent, the fuse or bulb has blown.
3. To indicate changes of resistance. Hold the ends of the test leads in each hand; you should hear a low note, because of the high resistance of your body. Squeeze the ends harder, and the frequency of the note should rise, because you are now making better contact. Repeat this with damp hands and the frequencies will be higher still.
4. As a thermometer. Connect the test leads to a thermistor (a device whose resistance changes with temperature) and warm it with a hair-dryer, or even in your hands, and you will hear the pitch changing with the temperature of the thermistor. A suitable 'bead' thermistor is available from Maplin (order code FX21).
5. As a diode tester. Use any diode, and connect the negative test lead to the end of the diode marked with the ring. This is the cathode of the diode. The other end, the anode, should be connected to the positive test lead, and a note should be heard from the speaker. This does not necessarily mean that the diode is working – yet. Reverse the connections and *nothing* should be heard. If this is the case, the diode *is* working.
6. As a light meter. Use a photoconductive cell (a device whose resistance changes with light intensity) connected between the test leads. A note should be heard. Shading the device with your hand will increase its resistance and the note should decrease in frequency. A suitable device is the ORP12 cell from Maplin (order code HB10).

There are many more applications. **Do not connect the test leads to other circuits that are switched on.** Your circuit, or the circuit you are connecting it to could be damaged. Think of a *passive* device or circuit (i.e. one *not* requiring a power supply or battery) where changes of resistance occur, and you have found another application!

Parts list

Resistors: all 0.25 watt carbon film types

R1	4.7 kilohms (kΩ) – yellow, violet, red
R2	39 kilohms (kΩ) – orange, white, orange
R3	330 ohms (Ω) – orange, orange, brown

Capacitors

C1	100 microfarads (μF) 25 V radial electrolytic
C2	22 nanofarads (nF) or 0.022 microfarad (μF) polyester type with 10 mm lead spacing

Integrated circuit

IC1	NE555

Additional items

- Miniature loudspeaker (preferably 35, 40 or 80 ohm)
- 8-pin DIL socket for IC1
- 0.1 inch Veroboard ('stripboard'), size 11 strips by 13 holes
- PVC-covered stranded wire for test leads, loudspeaker and battery connections
- PVC-covered solid wire for links on the board
- A power source of between 6 V and 14 V, such as a 9 V battery (PP3)

Tandy – many high street shops

6 A simple metronome

Introduction

A metronome is a device used by musicians to indicate the tempo of a piece of music. Until electronics came on the scene, this 'beating of time' was achieved in much the same way as a clock keeps time, i.e. with a pendulum device, the clicking of the escapement indicating the beats of the music.

Those of you who have already built the Morse Key and Buzzer from the designs in this book, will recognise the circuit of this metronome – it is exactly the same as was used to produce the note of the buzzer. This circuit is shown in **Figure 1**.

The circuit

Three components determine the speed at which the circuit oscillates – the speaker (LS), the resistors (VR1 + R1) and the capacitor (C1). VR1 is a variable resistor, so that the speed at which the oscillator operates can be varied. Compared with the component values of the Morse Buzzer (which operated at around 800 Hz), these components now give an oscillation frequency of around 1.25 Hz, which is far too low to be heard as a note. What we *do* hear, however, is a series of clicks, as the voltage across the speaker changes quickly from 0 to 9 V and back again.

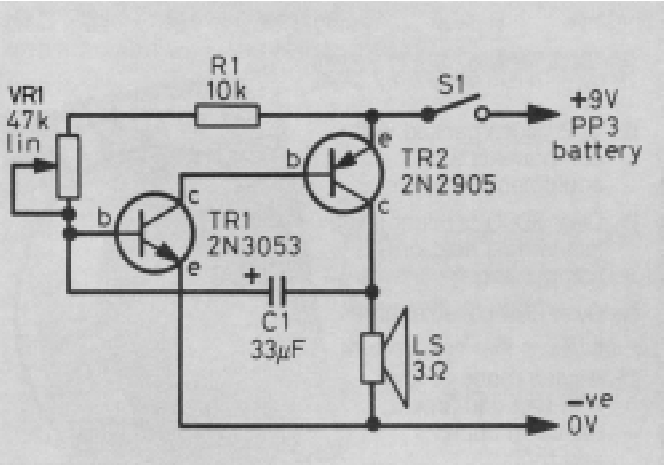

Figure 1 The metronome circuit is rather like the Morse oscillator

Figure 2 The component wires are pushed through holes in the circuit board and joined together underneath

Variation of speed could be achieved by varying resistance or capacitance. However, as you may already know, variable capacitors have values in the picofarad range, not the tens of microfarads used here, so it is very simple to employ a variable resistor (potentiometer) to control the oscillator. You could use a multi-way switch to switch in one of several capacitors, as well as having the variable resistor, but this was found to be an unnecessary complication. This design operates between about 100 clicks per minute and 200 clicks per minute.

Making the prototype

A single piece of plain matrix board (no copper strips) measuring about 40 × 40 mm is sufficient to hold all the components except the potentiometer and switch (see later). The case can be plastic or aluminium, and one measuring 65 × 100 × 50 mm is about right. Make sure there are holes in the case beside the speaker cone to let the sound out, and larger holes for the potentiometer and switch. If a potentiometer is used with a combined ON/OFF switch, then the extra hole for the switch is not necessary! It is advisable to construct the circuit *before* putting it in the box, so that it can be tested to ensure that everything is working. If it is, then you can exercise your ingenuity in mounting the speaker, battery and board inside the box. A final test can be made before starting the calibration process.

Calibration

There is no ‘easy’ way to do this. The frequencies involved are too low to be measured with the average frequency counter, so you will need to resort to using a stopwatch and counting the number of clicks per minute.

Parts list

7 What is a resistor?

Introduction

Materials that carry electricity easily are called **conductors**. They include all metals and salt water, for example. We use wire as a conductor, and the ease with which it passes an electric current depends upon the material, its thickness and its length. Silver (symbol Ag), gold (Au), copper (Cu) and aluminium (Al) are the best metallic conductors. Most wires are made of copper, although the best conductor, weight for weight, is aluminium.

Materials that *don't* carry current (or, at least, do so very badly) are called **insulators**, and they include dry wood, rubber, plastic and glass among their number. Wires are often coated with a layer of insulator to prevent adjacent wires touching and causing an accident.

Resistors

If there wasn't such a thing as resistance, the subject of electronics wouldn't exist; only infinite currents would flow and voltages wouldn't exist either! We need to reduce the flow of current if we are to make current do something useful for us. Components that resist the flow of current are called **resistors**, and they are said to have a **resistance** which is measured in ohms (Ω), named after Georg Ohm, who formulated the law (also named after him) by which the voltage and current through a conductor are related. His law gave rise to the formula *everyone* remembers:

$$I = \frac{V}{R},$$

where I is the current flowing, measured in amps,
V is the voltage across the conductor, and
R is the resistance of the conductor, measured in ohms.

From this equation, you can see that, for a constant value of voltage, V, if the resistance goes up, the current will go down, and vice versa. The circuit symbols for resistors are shown in **Figure 1**. You will find the upper symbol in older magazines; it is still preferred by many engineers. The lower symbol is the prevalent standard symbol.

Resistors are made in several ways, the cheapest using carbon; another type is usually made from a ceramic cylinder (used only as a support) on which

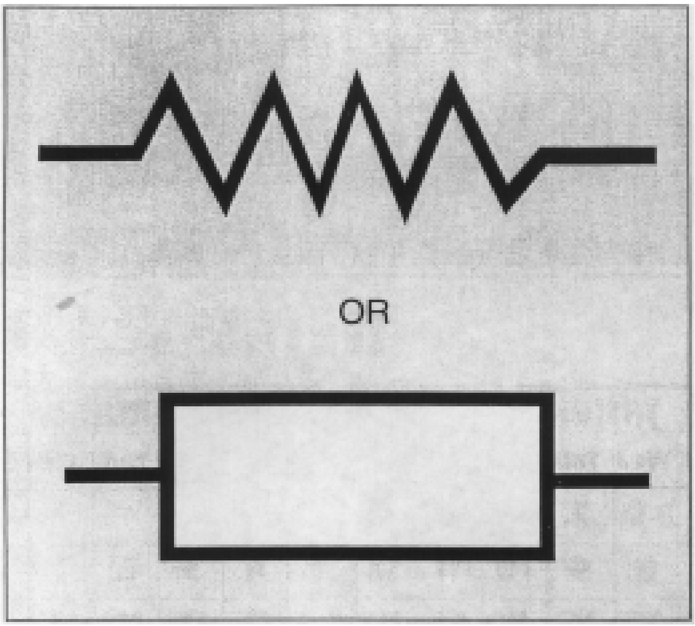

Figure 1 Circuit symbols for resistors

is placed a very thin film of metal – the thinner the film, the greater the resistance. All resistors are coated with a thin film of insulation, for the same reason we discussed earlier.

The colour code

Each resistor has coloured bands on it which enable us to see what value of resistance it has. There are normally three (but sometimes four) at one end, and a single one at the other (see **Figure 2**). The colours indicate figures, according to the list below.

Colour	*Value*	*Colour*	*Value*
Black	0	Green	5
Brown	1	Blue	6
Red	2	Violet	7
Orange	3	Grey	8
Yellow	4	White	9

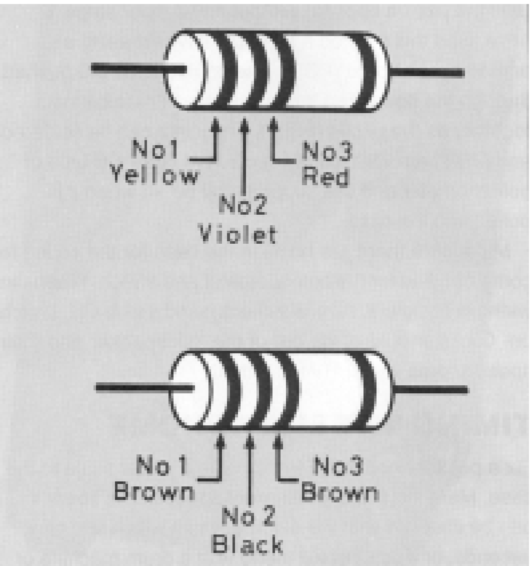

Figure 2 Some examples of resistor colour codes; top 4700 Ω (4.7 kΩ) and bottom 100 Ω

Using the colour codes is easy, once you see the logic behind it. Hold the resistor so that the single band is towards the right. The three colours on the left are read in the normal order from left to right. The first two bands *always* indicate numbers; the third band gives the number of zeros to add to the right of these two numbers. So, looking at the top resistor in Figure 2, yellow, violet, red means 4, 7, and two zeros, giving 4700 ohms! Looking at the lower resistor, brown, black, brown means 1, 0, and one zero, giving 100 ohms.

Remembering the order of the colours may be difficult at first. The colours from red to violet are the colours of the rainbow, in order, so if you know those, you're almost there! Around those colours are black and brown below the red, and grey and white above the violet, which you can imagine as getting brighter from black to white (well, almost!). It won't be long before you don't need to remember them at all.

The isolated band on the right-hand side is not part of the resistor's value; it indicates its *tolerance*, i.e. how close it might be to the indicated value. A brown band indicates ±1%, a red band ±2%, a gold band ±5% and a silver band ±10%. For example, a resistor marked as being 100 ohms with a ±5% tolerance will have an *actual* value somewhere between 95 ohms and 105 ohms.

8 Waves – Part 1

Introduction

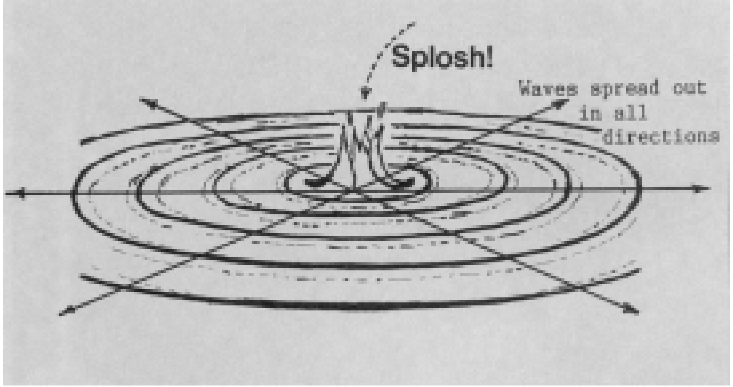
Waves are responsible for most of the processes in life where energy is transferred from one place to another. Heat and light energy from the sun, for example, come to us as *electromagnetic waves*. Sound travels through the air as a wave; it is not the same sort of wave as light or heat, but it obeys many of the same properties. Damage is caused to coastal margins by the waves of the sea – again, another type of wave, but still obeying many of the same properties. Radio waves are of the same type as heat and light waves, as are gamma rays, X-rays, ultra-violet waves and infra-red waves. So, once we begin to understand what radio waves do, we are also learning about a huge chunk of physics at the same time! All these waves are part of the *electromagnetic spectrum*. The word ‘spectrum’ simply means a ‘range’, so what we have is a range of electromagnetic waves – that’s all!

Sensing things

Light waves are invisible, but our eyes can detect the *effect* they have on different materials because the waves produce an effect on the retina of the human eye which the brain can interpret. We cannot see heat waves either, but we can feel the *effect* they have on our skin. Gamma rays and X-rays are also invisible, but their detrimental *effects* on human tissue are well known. It is not surprising, then, that we cannot see radio waves. We cannot sense them, either, until we produce a device upon which they have an *effect*. That device is a **radio receiver**; it is able to process certain characteristics of radio waves, and make these characteristics audible by generating sound waves from the loudspeaker or headphones. Other characteristics of the same waves may be turned into light as a TV picture on a cathode-ray tube, or as a fax image on a sheet of paper.

Visible waves

Let’s start our description with some waves that we can actually see! When a small stone is thrown into a pond, we see circular water waves *radiating* from the point where the stone fell into the water, as **Figure 1** shows. (Notice that we use the word *radiating*, even with water waves; it is not a radio term, but one which describes any motion where the *radius* of a circle is increasing. In this case, it is the radius of the circular waves which is



Splosh!
Waves spread out in all directions

Figure 1 The waves move out from the point where the stone landed

increasing.) If you were to watch the water waves down at the water level, perpendicular to the direction in which they are travelling, you would see something like the illustration in **Figure 2**.

The horizontal line represents the water level before the wave started, and the vertical line represents the direction in which the water is displaced at any instant.

All waves are described in the same way

'Freezing' the motion of the water in this way allows us to define two very important characteristics of a wave, characteristics which we talk about every day – *wavelength* and *amplitude*. The wavelength of a wave is simply the distance (measured in metres) from any point on one wave to the same point on the adjacent wave. Look at the diagram and you will see what is meant by 'the same point on the adjacent wave'. The amplitude of a wave

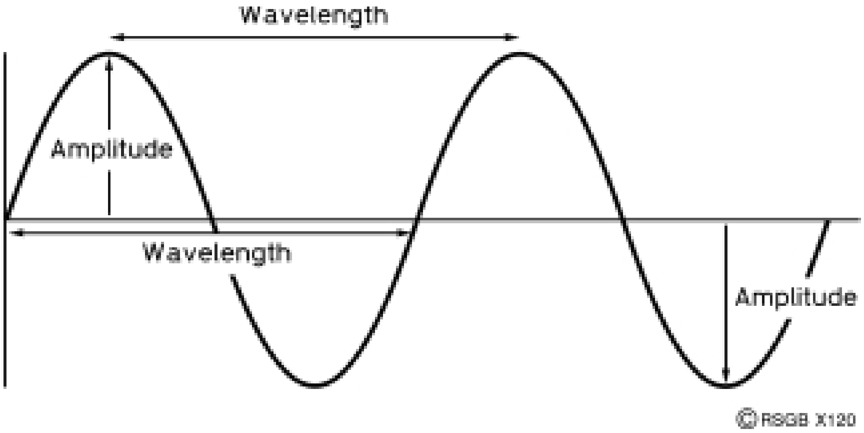


Figure 2 A water wave, viewed in cross-section

is always measured from the centre (undisturbed) position of a wave to the peak (or the trough) of the wave. Both these positions are shown, the arrow indicating that the measurement is taken *from* the centre *to* the peak or trough. The amplitude of a wave is defined as the maximum displacement of the wave from the centre position – the direction (up or down) of that displacement does not matter. Waves of greater amplitude carry more energy with them.

If we now ‘unfreeze’ the wave, we will see it travel from left to right (or right to left, depending on where we are looking). The speed at which it moves is called its *velocity*, and is measured in metres per second.

Another useful word is *propagate*; it means *travel*. We talk about radio waves propagating from a transmitter to a receiver. This velocity of propagation (for electromagnetic waves) is very fast indeed – they will cover 300 million metres in one second. This is virtually incomprehensible, so think of a radio wave travelling around the earth – it can travel 7½ times round the earth in one second! We use the symbol c for the velocity of radio waves (which is the same as the velocity of light, of course – all electromagnetic waves travel at this speed through air and space).

The last thing we need to know about the wave is its *frequency*. Imagine a cork floating on the water in the path of the wave; it will bob up and down. If we were able to count the number of times it went through its highest position in one second, then that number would be its frequency. Any periodic motion like this is said to go through one *cycle* each time one complete wave passes a point (in this case, our cork). We are thus counting the number of cycles per second of the cork’s motion. The unit of frequency is thus ‘cycles per second’; this unit is now named after Hertz, a radio pioneer, and is abbreviated to Hz.

Our description of the wave is now quite simple – we need only four quantities:

(a) **Frequency** symbol f – unit, hertz (Hz)
(b) **Wavelength** symbol λ (Greek letter lambda, pronounced ‘lamb-da’) – unit, metre (m)
(c) **Amplitude** symbol a – unit depends on application
(d) **Velocity** symbol c – unit, metres per second (m/s or $\mathrm{ms^{-1}}$)

The basic formula

Whatever may happen to a wave while it travels through different media (vacuum, air, brick, wood, etc.), one thing and **only** one thing remains constant – its frequency. Its wavelength, amplitude *and* velocity may change, but its frequency never does. Three of the four characteristics already identified are connected by the simple relationship

$$c = f \times \lambda.$$

Remember that c is constant if the wave travels in air or in a vacuum. This means that waves having higher frequencies (f large) must have smaller wavelengths (λ small) and vice versa. You can imagine frequency and wavelengths being on opposite ends of a see-saw!

Divisions of units

Because the frequencies of radio waves are so high (despite them having the lowest frequencies in the electromagnetic spectrum!) we have a problem with writing them down. Do you write in your log book that you have just heard a station on 14 100 000 Hz? Of course not, you write it as 14.1 MHz, knowing that the prefix mega (M) means ‘one million’. The prefixes which you need to know (when applied to frequency) are:

kHz	kilohertz	meaning	1000 Hz
MHz	megahertz	meaning	1 000 000 Hz
GHz	gigahertz	meaning	1 000 000 000 Hz.

Notice that the ‘k’ in kilohertz is a lower case letter. It is **incorrect** to write it as an upper case letter. ‘K’ is a computer-related prefix meaning **not** 1 000 but 1 024!

When we come on to discuss heat and light waves, we will use wavelengths rather than frequencies, because of the see-saw effect – as the frequencies get larger and larger, the wavelengths get smaller, and hence are numbers which are more manageable, both to talk about and to write down!

Bands

Gamma rays, X-rays, ultra-violet waves, light waves, infra-red waves are all part of the electromagnetic spectrum, but we divide them up because they have different properties. This is why we divide up our radio frequencies into different bands. The radio waves of top-band signals (around 2 MHz) have completely different properties compared with those in the 20 metre band, so we are dividing up the *radio spectrum* in the same way – by property.

9 A beat-frequency oscillator

Introduction

Many readers will know that, although they have a short-wave radio which covers at least one of the amateur bands (e.g. 7 MHz or 14 MHz), they are unable to listen to SSB or Morse signals. This is because the receiver lacks a Beat-Frequency Oscillator (BFO). We need the ‘carrier’ frequency of a BFO to replace the carrier that has been removed from the signal at the transmitter. When listening to Morse signals, the BFO signal ‘beats’ with the incoming signal to produce a note in the loudspeaker. If you are a musician, you will be familiar with the method of using ‘beats’ to tune one musical instrument from another; in the BFO, the beat frequency produced is the tone signal you hear.

In the more complex amateur radio receiver, a BFO is incorporated as part of the whole system. In our model, it is an external circuit that sits alongside your radio. The circuit diagram is shown in **Figure 1**.

Construction

Built on a small piece of matrix board about 80 × 50 mm, the circuit can be fitted inside a small plastic box. For once, we *don’t* want to screen the circuit to prevent it interfering with other equipment; we *want* it to interact

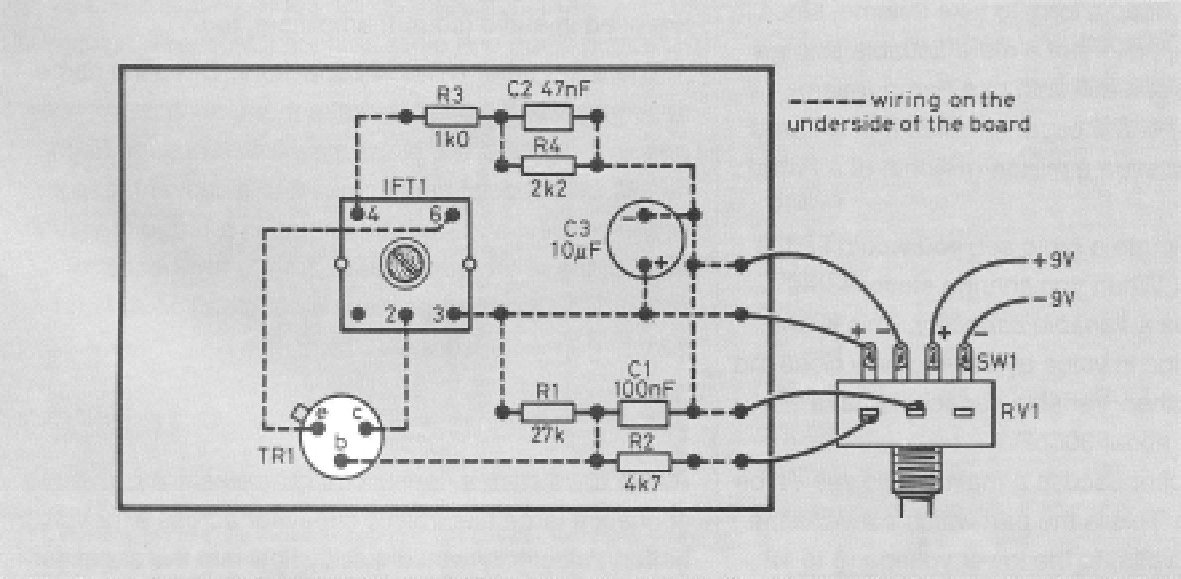

Figure 2 Matrix board layout shown from the component side. Adjust IFT1 carefully for the best results

with our receiver! This is why we use a plastic box. Maplin Electronic Components supply a suitable box, complete with the matrix board to fit inside (order code YU46).

Look at **Figure 2** carefully before you start to build the circuit, so that you can position the components correctly. Firstly, inspect the intermediate frequency (IF) transformer, IFT1, and remove its metal screening can very carefully. Again, this is to allow some signal to escape from our circuit and enter our radio. Having done this, solder the components, using the matrix board as a support. Underneath the board, the components are linked by single-conductor, insulated wire. Take particular care with the polarity of the electrolytic capacitor, C3, and the connections to the transistor, TR1 (see Figure 1).

The variable resistor, VR1, has a switch mounted behind the control itself, and the insulated leads to it from the battery should be about 10 cm long. Connect these before fitting VR1 into the case, so that the BFO can be calibrated (adjusted) correctly.

Calibration

After a final check that all the components have been fitted and soldered correctly, connect the battery, switch on, and hold the transistor between your fingers, to check that it is not getting hot. Place the circuit close to your receiver, and set RV1 to mid-position. Tune your receiver to find an amateur SSB transmission; the frequencies listed below will help you in knowing where to look. It may sound very strange, but don't worry. *Slowly* turn the core of IFT1 with a small, non-metallic screwdriver or with the correct 'trimming tool'. The core into which the blade fits is very fragile, so attempt this process with care. When the speech sounds as natural as you can get it, leave the core at this position, and use RV1 to make the speech sound natural.

Using the BFO

For best results, you may have to move the BFO nearer or further away from your radio. At the lower end of most bands (for instance just above 7.000 MHz or 14.000 MHz) you should be able to resolve Morse code (CW) signals. If you find that the BFO signal is a little weak, solder a 15 cm length of insulated wire to pin 2 of IFT1, and place it alongside your radio. This should improve signal intelligibility. When you are happy with the performance, switch off, drill a 10.5 mm hole in the box and fit RV1, followed by the matrix board assembly. Screw the base to the box, fit the knob, and the BFO is complete!

Where to listen

Band	**Frequencies (MHz)**
15 m	21.000–21.450
17 m	18.068–18.168
20 m	14.000–14.350
30 m	10.100–10.150
40 m	7.000–7.100
80 m	3.500–3.800

Parts list

Resistors: all 0.25 watt, 5% tolerance

R1	27 kilohms (kΩ)
R2	4.7 kilohms (kΩ)
R3	1 kilohm (kΩ)
R4	2.2 kilohms (kΩ)
VR1	4.7 kilohms (kΩ), linear, with DPST switch

Capacitors

C1	100 nanofarads (nF) or 0.1 microfarad (μF), ceramic
C2	47 nanofarads (nF) or 0.047 microfarad (μF), ceramic
C3	10 microfarads (μF), 25 V radial, electrolytic

Additional items

TR1	2N2222A npn

Box	plastic, approximate size 100 × 70 × 45 mm
Board	matrix, to fit inside the box
Connector	for PP3 battery
Knob	for RV1

10 What is a capacitor?

Introduction

A capacitor is a device that stores energy in the form of electricity. Much less energy than a battery, and for a shorter time, however. The simplest form of capacitor takes the form of two flat metal sheets separated by air; connections are made to each plate, as **Figure 1** shows. If you imagine a pair of these plates, 30 cm square and separated from each other in air by 1 mm, the capacitance of this device would be almost exactly 80 picofarads (pF), i.e. 80 million-millionths of the unit of capacitance, the farad. Now this is quite a small value, you will agree, and it comes about because the farad is such a large unit. Nevertheless, as you will probably know, we may have capacitors of value 10 000 microfarads (μF) in our radio equipment, and they can be smaller than your little finger, so they are obviously not made the same way!

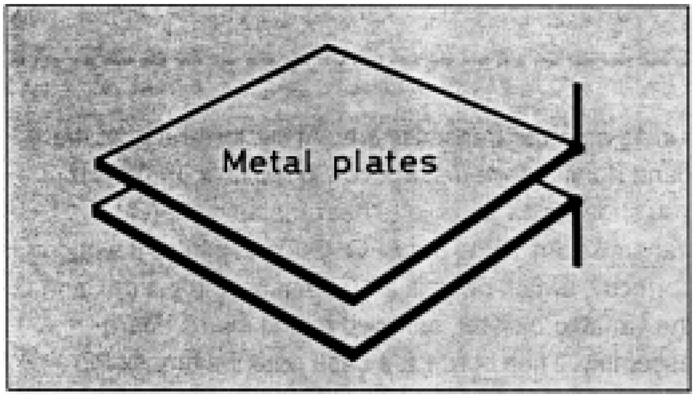

Figure 1

Large and small

We cannot go into the manufacture of capacitors here – after all, we are users of the devices, not the designers! First of all, beware of incorrect statements; the words ‘capacitor’ and ‘capacitance’ are *not* the same. For example, a large capacitor would be a description of one the size of a toilet roll. It need not have as large a capacitance as one the size of your little finger. A ‘large capacitor’ is one which is physically *big*, a ‘large capacitance’ refers to a capacitor which can store a larger amount of energy when a certain voltage is applied between its plates. The capacitors in a mains power supply are usually big **and** have large capacitances. High-power RF amplifiers may have large capacitors with small capacitances!

Electrolytics . . .

Electrolytic capacitors usually have capacitances of 1 µF or above. They differ from other capacitors in that they **must** be connected the right way round (i.e. they have positive and negative connections, just like a battery). They may explode if the connections are reversed!

. . . and the others

Other capacitors may be connected either way round, despite their names. We have *polystyrene*, *ceramic*, *silver-mica* and *tantalum*. Each has its own advantages and disadvantages, and the parts list for a project will always tell you which type is best.

Storing energy

If you were to connect a large capacitance across a 12 V power supply, nothing would appear to happen. Removing the capacitor from the supply and connecting it to a voltmeter would show that the capacitor has 12 V between its ends. This shows that, while the capacitor was connected to the supply, energy flowed from the supply into the capacitor. We say that the capacitor was *charged up* by the supply. If you are using an *analogue* voltmeter (i.e. one with a meter and pointer), you will notice that the indicated voltage slowly drops until, eventually, there is no voltage across the capacitor. This is because the capacitor has *discharged* its energy into the voltmeter. If you had used a smaller capacitance, the same would happen, except that the voltage would drop to zero more quickly – the capacitor stores a smaller amount of energy because its capacitance is smaller. Capacitors behave like other things in life – a small car can move more quickly than a large bus – a small piccolo emits a higher note than a flute – the voltages in a circuit containing a small capacitance will change more quickly than those in a circuit with large capacitance.

Varying the capacitance

Some capacitors are capable of having their capacitance changed manually; these are called *variable capacitors*. They work like the basic capacitor of Figure 1. Imagine moving the top plate of the pair a little to one side; the capacitance is determined, not just by the size of the two plates, but by their *area of overlap*. As this decreases, so does the capacitance. Such devices are limited in their capacitance, about 500 pF being the maximum value.

AC and DC

Because the plates of a capacitor do not touch each other, a direct current (DC) cannot pass between them. However, an alternating voltage on one plate can induce an identical alternating voltage on the opposite plate, and thus a capacitor appears to pass an alternating signal, even though currents as such, do not pass between the plates. This property of passing AC and not DC is very important, and a capacitor used in this way is called a *DC blocking capacitor* or, simply, a *blocking capacitor.* A blocking capacitor can be used at the same time, to couple a signal from one circuit to the next; here it would be known as a *coupling capacitor. Decoupling capacitors* are to be found where the capacitor is employed to remove an AC signal while retaining a DC component.

Finally. . .

Unlike resistors, the manufacture of capacitors renders them susceptible to excess voltage, so if you find a capacitor labelled 10 μF 16 V, it means that operating it above 16 V may fatally damage the device (and the circuit around it). This voltage is called the *working voltage* of the capacitor; on some electrolytics, you may find it expressed as *volts working* (i.e. 8 μF 450 V WKG).

Many smaller capacitors have their properties marked on them in a colour code, like resistors. **Figure 2** shows these codes, and their meaning, and the table below summarises the values of the colours.

Table 1

Colour	*Value*	*Voltage (tantalum capacitor)*	*Voltage (polyester capacitor)*

Figure 2 Some capacitors have coloured bands or stripes, rather like resistors. The colour code, which is the same as the resistor code, is shown in Table 1. The band shown on the chart as '1st' is the first number of the capacitor's value in pico-Farads, '2nd' is the second number and 'M' is the Multiplier or number of noughts. For example, a capacitor reads from the top: Brown, Black, Yellow, Black, Red. Its value is One, then Nought, then Four more noughts = 100 000 pF (also referred to as 0.1 μF or 100 nF). Its tolerance (Black) is 20% and the working voltage (Red) is 250 V. The 'V' means the maximum working voltage. The band marked 'T' shows the tolerance, just like resistors, and the one marked 'TC' is only used on special capacitors designed to change their value with temperature

11 Waves – Part 2

Introduction

We left Part 1 with the concept that radio waves are divided up into bands which have different properties. Not *all* the properties are different, though. We need to discuss several wave properties, so we will start with what happens to waves as they propagate over long distances.

Getting weaker

Imagine a torch battery connected to a bulb by wires about 1 metre long. The bulb lights normally. If we now take the bulb 100 metres away from the battery and wire it up, we would expect the bulb to be somewhat dimmer, which is exactly what would happen. It happens because of the resistance of the wires – the wires do not form a perfect conductor. A similar situation occurs with radio waves.

All waves suffer from *attenuation* – they get weaker the further they travel. In cases of extreme attenuation, we need to apply some *amplification* before the attenuated wave can be used in a receiver.

Carrying information

When we speak over the telephone, the range of frequencies in our voices extends from very low frequencies up to about 15 or 20 kHz. In audio terms, this is quite a large *bandwidth* (meaning a wide band of frequencies). For communications purposes, however, most of this bandwidth is not needed, and in the telephone system (and in our transceivers), this is cut down so that it extends from about 200 Hz to 3 kHz, a reduction in bandwidth from 20 kHz to about 3 kHz. A bandwidth of 3 kHz has been found to be sufficient to convey speech intelligibly which, after all, is just what we need!

The radio waves coming from an amateur transmitter convey our speech signals over long distances. By themselves, the speech signals do not travel very far, so they have to be combined with a radio signal that *will* travel long distances. This extra signal is called the *carrier wave* (or just the *carrier*), because its job is to *carry* the speech signals along with it! The process of combining the speech (or Morse code) with the carrier is called *modulation*.

Wider and wider

Sending Morse code is achieved simply by switching (or *keying*) the carrier on and off. The bandwidth of the transmitted signal is only about 100 Hz. Speech, with its reduced bandwidth of 3 kHz, will produce a *single-sideband* (SSB) transmitted signal with a bandwidth of 3 kHz. If the same speech signal were used to produce an *amplitude-modulated* (AM) signal from the transmitter, it would have a bandwidth of about 6 kHz. Perhaps you can now understand why the bandwidths needed to produce hi-fi broadcasts need to be so large. TV signals need bandwidths running into tens of megahertz!

Waves need aerials

Radio waves are produced whenever changing currents flow through a wire, and when that wire is made in such a way as to maximise the *radiation* from the wire, it is called an *aerial* or *antenna*. The same piece of wire will receive radiation from other aerials; an aerial will transmit and receive. This is an important property of the aerial: when a current flows through it, electromagnetic waves are launched into the air; when electromagnetic waves in the air encounter the aerial, currents are produced in it.

From the simplest transmitting aerial, waves travel in all directions, like the waves on the pond that we considered in Part 1. They will travel a long way through air and space before they become too week to be received. They won't travel very far into the earth, however! The earth will *reflect* some of the wave and will *absorb* the rest. That portion of the wave which is reflected will again travel through air and space until it is totally attenuated.

Look at **Figure 1**; A represents a radio transmitter, with B1, B2 and B3 being receiving stations. The two arrows pointing 'downwards' from A represent two of the waves from A which just graze the earth's surface. Waves above

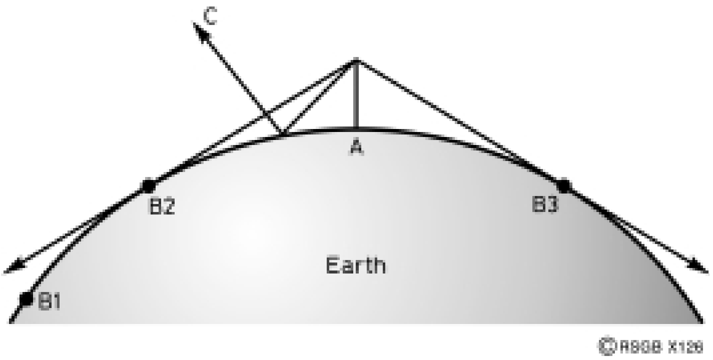

Figure 1 Stations between B2 and B3 receive the *ground wave*

these will travel on into space; waves below them will either be absorbed and reflected by the earth or received by aerials. B1 will not receive any signals from A, because it is below A's horizon. B2 and B3 can receive A's signals because they are *just* on A's horizon. Any stations between B2 and B3 will also receive A's signals, which are known as *ground-wave signals*. The wave at C represents one which is reflected by the ground and travels into space.

This description begs the question of how signals are received from stations well beyond the ground-wave range.

Mirrors in space

Suppose that there was something, out in space, that would reflect radio waves. Waves from A that travel out into space could be reflected off it and return to earth, enabling stations such as B1 to receive A's signals. The situation just described is illustrated in **Figure 2**.

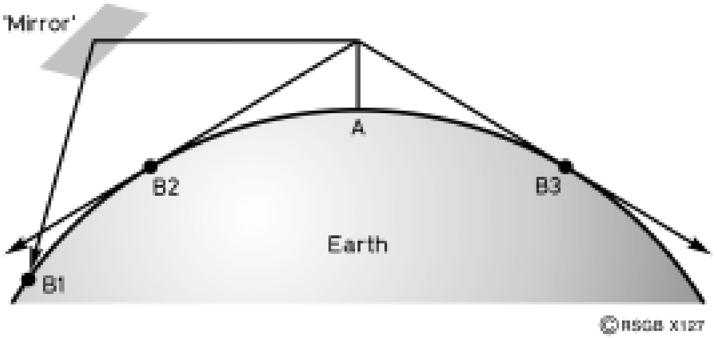

Figure 2 Reception of A's signals at B1 using the *sky wave*

Just such a mirror in the sky really *does* exist. It is not man-made, of course! The earth is surrounded by the atmosphere, a mixture of many gases, such as nitrogen and oxygen. The energy contained in the radiation from the sun is more than sufficient to *ionise* these gases, thus making them into electrical conductors. When a gas is ionised, some of its electrons are physically stripped out of the atoms and are free to move about, just as the electrons of a metal do in a wire. Consequently, we can regard this part of the atmosphere (the part illuminated by the sun) as acting like a sheet of metal, which *reflects* radio signals! It is not a perfect reflector, but is sufficient to produce long-range (DX) radio propagation via the *sky wave* under the right conditions. (A more down-to-earth example of ionised gases conducting electricity can be found in the fluorescent tube and the neon sign – many gases glow when they are continuously ionised.)

This conducting region at the extremity of the atmosphere is called the *ionosphere*, and it exists in layers between 60 km and 700 km above the earth's surface. When the ionosphere is sufficiently ionised, it glows; this is the natural phenomenon known as the *aurora borealis*, or the *northern lights*.

The property of the ionosphere that enables radio waves to be reflected does not act in a uniform way; it is very selective about which waves it reflects, and which waves go straight through it and into outer space. In general, it reflects only those waves with frequencies below about 30 MHz – the HF bands!

In Part 3 we will look at families of waves.

12 An LED flasher

Introduction

The LM3909 is an integrated circuit (IC) which will flash a light-emitting diode (LED). Using only two extra components and a battery, the circuit is cheap and has a very low current drain from a 1.5 V cell. The circuit can be used as a novelty flasher, an indicator for a dummy alarm bell box, or it could be attached to a torch so that it could be found easily in the dark! The simple circuit is shown in **Figure 1**.

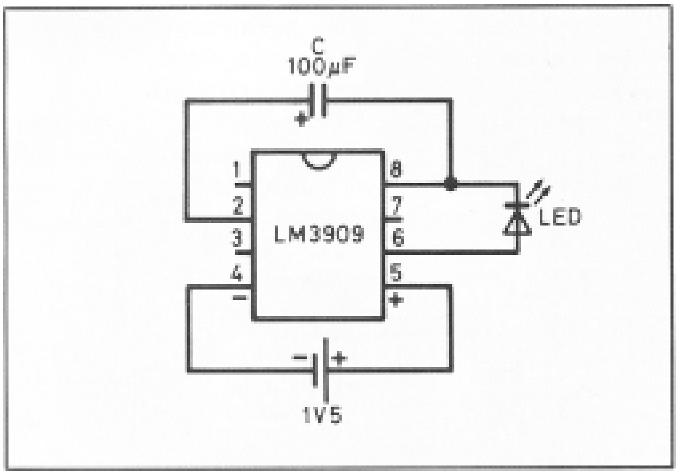

Figure 1 Circuit diagram of the LED Flasher. Pins 1, 3 and 7 of the IC are not used

Assembly

The circuit can be built on a small piece of Veroboard (the piece shown in **Figure 2** measures 15 holes by 10 strips). Using such a board, follow these instructions.

1. Depending on how far away you want the LED from the circuit board, solder a length of insulated wire to each lead of the LED. Use different colours of insulation – say, red and black, connecting the *red* lead to the *anode* (a) lead (the longer one) of the LED, and the black one to the *cathode* (k). Figure 2 shows these leads.
2. Cut the copper tracks as shown in Figure 2, using a 3 mm (⅛ inch) diameter drill, rotated between thumb and forefinger, or use the proper tool. Make *absolutely* sure that the tracks are completely broken!
3. Fit the IC holder in the correct position, using the cut tracks as guides, and make sure the small notch is facing towards the top of the board. Solder the pins to the copper tracks.
4. Mount the capacitor, positive end to the left, so that the positive lead is soldered to track F, which connects it to pin 2 of the IC; the negative lead is soldered to the right-hand side of track E, this being connected to pin 8 of the IC.
5. Solder on the battery leads, positive to the right, and the extended LED leads, positive downwards.

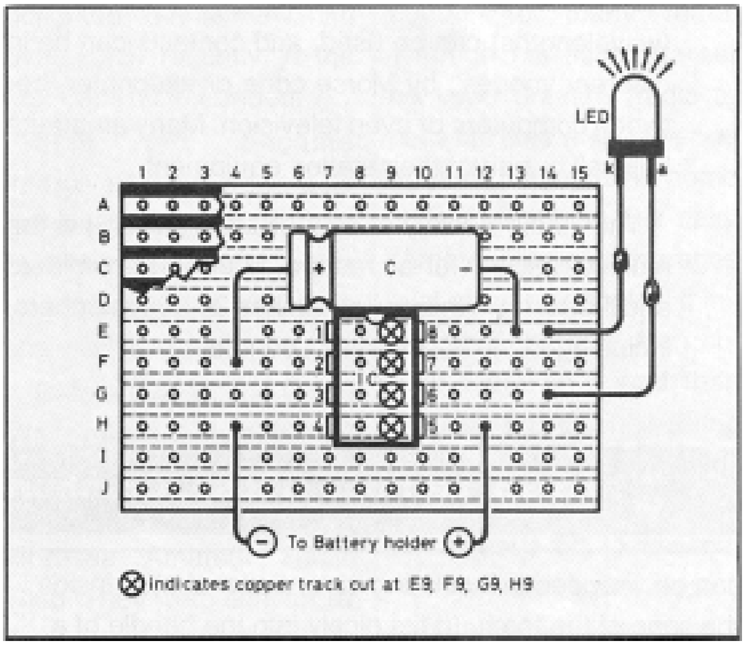

Figure 2 Board layout viewed from the component side. The tracks are cut under the board where shown

6. Check the circuit, and hold up the board to a bright light and look carefully for solder bridges between the tracks and pieces of copper swarf which may have escaped your inspection in 2 above! Remove whatever you find.
7. When all seems well, put the IC into the socket, ensuring that the notch or dot on the upper surface of the IC lines up with the notch on the holder. Line up each pin on the IC with the hole below it before pressing *gently* on the IC with the board supported on a firm surface.
8. Connect the battery; the LED should start to flash. The circuit is complete and working!

If you prefer, the whole circuit (battery included) can be mounted in a small plastic box, with the LED mounted on a clip and protruding through the panel. There are many other possibilities, and it is up to you to find an application for your own use.

Parts list

		Maplin code
LM3909	Integrated circuit	WQ39N
IC socket	8-pin DIL	BL17T
LED	5 mm diameter	WL27E
100 microfarad (µF)	Electrolytic capacitor (10 V)	FB48C
Battery holder	For AA-size cell	YR59P
Battery	1.5 V AA cell	

Small piece of Veroboard (15 holes by 10 strips)
Small plastic box (if required)
LED clip (if required)
Two lengths of coloured, insulated wire for LED (as required)

Availability

All parts can be obtained from Maplin Electronics Ltd.

13 Waves – Part 3

Introduction

When we talk about the spectrum being divided up into bands, this is just for our convenience; there are no natural divisions although, as we have seen, some of the properties of different bands really *are* different! Let's look at **Figure 1**, and see how the frequencies are divided up.

The divisions

- **Very low frequencies** (VLF) cover the range from a few kilohertz up to 30 kHz. Very long-range communication is possible, but at *very* small bandwidths. It is used for special purposes.
- **Long waves** (LW) are used for medium-distance commercial broadcasting and have frequencies from 30 kHz to 300 kHz.
- **Medium waves** (MW) are used for commercial broadcasting, and use frequencies from 300 kHz to about 1.5 MHz (1500 kHz). Typical range is about 200 km.
- **Short waves** (SW) encompass both the low-frequency (LF) and high-frequency (HF) amateur radio bands. There are nine narrow amateur bands in the SW spectrum between 1.8 MHz and 30 MHz. Some of these bands give round-the-world communication.
- **Very high frequencies** (VHF) span the range between 30 MHz and 300 MHz. Relatively short-range communication is possible. They were once used for broadcast TV before it moved to UHF. There are now three

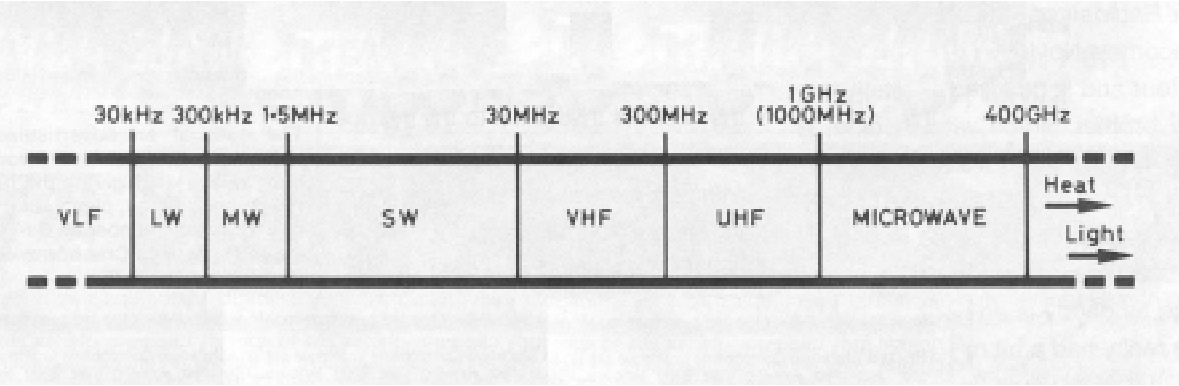

Figure 1 Diagram of radio frequency spectrum

amateur bands here – 6 m, 4 m, and 2 m. Repeaters are used to extend the usable range of mobile stations. VHF waves are not usually reflected by the ionosphere, but when they are, ranges of several thousand kilometres are possible. Weather affects these waves on a regular basis, however. In addition to amateur users, the VHF part of the spectrum is also used by the police, the fire and ambulance services, weather satellites, and many others,

- **Ultra-high frequencies**, sometimes called *centimetre waves*, cover the range from 300 MHz to 1000 MHz (or 1 GHz). The only amateur band in this range is the 70 cm band, and we share it with radar, TV and cellular telephone users as well.
- **Microwaves** begin at 1 GHz and extend to about 400 GHz. They are *never* reflected by the ionosphere, are partially attenuated by buildings, and are reflected from aircraft and cars. Microwave absorption in the atmosphere is quite significant, and rain and fog can attenuate microwaves quite heavily.
- **Heat, light** . . . Above 400 GHz we run into the infra-red bands and on into the visible light and ultra-violet bands. We generally take 400 GHz as being the limit of what we class as radio waves.

Bandwidth again

Complex signals need more bandwidth than simple signals. Even if it were possible, we would not be able to transmit a single television channel in the whole of the MW broadcast band! When TV used part of the VHF band, only five channels were possible in the range from 45 MHz to 68 MHz. By moving TV to the UHF band, we now have 47 channels between 470 MHz and 855 MHz!

It’s your choice!

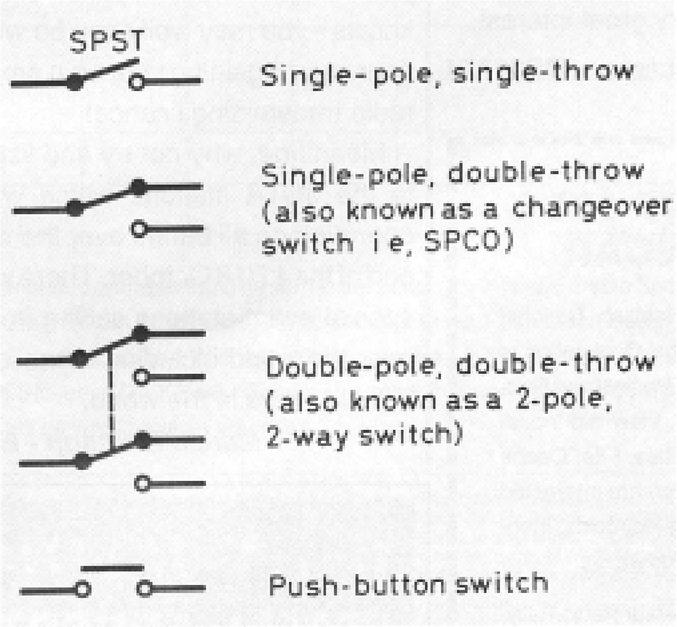
The number of permutations you have amongst all the modes and all the bands is enormous! Only you can decide what you are interested in and what you want to learn about. That is the attraction of amateur radio!

14 Choosing a switch

Simple, but be careful!

A switch is the simplest electronic component, but care is needed in choosing the correct one for the job. Here is a list of the main characteristics of a switch, which will help you to select what you want.

1. **Rating**. This gives the maximum voltage and current that a switch can handle. For example, a 250 V 1.5 A switch will switch mains voltage at a current not exceeding 1.5 A. If the current is greater than 1.5 A, the switch may get hot and fail. If the voltage is too great, the switch may arc each time it is switched off, thus wearing away the contacts.
2. **Number of poles**. A single switch can control many circuits; the number of poles tells you *how many* different circuits it can handle. See **Figure 1**.
3. **Number of throws**. This tells you the number of positions each pole can have. This is best illustrated in Figure 1. The simplest ON/OFF switch is a Single-Pole, Single-Throw (SPST) switch. A Single-Pole,



SPST
Single-pole, single-throw
Single-pole, double-throw (also known as a changeover switch i e, SPCO)
Double-pole, double-throw (also known as a 2-pole, 2-way switch)
Push-button switch

Figure 1 Some circuit symbols for different types of switch

Double-Throw (SPDT) switch may also be used as an ON/OFF switch, but is used mainly to change between two parts of a circuit, and is commonly known as a Single-Pole Change-Over (SPCO) switch. Two or more SPCO switches can be operated at once; Figure 1 shows an example. The two switches are said to be *ganged*. See also 'Types of switch' below.

4. **Number of ways**. When a switch has more than one throw, we tend to use the word 'ways' instead. This means that if a switch has one pole and six throws, we would normally call it a '1-pole 6-way' switch. Such switches tend to be rotary switches, as are described below.

Types of switch

(a) **Push-button**. These are found on calculators, telephones, electronic games and most equipment with a digital display.

(b) **Rotary**. These are switches controlled by a knob, and are turned instead of moved up and down. **Figure 2** shows the rear of such a switch and its circuit symbol. The commoner types of rotary switch are: 1-pole, 12-way; 2-pole, 6-way; 3-pole, 4-way; 4-pole, 3-way; 6-pole, 2-way. All these switches have 12 click positions, as you may have guessed, but each one comes with an adjustable end-stop so that you can set the correct number of ways according to the contacts on the switch.

(c) **Slide**. This switch is common on the cheaper types of radio, mainly as an ON/OFF or band-changing switch. They are not very rugged, but are small and cheap to produce. Very small types are manufactured for use on PCBs.

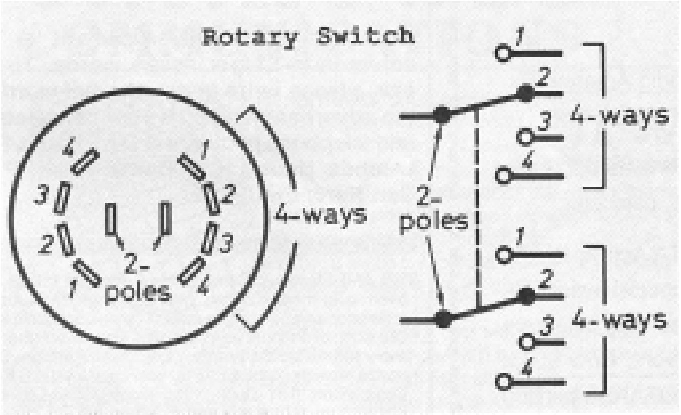


Figure 2 The rotary switch can select several different circuits at once

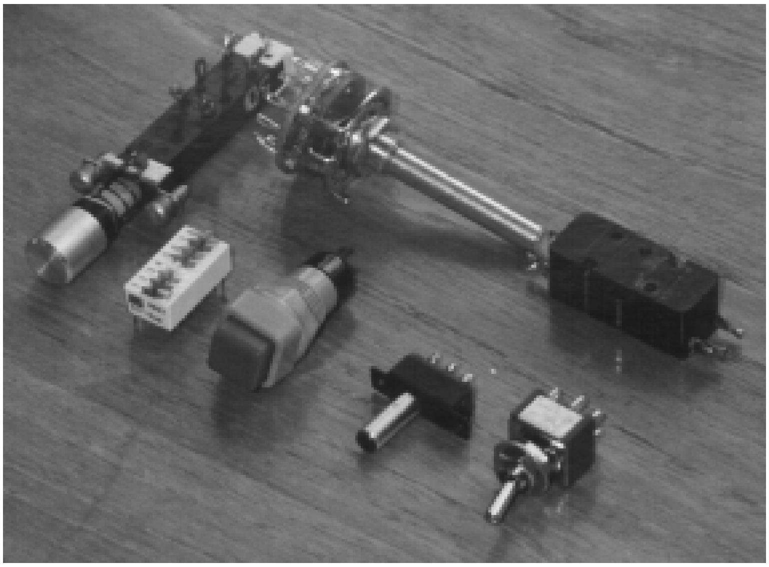
(d) **Toggle**. Available as two-way types or three-way, with a centre-off position. Can be manufactured to handle very high currents.

(e) **Micro-switch**. These are devices which are usually operated indirectly, such as when the cover is removed from a high-voltage power supply, or when the door of a fridge is opened. The ‘micro’ part of the name doesn’t refer to the size of the switch, but to the *small* movement that is required to activate it.



15 An aerial tuning unit for a receiver

Introduction

Any length of wire will act as an antenna (or aerial) but, to get the best results from a transceiver or receiver, an aerial tuning unit (ATU) is required. This matches the *impedance* of your aerial to the impedance at the aerial socket of your radio. Impedance is like resistance, and is measured in ohms, but it is used for alternating currents, and hence is common in audio and RF engineering. Most receivers have an impedance at the aerial socket of about 50 ohms (Ω); aerial impedance, on the other hand, can be anywhere between 20 Ω to over 1000 Ω, depending on its length and its height above ground.

Fortunately, you don't *need* to be able to calculate your aerial's impedance; all you need is a device that will perform the matching operation for aerials with a large range of impedances, and this is exactly what is described here! The subject of *matching* is a complex one, but all you need to know is that most signals will become clearer, and that there will be less noise and interference. Stations will become louder, so you will probably be able to reduce the setting of your RF gain control (always a good thing to do).

This design of ATU covers all amateur and broadcast bands from 10 m (28 MHz) to 80 m (3.5 MHz), and is very easy to build. The circuit is shown in **Figure 1**.

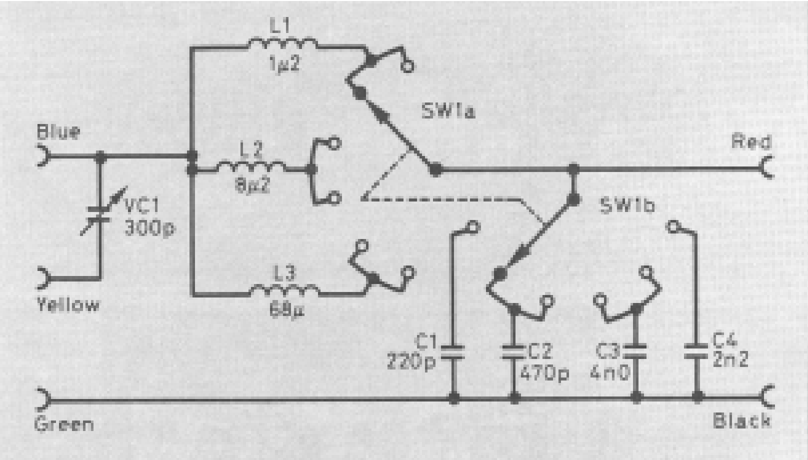


Figure 1 Circuit diagram of the Antenna Tuning Unit, showing the use of a 2-pole, 6-way rotary switch to select inductors (L) and capacitors (C)

Construction

1. Firstly, you will need a simple plastic case in which to house the ATU. The size should be approximately 85 × 145 × 50 mm.
2. Start by drilling two 10.5 mm holes in the front of the case; these are for the 6-way switch and the tuning capacitor.
3. Drill three 8 mm diameter holes in the left-hand side of the box, for the three sockets, coloured blue, yellow and green.
4. On the right-hand side of the box, drill two 8 mm diameter holes for the red and black sockets.
5. Now, fit the 6-way switch (SW1), the tuning capacitor (VC1), and all the sockets to the case. Check that the vanes of the capacitor rotate smoothly when the shaft is turned.
6. Wire up the inductors (coils). Figure 1 and the wiring diagram of **Figure 2**, will help with this. As you can see, each one side of each coil is connected to two switch connections, the other end going to VC1.
7. Solder in the fixed capacitors. One end of each goes directly to the ground socket (black), and the other end goes to the switch.
8. Solder a wire between the green and black sockets. The output from the ATU comes from the red socket, and this is connected to the two tags in the centre of the switch, as Figure. 2 shows clearly.
9. Finally, connect the blue and yellow sockets to the tuning capacitor, and the ATU construction is complete.

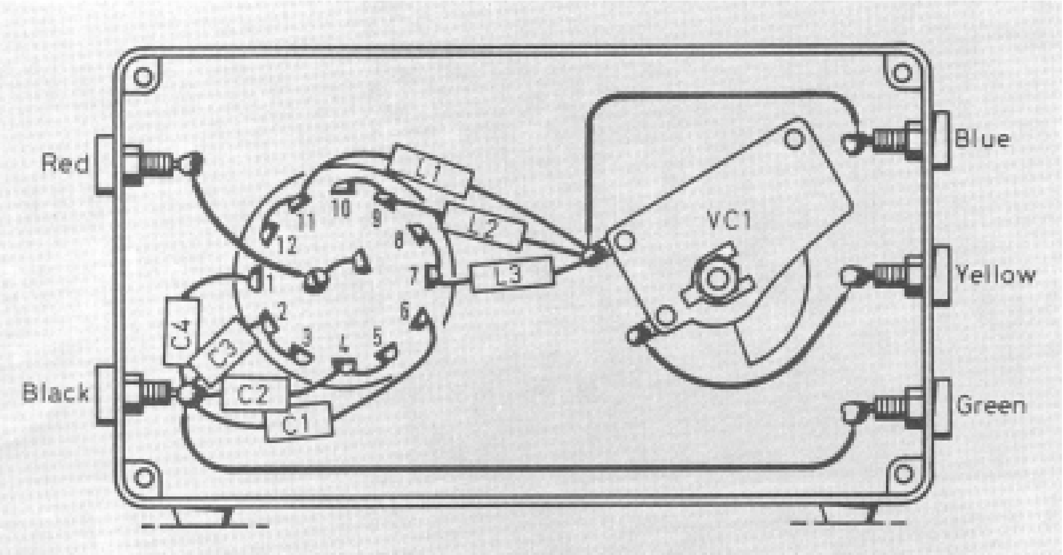

Figure 2 The internal view of the case shows the main tuning capacitor, VC1. This is a solid dielectric type, which has adjustable brass plates

In practice . . .

Figures 3 and **4** show two different ways of connecting your aerial to your ATU. In each case you will need to select each switch position in turn, and rotate the tuning capacitor through its full range while listening to a station. You should find that one switch position enables VC1 to produce a peak in the signal strength in the loudspeaker. At this point, your aerial and receiver are said to be *matched*. Stations in the same band will probably peak with VC1 at the same setting of SW1, but different bands will almost certainly require different positions of SW1.

Parts list

Capacitors (all rated at 16 V or more)

C1	220 picofarads (pF) polystyrene
C2	470 picofarads (pF) polystyrene
C3	1000 picofarads (pF) or 1 nanofarad (nF) polystyrene
C4	2200 picofarads (pF) or 2.2 nanofarads (nF) polystyrene

Inductors

L1	1.2 microhenries (μH)
L2	8.2 microhenries (μH)
L3	68 microhenries (μH)

Switch

SW1	2-pole 6-way rotary

Sockets

4 mm type, one each of red, black, yellow, blue, green

Additional items

Plastic or metal case, e.g. Maplin type YU54
Two large knobs for SW1 and VC1

16 A simple 2 m receiver preamplifier

Introduction

Designed specifically to complement the modified air-band portable (also described in this series), this can be used with some success on many receivers suffering from ‘deafness’ on VHF.

The circuit

An RF preamplifier is a device which improves the input signal to an existing receiver, enabling it to work more effectively. Because of the noise which is added to the signal by the preamplifier, *very* weak signals may not be usefully enhanced, but stronger signals will be improved considerably.

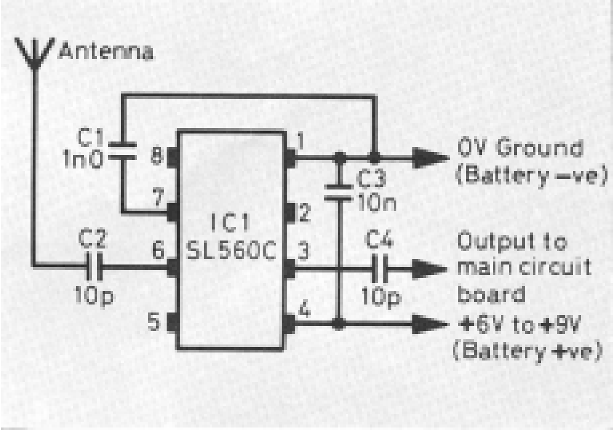

Figure 1 The integrated circuit is mounted upside down. Make sure you identify pin 1 which has a small dot next to it

This little circuit (shown in **Figure 1**) uses a GEC/Plessey integrated circuit type SL560C. With the addition of four capacitors, it is used between your aerial and the aerial input of the radio's PCB.

Putting it together

1. Use a small piece of prototype (matrix) board about 25 mm square. Use an 8-pin DIL socket for the integrated circuit (don't risk soldering the chip – it is seldom a risk worth taking). Figure 1 shows the connections to the socket, *looking from underneath*.
2. Make special note of the pin numbers, so that you know how to put the chip into the socket when you have finished. The positive and negative connections to the circuit are taken from the main PCB *after* the ON/OFF switch – so that the switch operates the preamplifier, too.
3. Unsolder the lead to the radio's telescopic aerial and connect it to the free end of C4, as shown. Then solder a short lead between the telescopic aerial and C2.
4. Sometimes it is possible to cajole your little preamplifier into the radio's plastic case, provided there is room and that you make sure that none of the soldered joints on your little board touch any of the metal inside the case when you replace the back and screw it on again.
5. If there is not enough room inside, then put the preamplifier into its own box, with battery and switch, and its own aerial. Keep the lead from the preamplifier to the aerial connection of the radio as short as possible – perhaps using screened cable.

Because your preamplifier is untuned, you will find not only that it helps with reception on 2 metres, but also that reception on the FM broadcast band is improved!

17 Receiving aerials for amateur radio

Introduction

For any radio receiver to work well, it must have some form of antenna, or aerial. In almost all domestic transistor radios, the aerial is built into the set, either as a ferrite rod (which looks like a rod of dark grey metal) on which are wound coils of wire, or as a chromium-plated telescopic metal rod. Some radios have both forms of aerial, using the ferrite rod aerial for long waves (LW) and medium waves (MW) and the metal rod for very high-frequency (VHF) stations using frequency modulation.

There's broadcast reception . . .

No aerial is perfect, and these two types are *far* from perfect! As in most mass-produced equipment, *they serve their purpose*, which is not critical, and they allow the radio to be carried around easily, because they are not big and bulky. The broadcast stations are very powerful, usually quite close, and the circuits in the radio are quite sensitive, so the need for large aerials disappears.

. . . and there's amateur DX

Here we have an application which, in comparison with the broadcast situation, couldn't be much more different. The stations do not use much power, they may be half the world away, and the requirement for good aerials and very sensitive receivers is paramount. The aerials must be large and they must be as high as possible, away from buildings and trees, which cause reduction in signal strength, and away from man-made sources of interference.

You may not have thought about this but, in general, the larger an aerial becomes, the longer the cable (or 'feeder') must be in order to reach your shack and the receiver inside it. Cables reduce the received signal, so what your aerial gains by being large, the feeder (if you're not careful) will lose!

A simple aerial . . .

We now know that a 'good' aerial is essential. But what is a 'good' aerial? It depends on your purse, your property and your enthusiasm! One of the simplest (and, incidentally, one which is *not* subject to the cable loss problem discussed above) is the **Long Wire**, shown in **Figure 1**. This is, quite literally, a long piece of wire going from a chimney stack to a tree or pole

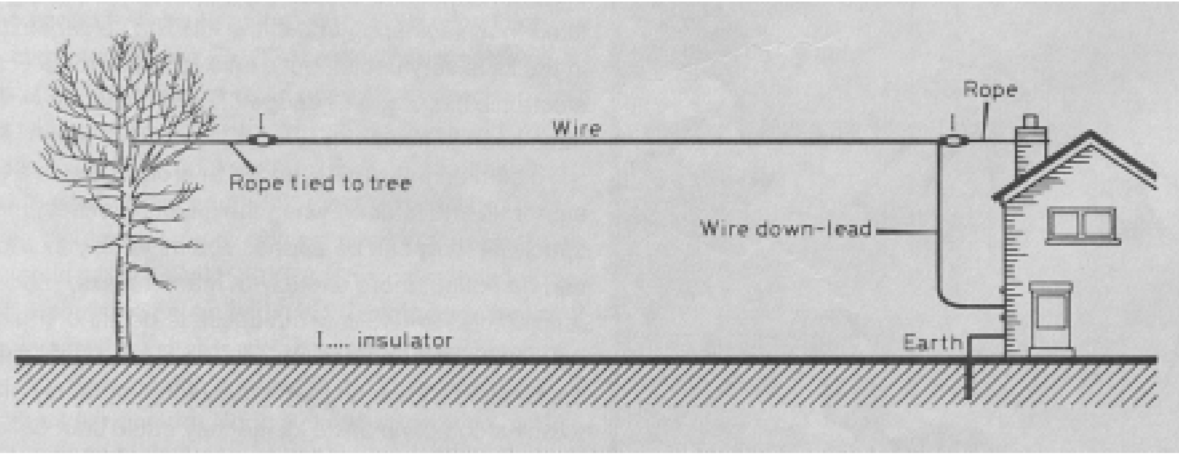

Figure 1 A tree at the bottom of the garden can provide a useful antenna support. Insulators can usually be obtained from Tandy stores or TV aerial suppliers

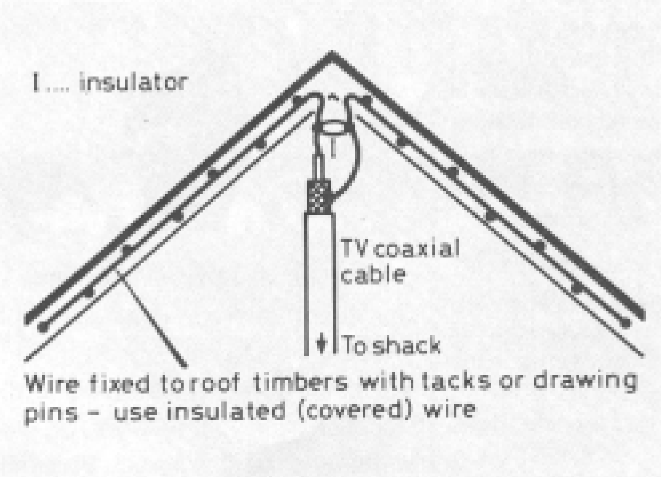
at the end of the garden. The longer it is, the better. Notice that the wire itself is *not* used to loop around the tree or chimney. Rope is used for both, and is secured to the end of the wire using an insulator of the 'dog bone' or 'egg' variety, to be found in profusion at rallies.

The wire is brought into the house through a window into the shack where the receiver is situated. The long wire aerial is best used with an aerial tuning unit (ATU), which is also described in this book. One of the advantages of the long wire is that it can be used on several frequency bands.

. . . and more complicated ones

Next up the ladder of complexity is the **dipole** (meaning two poles, or two elements). One form of dipole for lower frequencies would take the same basic form as the long wire, except that the feed to the receiver is taken, not from the end, but from the centre. The wire is essentially cut into two halves, and the two ends at the centre are connected to one end of a coaxial cable, which is then taken to the receiver. A smaller form of this is shown in **Figure 2**, which is conveniently mounted in a house loft. Aerials should always be mounted outside for best results, but will work when mounted inside, and the loft space is the logical situation.

The total length of the dipole should ideally be one-half of the wavelength of operation – hence the term 'half-wave dipole'. For example, a dipole for use on 20 m should be about 10 m long. Dipoles are thus 'single-band' aerials. They can be modified for use on several bands, and then become known as 'trapped dipoles', having coils and capacitors at certain points along their lengths.

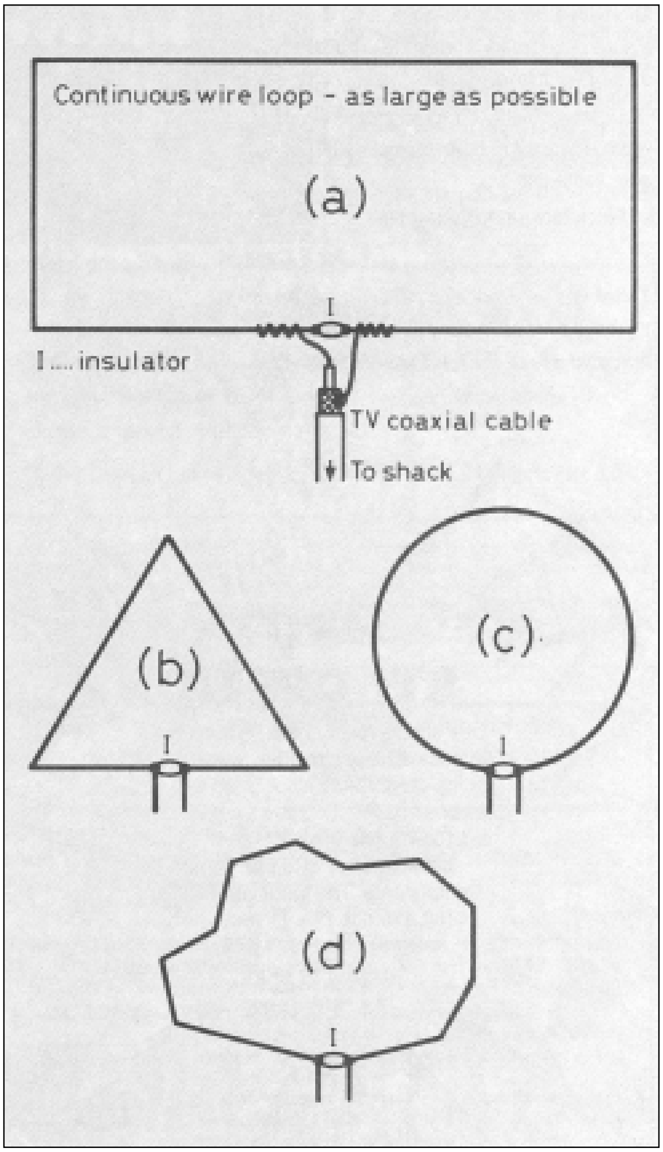


I.... insulator
I
TV coaxial cable
To shack
Wire fixed to roof timbers with tacks or drawing pins – use insulated (covered) wire

Figure 2 An indoor antenna should be mounted as high as possible

Indoor aerials

For flat- or apartment-dwellers, an indoor aerial is often the only solution, in which case the dipole of Figure 2 may be of great use. Other popular types include the **loop aerial**, of which several types are shown in **Figure 3**. The shape of the loop is of secondary importance, but it should be as large as possible.



Continuous wire loop – as large as possible
(a)

I.... insulator
TV coaxial cable
To shack
(b)
I
(c)
I
(d)
I

Figure 3 Try different shapes of loop antenna to see which works best

Ingenuity is called for when considering indoor aerials. A dipole can be mounted along a picture rail or pelmet. A vertical loop of aluminium foil can be stuck to an inside wall and covered with wallpaper! The designs are limited only by your imagination, and will give you hours of listening pleasure

Outdoor aerials

If you want to venture beyond the simple long-wire discussed earlier, then the erection of outdoor aerials can be a bit tricky; they can be more than a one-man job, and can involve seeking planning permission. Get some help advice from someone who has done it before – what about your local radio club? Plenty of designs for aerials appear in *RadCom*, so you should never be short of ideas!

18 The Colt 80 m receiver – Part 1

Introduction

This is the first of four parts detailing the design and construction of a simple radio capable of good reception of amateur radio signals on the 80 metre band. If you can solder and have some basic hand tools, at the end of Part 4 you will have a working receiver, in which you can take pride, and start some serious listening on 80 m! For testing, all you will need is another receiver and a multimeter.

Description

The radio will be built in three modules, or stages, as illustrated in **Figure 1**. Each of these is built on a printed-circuit board (PCB) or matrix board and can be tested in its own right. The case will need some holes drilled, and care will be needed to mount the PCBs in the case.

Get to it!

Surprisingly enough, when you are building a radio section by section (which is *always* the best way), it is easiest to start at the output and work

towards the input, and you can test what you have done stage by stage. You will see what this means as you progress with your construction.

Every receiver needs some audio frequency (AF) amplification to make the sound signals big enough for you to hear. The circuit for the AF amplifier is shown in **Figure 2**. It uses the TDA7052 integrated circuit (IC) plus a handful of extra components. R1 in conjunction with C2 and C3 *decouple* the battery supply, preventing any audio signals getting through to it and affecting other parts of the radio, when they are connected. C1 acts to prevent high frequencies (above the 3 kHz bandwidth) going into the amplifier input. A volume control, VR1, is connected across the amplifier input, so that the amplifier can accept signal inputs over a wide range. **Figure 3c** shows the connections, which are made with screened cable. Figure 2 The Philips TDA7052 integrated circuit (IC) used in the audio amplifier needs very few extra components. It has a signal voltage gain of 100 times and the output is suitable for a loudspeaker or headphones

centre conductor of the left lead goes to the point marked 'input' in Figure 2, the braid being connected to the amplifier earth (0 V) tag. The right lead to VR1 goes to whatever signal source you have for testing – see later. VR1 is *not* mounted on the PCB.

The circuit is constructed on a small PCB or matrix board. Make sure that the electrolytic capacitor, C3, is soldered into the board the correct way – its positive and negative connections are shown in **Figure 3b** for reference. If you are **at all** concerned about soldering the IC into the board, enlist some help, *or*, obtain an 8-pin DIL socket, which you can solder in and then carefully insert the chip into the socket, making sure that is the correct way round. The markings on the chip are shown in **Figure 3a**.

The output leads from the amplifier go to a plastic 6.3 mm (¼ inch) mono jack socket, so that *neither* output lead is connected to the metal case. The amplifier will drive a pair of headphones or a small 8 Ω loudspeaker.

The battery leads must be the right way round also; the battery itself can be a PP3 or PP9, or you can use a small DC power supply.

Testing

First, check that all the components are in the right places, that your soldering is good, and that you have headphones or a loudspeaker connected. Set VR1 about halfway along its travel. Connect the battery.

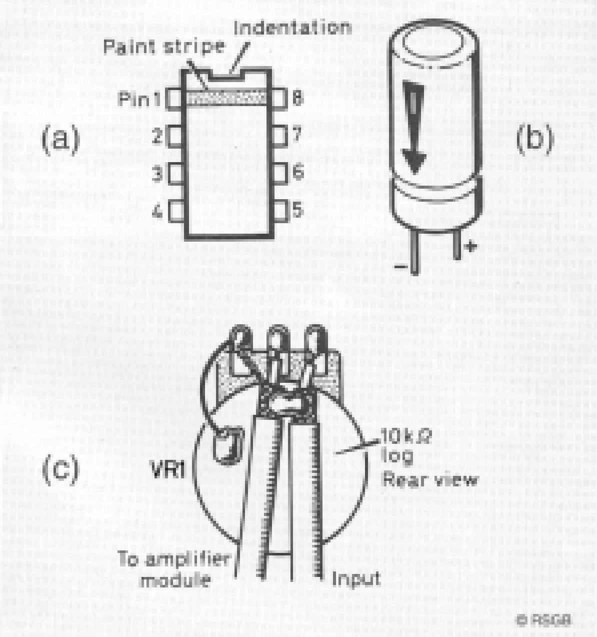

Figure 3 It is important to check the component connections carefully. The diagram shows (a) top view of the IC, (b) electrolytic capacitor and (c) volume control (VR1) connected across the input of the amplifier

A slight hissing noise should be heard; touching the input lead to the amplifier (the centre of the three connections on VR1) should produce a loud buzz. Touching the shaft at the same time will make the buzz quieter. This is the quickest way of confirming that your amplifier *seems* to be working. The only real test is to give it something meaningful to amplify! See the design of our *Crystal Radio Receiver* for full details.

19 A crystal radio receiver

Introduction

Here's a quick project to fill in a winter's evening! It was originally designed as a piece of test gear for the *Colt* receiver, but can be successfully used by anyone as a first radio project. Another use for it would be as test gear for any audio amplifier project requiring an audio input for test purposes; this is ideal, as it does not require any power supply!

Details

The initial rough-and-ready test for the audio amplifier of the *Colt* receiver will have whetted your appetite; you will want to prove more conclusively that your amplifier works, and in a way that others in the household will appreciate. Buzzing noises are not convincing in this respect! You are going to put together a simple crystal set – the simplest type of radio that there is – and use it as a signal injector for your amplifier. In this way, you build a real medium-wave (MW) receiver which drives a loudspeaker, as an intermediate product of the construction of an 80 metre amateur band receiver!

The circuit diagram is shown in **Figure 1**. It has a 60-turn coil mounted on a small piece of paper or card wrapped round a ferrite rod. The coil has a connection made to its centre-tap (the middle turn of the coil). The tuning capacitor, VC1, is the most expensive part of the circuit but don't worry, it will be used in the final design of the receiver also! Connect the diode, D1, from the centre-tap to the input to the potentiometer of the amplifier circuit of the *Colt*. Be careful to connect the aerial to the *vanes* of VC1, and not to its *frame*, or you will experience some strange effects when you are tuning. If your amplifier is working correctly, you should be able to receive local stations on medium-waves quite well.

If you think the crystal set will be of use to you in the future as a signal injector, all you will need will be another variable capacitor! If you do not intend to use the amplifier, a small crystal earpiece will allow you to listen. Walkman-type headphones will *not* work!

20 The varactor (or varicap) diode

Introduction

Many of the circuits for receivers and transmitters presented in this series rely upon the variable capacitor as a means of tuning. Another method of varying capacitance (without any moving parts) is provided by the *varactor diode*, sometimes called a varicap diode. This is a component which changes its capacitance as the voltage across it is varied.

The details

Figure 1 shows how a varactor diode might be connected to demonstrate its operation. Its symbol is that of an ordinary diode, with a capacitor symbol next to it. A variable voltage is applied across it in such a way that the diode is *reverse-biased*. This means that virtually no current passes through it – the positive voltage is applied to the cathode. Varactors are cheaper than variable capacitors, and they are tiny in comparison, very suitable for today's miniature circuits. If A and B were connected across the tuning coil in a simple receiver (with a series capacitor to block the DC from the battery reaching the coil), the tuning operation would be accomplished by turning the knob on the 10 kilohm potentiometer.

Varactors are available with different values, from less than 20 picofarad (pF) for VHF applications to 500 pF for medium-wave radios. They are

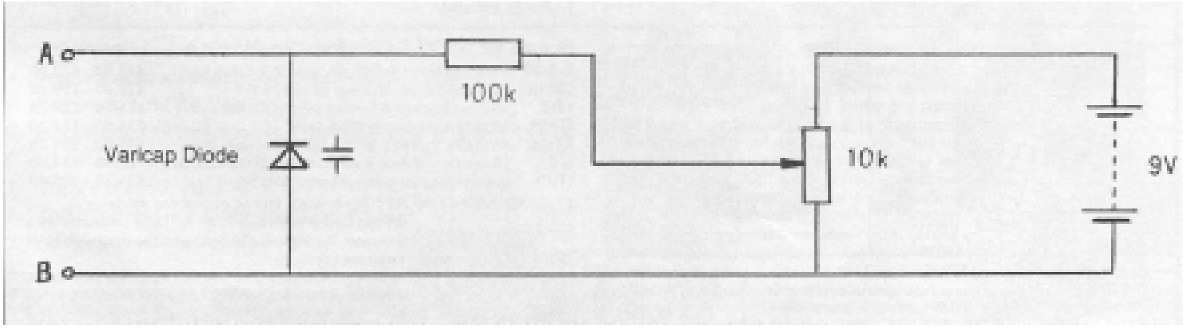

Figure 1 The capacitance of the varicap diode (between A and B) increases as the voltage is reduced, using the variable resistor

tuned usually by voltages between 2 V and 9 V. For a real application of varactors, you should consult the circuit diagram of the *Yearling* 20 metre receiver, elsewhere in this book.

In some circuit designs, several circuits are all tuned to the same frequency in order to improve the overall *selectivity* (the ability of the circuit to reject signals very close in frequency to the wanted signal). Special dual- and triple-varactors are available for circuits like this. Having been made at the same time from the same materials makes their individual characteristics virtually identical. Like all other diodes, they must be correctly wired into the circuit – their *polarity* is important.

Changes in temperature will cause the capacitance to change which, if it were part of an oscillator circuit, would cause the oscillator to drift – you would have to keep retuning the radio! This can be corrected by using a special integrated circuit called a *phase-locked loop* (PLL). Modern TV sets and satellite receivers use varactors and PLLs in this way.

Some useful varactor types

Type No.	*Tuning range*		*Description*
	pF/V	*pF/V*	
BB204B	42/2.0	15/12	Dual VHF
BB212	560/0.5	22/8	AM tuning

KV1236	450/2.0	30/8.5	Dual AM
MV1404	120/2.0	9/10.0	HF tuning

21 A portable radio for medium waves

Introduction

The ZN415E integrated circuit (IC) can be used to make a very efficient AM portable MW broadcast radio with a built-in loudspeaker. Here's how!

The circuit

Figure 1 shows the circuit diagram of the portable radio. It's not as complicated as it may appear, especially after you have got started. L1 is a coil of wire mounted on a ferrite rod, acting as an aerial; VC1 is a variable capacitor which works, with L1, to tune in different stations. IC1 contains circuits of its own which boost the selected signal and it includes a *detector* which extracts the audio signal from the incoming RF signal. Earphones could be connected to the output of IC1 (between pins 4 and 5), but the output would not be powerful enough to drive a loudspeaker.

More sound

This is where IC2, an LM386 comes in. This is a small audio *power* amplifier which produces audio signals with enough power to drive a small

Figure 1 The circuit diagram of our easy-to-build portable radio. Take care to mount the ICs and LED the correct way round

loudspeaker, LS1. The radio uses a 6 volt battery, which is made by connecting four 1.5 volt AA cells in series (4 × 1.5 V = 6 V) using a battery holder designed for this purpose. Although a 6 V supply is ideal for IC2, it is far too great for IC1, which needs only about 1.3 V. This lower voltage is provided from the 6 V supply by TR1 (an npn transistor), R2 and LED1 (a light-emitting diode). When current passes through an LED (see the description of the LED in this series) a reasonably constant voltage of 1.9 V appears between the anode and the cathode. Because of the voltage (0.6 V) that *always* exists between the base and emitter of a working transistor, the voltage on the emitter is about 1.9 V – 0.6 V = 1.3 V, and this is used as the power supply for IC1.

To keep the radio as simple as possible, no volume control has been fitted. Instead, you can use the directional properties of the ferrite rod aerial (see the information on ferrites in this book) to reduce the volume by rotating the set about a vertical axis using the handle provided.

Putting it all together

1. Start by covering the ferrite rod with Sellotape, or alternatively wrap a piece of paper tightly around it, and secure it with Sellotape. Then, with at least 2 metres of 24 SWG enamelled copper wire, wind 75 turns tightly around the rod. To be safe, leave about 50 mm of wire at the ends of the coil, then wrap the whole coil with Sellotape to hold the turns in place, leaving only the ends free. Then, using a small piece of sandpaper, remove the enamel from the last centimetre of each end of the coil.
2. Most of the components are mounted on a piece of Veroboard (the type with parallel copper strips on one side). The piece used on the prototype measured 32 holes by 10 strips, as **Figure 2** shows. Before you start fitting components, cut the copper strips as shown. It is easier to do it now than when the board is littered with components! The strips may be cut with a 3 mm (⅛ inch) twist drill rotated between thumb and forefinger. Resist the temptation to use a hand drill – the idea is just to cut the copper, **not** to drill right through the board!
3. Solder the IC sockets and the other components on the board as shown in Figure 2. Make sure that the IC sockets are fitted with their notches towards the *top* of the board, as viewed in Figure 2. Do not insert the chips yet. Always keep the wires left over from cropping resistors and capacitors, they will come in handy at times like this: make the wire links that are clearly shown in Figure 2. Connect the electrolytic capacitors (C5, C6, C8 and C9), the transistor and the LED the correct way round; then check it again when you have done it!
4. Finally, solder lengths of stranded insulated wire to act as 'flying leads' for future connection to L1, VC1, LS1, S1 and the battery connector.
5. Apart from the battery holder, everything is mounted on the case *lid*. This makes assembly and testing much easier, and eases fault-finding if

the need arises! At the speaker position, make one large hole or a series of small holes to let the sound out. The ferrite rod may be stuck to the lid, as may the loudspeaker. Drill holes of the correct size to fit the particular types of variable capacitor (VC1) and switch (S1) that you are using. The Veroboard may be held in position by Blu-Tack or double-sided sticky tape.

6. Before inserting IC1 and IC2, connect the battery and switch S1 on. The LED should glow dimly (you may have to shield it with your hand in order to see it). If you have a test meter, check that there is about 1.3 V between pins 6 and 4 of IC1. If the reading is around 6 V or there is no glow, you may have connected the LED the wrong way round! When everything seems normal, switch off and disconnect the battery. Insert IC1 and IC2, making sure that the pins are straight and lie immediately above their corresponding holes in the sockets, and that the notches line up with the notches in the holders. Then push *gently* downwards on each IC in turn until the chip is firmly seated in its socket.
7. Switch on! By rotating the tuning capacitor, VC1, you should now be able to tune in many stations, rotating the radio to give you some volume control.

Final touches . . .

The handle was made with part of an old leather belt, secured to the case with 'number plate' nuts and bolts from Halfords. The loudspeaker grille is the lid from a *pot-pourri* container, and some extra holes were drilled in the back to improve the sound. See what you can find to finish off your radio!

Parts list

Maplin order codes are given for most of the parts, but you should get used to using the 'beg, borrow or steal' technique, or to use your ever-expanding junk box.

Additional items (*continued*)

VC1	Tuning capacitor 140 to 300 picofarads (pF)	FT78K
	Tuning knob	FK41U
	8-pin DIL IC sockets (two required)	BL17T
	4 × AA-size battery holder (long)	HF94C
	PP3-type clip for battery holder	HF28F
	Plastic box approx. 158 × 95 × 54 mm	LH51F
	0.1 inch Veroboard, min. size 32 holes × 10 strips	JP46A

Plus

- Stranded insulated conductor for flying leads
- Multicore solder
- Materials for handle and speaker grille
- Double-sided sticky tape or Blu-Tack
- Sellotape
- Glue
- Four AA-size 1.5 V batteries

22 The Colt 80 m receiver – Part 2

Introduction

In Part 1 we constructed the audio amplifier module for the system and tested it in a very simple way. If you did what was suggested and built the simple Crystal Set to use as a signal source, you will know just how well the amplifier works.

The case

Metal cases for the project are available from Maplin, telephone 01702 554 161 (code XB67). From the photograph on p. 72 you can see the way the components are mounted. The audio amplifier is seen at the top right of the base, to the right of the tuning capacitor VC1. The next in this series will deal with the variable-frequency oscillator (VFO) and VC1. The current part deals with preparing the case to receive the components.

Figure 2 Position the slow motion drive to allow viewing of the tuning dial

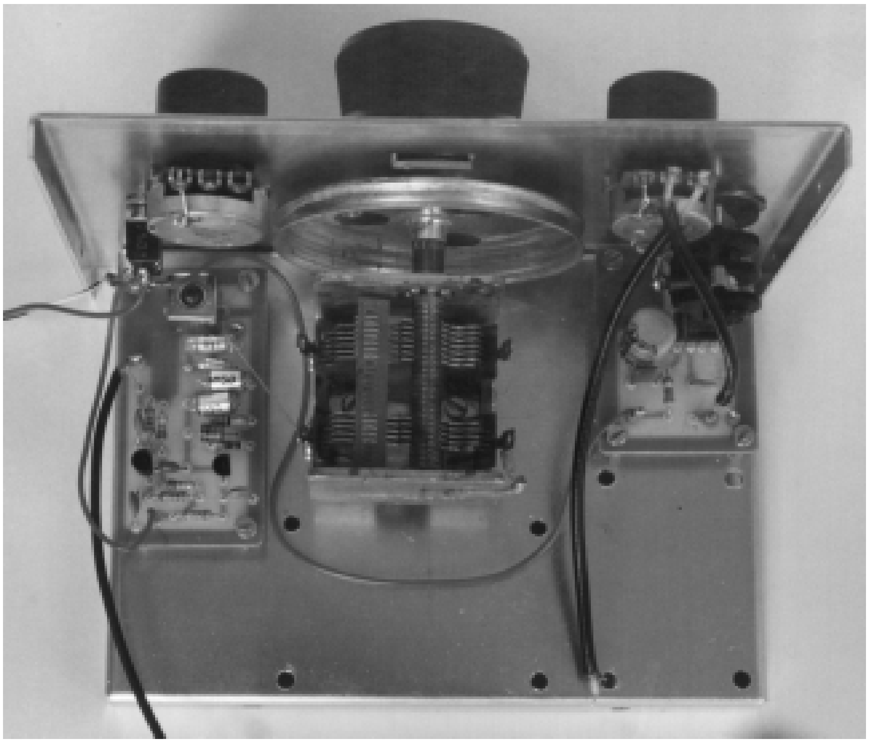
Figures 1 and **2** show the markings for preparing the front panel and base. All the circuit boards and the tuning capacitor are mounted on the base using 10 mm stand-off pillars with 6BA bolts. The board locations are shown in Figure 1. The front panel control positions are shown in Figure 2, together with the small rectangular hole for viewing the tuning dial.

The best way to mark out the holes for the boards is to lie the boards flat on the base (before you've started soldering the components in) and marking the base through the holes in the boards. This minimises the scope for errors!

A *reduction drive* is used between the tuning knob and the capacitor shaft. This is simply a gear mechanism that slows down the capacitor shaft by a factor of six compared with the tuning knob, and makes tuning very much easier. The recommended variable capacitor also has a pulley wheel mounted on the shaft. Glued to this wheel will be a scale marked with frequency and is visible through the rectangular hole in the front panel.

The next part . . .

The variable-frequency oscillator and mixer will be added to the project.



23 A simple transistor tester

Introduction

Although transistors aren't used as much as they were before integrated circuits came along, a transistor tester is still a useful piece of test equipment to have around the shack. This design is about the simplest possible and will produce an indication of whether a transistor is giving any current gain; this does not necessarily mean that the transistor is perfect but that it is working to a certain extent. This tester will **not** test field-effect transistors (FETs). If you buy a bag of transistors at a rally, this tester is useful for giving a yes/no indication of which ones go straight in the bin and which are kept for further use.

How it works

Figure 1 shows the simple wiring circuit. In order to explain the working of the circuit, a circuit diagram is shown in **Figure 2**, with the npn transistor, TR1, under test shown as part of the circuit. The pnp/npn selector switch, SW1, is omitted for clarity.

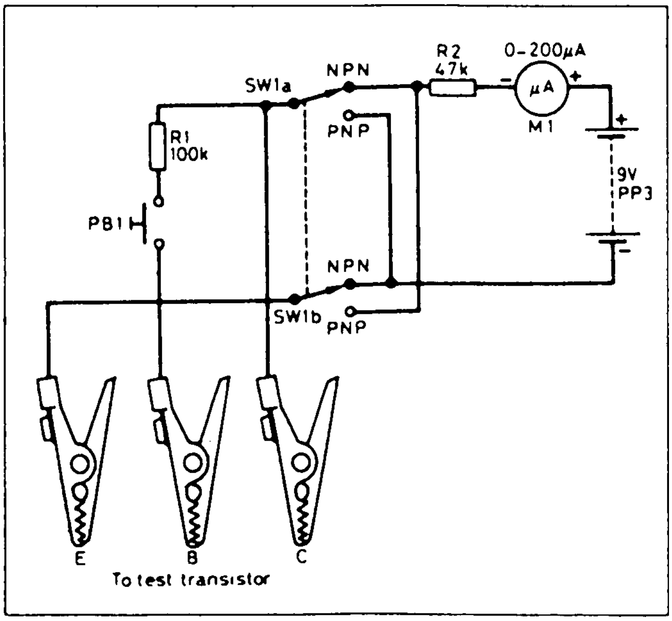


Figure 1 Circuit diagram of the transister tester

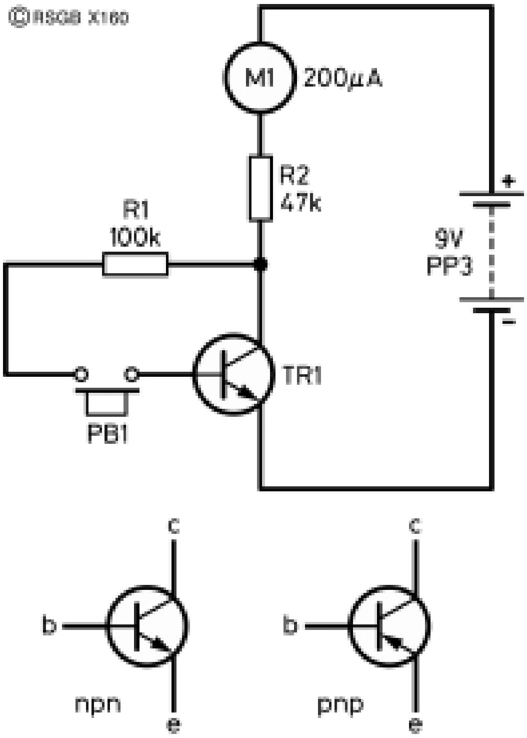

Figure 2 Testing an npn transistor

Any current that flows through the transistor, TR1, must flow from the battery, through the meter, M1, and through the protective resistor, R2. R2 prevents excessive current flowing through the meter and damaging it. Even if there is a short-circuit between emitter and collector, the maximum current that will flow is given by the simple equation

$$I = \frac{V}{R},$$

where I is the current flowing in amps,
V is the battery voltage, and
R is the total circuit resistance in ohms.

Putting in the correct values, gives

$$I = \frac{9}{47\ 000} = 0.000191 \text{ A, or } 191 \text{ microamps } (\mu\text{A}).$$

The resistance of the meter, M1, will cut this down a little more, but it is within the indicating range (200 µA) of the meter.

As shown, with the push-button switch, PB1, *open*, a good transistor will not draw any current from the battery, and M1 will thus remain at zero. When PB1 is *pressed*, a *very small* current is injected into the base of the transistor. If the transistor is working, it will produce a much larger current between the collector and emitter, and this current will also flow through M1 and R2, giving a significant reading on M1, showing that all appears to be well. If an appreciable current flows when PB1 is *open*, then your transistor is suspect.

Don't be put off by the apparently complicated switch, SW1. It is there to allow the other type of transistor, the pnp type, to be tested. All it does is reverse the battery connections, so that the emitter goes to the *negative* battery terminal for testing an npn transistor, and to the positive terminal for a pnp type!

Most transistors in common use are of the npn type, which is why Figure 2 shows the testing of an npn type. The connections to the different transistor *encapsulations* (shapes) are given in any good component catalogue. Avoid the trial-and-error method to discover the connections to a transistor. This is unscientific, and can be very frustrating, particularly if the transistor is faulty in the first place!

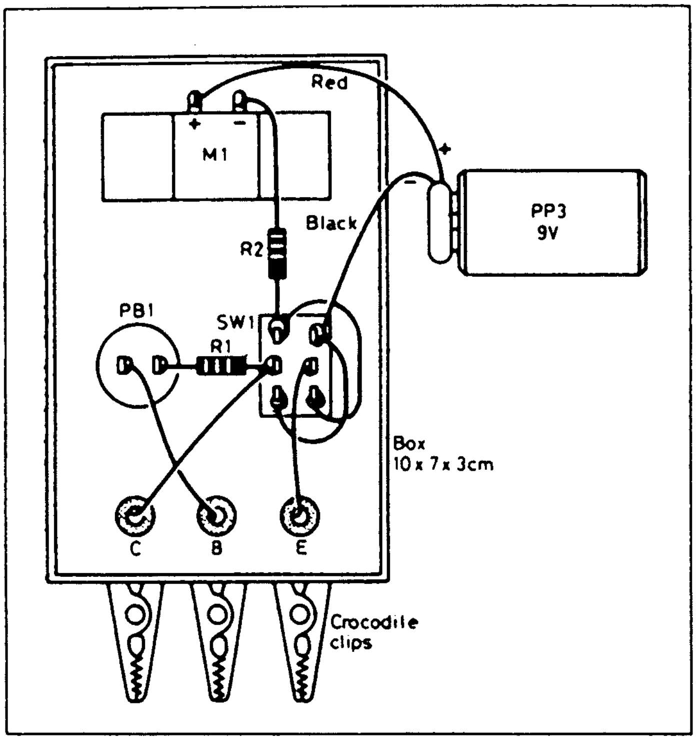

Figure 3 This shows how to wire up the tester

Construction

The unit can be built into a small plastic box, the components being soldered directly to the fixed terminals of the meter and the two switches; no circuit board is necessary! Use different colours of wire for the three test leads, and make sure you know which is which! Check the connections against the wiring diagram of **Figure 3**. When you are confident that all is correct, connect the battery and make sure there is no reading on the meter when nothing is connected to the crocodile clips!

Find any transistor for which you know the connections and the type (npn or pnp). Set the npn/pnp switch accordingly. Connect the three clips, making sure that they do not touch each other. A small reading on the meter at this stage means the transistor is suspect; a large reading means it is not working and should be thrown away! Press PB1 and watch the meter; a reading greater than half of full-scale indicates a good transistor. If it is less than half, you may have a transistor with 'low gain'; it may be usable for non-critical applications, but if you are in any doubt – throw it away!

Parts list

Resistors: all 0.25 watt, 5% tolerance

R1	100 kilohms (kΩ)
R2	47 kilohms (kΩ)

Additional items

PB1	Push-button switch
SW1	DPDT (double-pole double-throw) switch
M1	Micro-ammeter – *not* less than 200 μA full-scale deflection
	Crocodile clips (3 needed)
	PP3 battery and connector
	Plastic box about 10 × 7 × 3 cm

Common types of transistor

BC108, BC109, 2N2369A

These are small-signal npn types, used in audio amplifiers. They are in metal cases (called TO18) and have a tab next to the emitter lead. Common types have a B or C suffix (e.g. BC109C). The C suffix indicates a higher current gain than those with a B suffix. The 2N2369A is specially designed for radio use at high frequencies.

2N3703, BC212L, BCY71
These are pnp transistors, and so must be used with the collector and base *negative* with respect to the emitter. These three types are used in small amplifiers and audio oscillators. The first two have plastic encapsulations (TO92), while the BCY71 has a metal case (TO18).

BFY50, BFY51, BFY52
For slightly higher powers, these are ideal. They have been used in novice transmitters up to 600 milliwatts (mW). The TO5 case is a scaled-up version of the TO18 case. They are all npn types.

2N3055, 2N3773, TIP35C
These are high-power transistors in bigger encapsulations. The thick metal TO3 case of the 2N3055 and 2N3773 is designed to bolt to a heat sink, a large piece of metal which conducts the heat into the air more rapidly than the transistor itself can. The TIP35C is made of plastic but has a thick metal tab by which it, too, can be bolted to a heat sink.

24 An introduction to transmitters

Introduction

We usually think of a transmitter as being a ‘black box’. However, that is the form a transmitter takes for our use on the amateur bands. Many electrical circuits are transmitters, even though transmitting may not be their primary function!

Anything that emits electromagnetic energy at *any* frequency is a transmitter, from radio at the low-frequency end of the spectrum, to gamma rays at the high-frequency end. We all know that a magnet will attract certain metals and that a comb rubbed on your coat sleeve will pick up small pieces of paper. The former is an example of the effect of a magnetic field, the latter of an electric field. Electromagnetic fields are combinations of both types of field, and are produced whenever an electromagnetic wave is transmitted.

What frequency?

Many everyday objects have a natural frequency of oscillation. This is called their *resonant frequency*. A wine glass will ring when struck gently; an empty wine bottle will sound if you blow across the top; a guitar string will vibrate when plucked. These are all examples of resonance, and the resonant frequencies will **not** change unless the objects themselves are changed physically in some way. These are resonances in *sound*; we are primarily interested in electrical resonances.

The basic electrical resonant circuit is the combination of an inductor (coil) and a capacitor, as shown in **Figure 1**.

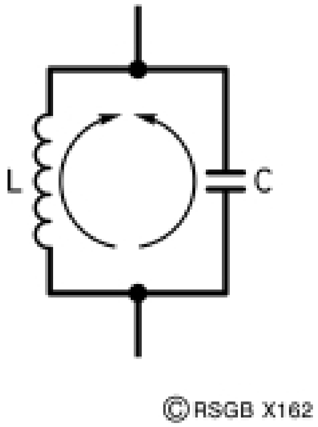

Figure 1 The basic electrical resonator. The energy in the circuit alternates between the inductor and the capacitor

A pulse of energy applied to this *tuned circuit* will make it *ring* (oscillate) at its resonant frequency. The energy in the circuit transfers between the inductor and the capacitor every cycle of the oscillation. Just like the wine glass, its oscillation dies away because it is losing some energy to its surroundings – it is transmitting! The frequency of the resonance depends on the values of L and C.

Keeping it going

If we want to keep the circuit oscillating, rather than having it die away, we must supply the circuit with just enough energy to replace the energy lost both by radiation and by losses in the circuit itself. Because of this, you will find in all oscillator circuits, a transistor, valve or FET working with the tuned circuit to provide this extra energy.

As it stands, of course, even with its transistor, our oscillator will not radiate very far. Connecting an aerial to it, and a Morse key to interrupt the power supply, it would become a very low-power CW transmitter. Add a couple more transistors to form a radio-frequency (RF) amplifier, and you have the basis of a simple low-power (QRP) transmitter.

Resonant circuits can also be made using quartz crystals; these work at the crystal frequency only, and this is marked on the crystal case.

A tiny spark transmitter

This is a simple piece of test gear that will increase your knowledge and understanding of resonance. You can use it to estimate the resonant frequency of most of the inductor/capacitor (LC) tuned circuits that you build. The circuit is shown in **Figure 2**. It operates around a relay. Any relay that operates from a 6 V to 9 V source and has contacts which are normally closed (i.e. closed when the battery is not connected). Fit the relay, a toggle switch and the battery in a metal box, and connected up as shown in the diagram. Some foam rubber inside the box may help to reduce the escaping noise of the relay. A small hole in the side of the box enables the 2-turn loop to emerge. This should be about 40 mm diameter, made with insulated wire. Switch on; there should be a loud buzzing noise from the relay. If not, you have probably chosen the wrong contacts on the relay!

When it is working, bring the loop close to the aerial of a radio – it should produce a loud noise from the speaker!

How it works

When you switch on, current flows through the relay contacts and through the relay coil. The relay operates and opens the contacts, causing the relay to 'drop out'. When it does, the circuit is completed again and the contacts are opened, and the cycle repeats. Each time the relay contacts open, there is a small spark between them, causing very rapid current surges through the wire loop. This makes the loop transmit RF energy, very briefly. In the early days of radio, this type of circuit was known as a *spark transmitter.*

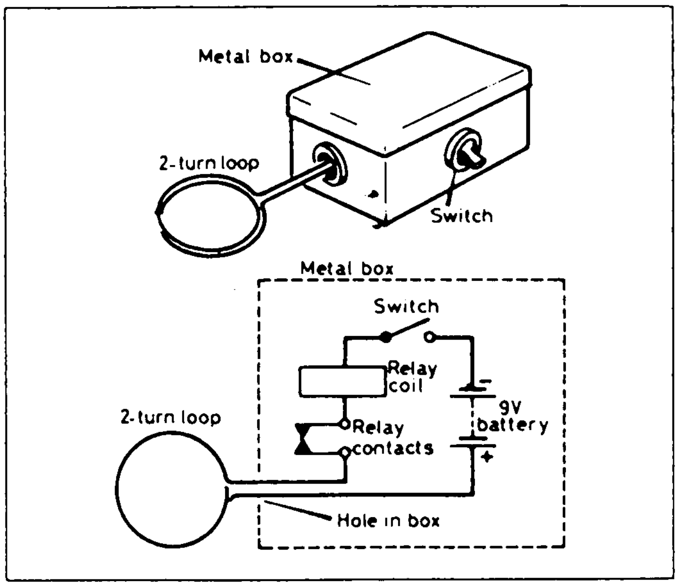

Figure 2 The current path is interrupted when relay is energised as shown above

Make a tuned circuit

Use a discarded toilet-roll centre, and wind about 10 turns of enamelled copper wire round it, keeping each turn close to the next. Scrape off the enamel for about 1 cm at each end, and solder a 100 picofarad (pF) capacitor (or a variable capacitor of about the same value) between the ends. The resonant frequency should be about 10 MHz. If you have used fewer turns or a smaller capacitor, the frequency will be higher.

Measuring the resonant frequency

Set up the buzzer as shown in **Figure 3**, with the loop around one end of your coil. Then make a similar loop, solder it to the end of a piece of coaxial cable going to the aerial socket of a calibrated receiver. Set the buzzer going, tune the receiver around 10 MHz, and search for the maximum noise level from the speaker. When you have found it, move the two loops as far away as possible from the main coil. This is called reducing the *coupling* between the coils, and it may result in a slightly different, but more accurate, resonant frequency.

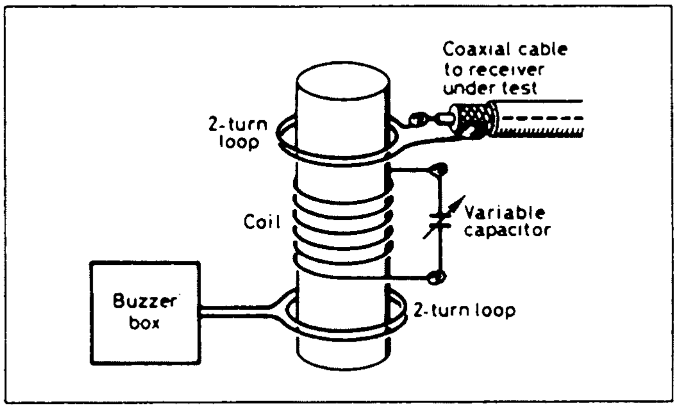

Figure 3 Experiment with the spacing between the loop and the tuned circuit

Parts list

Metal box – do not use a plastic box!
9 volt battery and connector
On/off (SPST) toggle switch
Plastic foam, as required

25 The Colt 80 m receiver – Part 3

Introduction

In Part 2 we marked out the case ready for installation of the modules when they are completed. In this part, the building of the variable-frequency oscillator (VFO) and mixer will be described. This will produce a type of receiver known as *direct-conversion*, because it converts the radio-frequency (RF) signal directly into an audio-frequency (AF) signal which we can hear in a loudspeaker after amplification. A block diagram of the system is shown in **Figure 1**. The modifications needed to make a full superheterodyne receiver will be left until later.

The direct-conversion receiver covers the 80 metre amateur band and will receive both Morse (CW) and speech (SSB) signals. The audio amplifier was covered in Part 1, so your *Colt* is rapidly taking shape! By the time your construction has reached the end of this part, you will have a receiver ready to use, even if the project is not yet complete!

The direct conversion process

Like most things in radio, the principles of direct conversion are not difficult. From the aerial, the signal we want to hear is selected by the *tuned filter*, which rejects the signals we don't want. The signal then enters the

mixer, along with the signal from the *VFO*. The VFO produces a sine wave whose frequency can be varied across the whole of the 80 metre amateur band (3.5–3.8 MHz), by turning the knob on the tuning capacitor, VC1. The mixer produces, at its output, *two* signals; one signal is at the frequency of the **sum** of the signal and VFO frequencies, the other is at the **difference** of the two frequencies. It is the latter that we want. Let's look at the numbers involved. If the signal is at 3650 kHz and the VFO is at 3651 kHz, then the sum frequency is 7301 kHz, and the difference frequency is 1 kHz. If we feed the output of the mixer into our audio amplifier, the 7301 kHz signal is automatically removed (it is far too high to be considered an audio signal!) and the resulting 1 kHz signal is amplified and fed to the speaker, producing a note which we can hear!

Building the VFO

Figure 2 shows the circuit of the VFO. It is a tried and tested circuit, and should work first time. It uses a *field-effect transistor* (FET) for TR1, the oscillator itself. RFC is a *radio-frequency choke*, a coil of wire which will pass a direct current (DC) but which will prevent radio-frequency (RF) signals getting through.

All VFOs have a tuned circuit which, in this case, is formed by the coil L1 and the capacitors C1 and VC1. The frequency will also be affected to some extent by C2, C3, C4 and C5. Transistor TR2 is an *emitter follower*, a stage which gives no voltage gain but provides a good *buffer* stage, isolating the VFO from the effects of the stages that follow it. When building a VFO, the

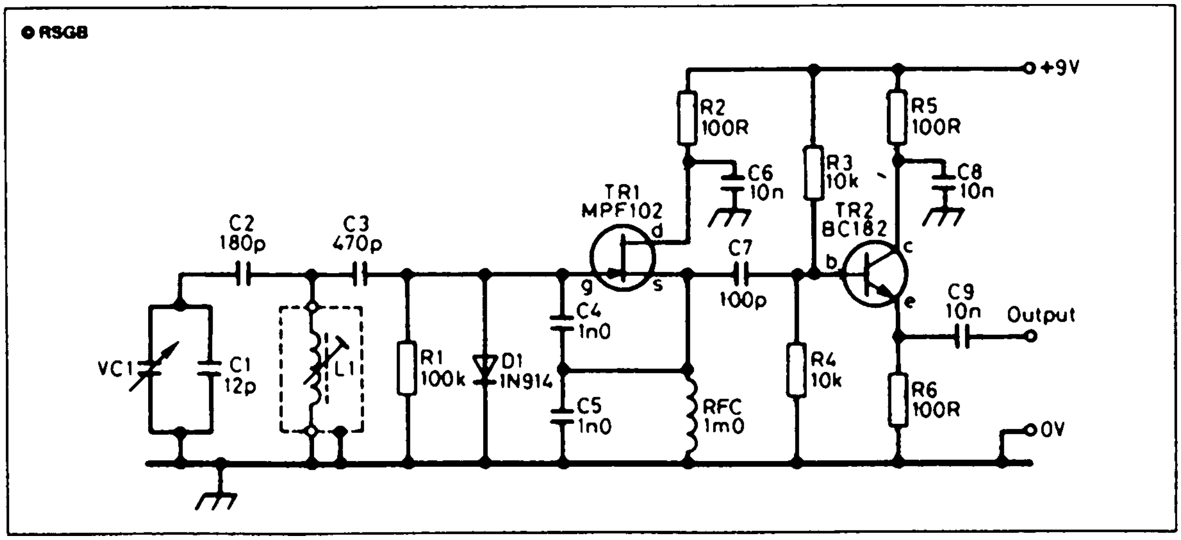

Figure 2 The variable-frequency oscillator uses a field-effect transistor (FET)

parts must be securely mounted. If components move, so does the frequency! At worst, the oscillation will become unstable and the VFO will be useless. Keep the component leads as short as possible – this improves their mechanical stability as well as their electrical stability!

Mount the parts on the printed-circuit board (PCB) or matrix board and, when completed, the VFO should look like the one shown on the left in the photograph on p. 72. Make sure that TR1, TR2 and D1 are the right way round.

On completion, check the component positions then mount it in the case as shown in the photograph, to the left of the tuning capacitor when viewed from the rear. The VFO coil, L1, will need some adjustment, but that will have to wait until the mixer is built. Connections to the other boards are made with screened cable.

The mixer board

So far, we have an audio-frequency (AF) amplifier and a VFO; the addition of a mixer board gives us a complete direct-conversion receiver for 80 m. The mixer circuit diagram is shown in **Figure 3**. Let's follow the signal path.

- From the aerial, the RF signal goes to the gain control potentiometer, RV1. This reduces very strong signals, to prevent them overloading the mixer.
- To select the required band of signals, a *bandpass* filter is made up of RF transformers T1 and T2; these are tuned by C1 and C3, and are coupled together by C2.

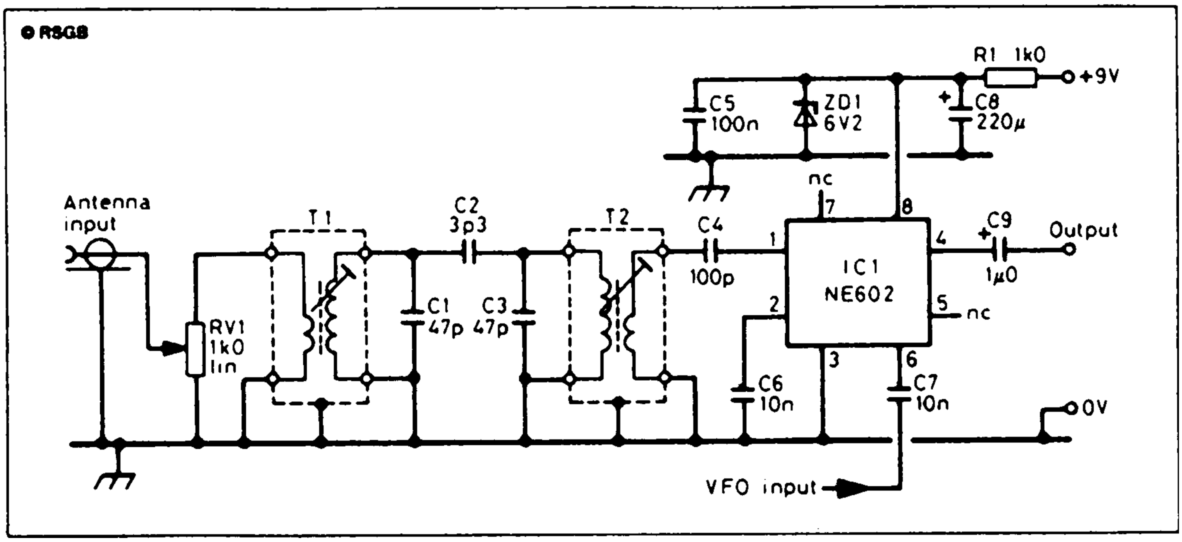

Figure 3 The mixer board has a bandpass filter and stabilised supply

- After the filter, the signal is coupled into the integrated circuit (IC) mixer type NE602, by the capacitor C4. Capacitors C5 and C8 *decouple* the supply line, to prevent unwanted signals on the supply from disturbing the VFO operation. The use of the term *decouple* is exactly the opposite of *couple*; when two circuits are *coupled* together, the signal passes from one to the other; when two circuits are *decoupled*, signals **cannot** pass from one to the other.
- The NE602 works with a 6 V supply; it is produced here from the 9 V supply by the *Zener diode* ZD1 and the resistor R1. ZD1 operates at 6.2 V, and gives a steady output for the mixer. The audio output from the mixer appears at pin 4 or IC1. This is taken to the audio amplifier board via C9 and the volume control (see Part 1).

Care must still be taken to insert some components the right way round. These are the electrolytic capacitors, C8 and C9, the Zener diode, ZD1, and the integrated circuit, IC1. Check all component positions and make sure all your soldered joints are bright and shiny.

Putting it together

The interboard wiring, shown in **Figure 4**, uses screened cable; ideally, this should be thin coaxial cable, but screened microphone cable is suitable. The diagram shows how the two controls, the RF Gain and Volume, are connected to the boards. The leads marked '+9 V' are all connected to the battery supply via a miniature on/off toggle switch. Double check all connections before connecting the battery.

Setting the VFO

Very little adjustment is needed to get the receiver going. Firstly, the VFO must be adjusted to cover the required band, in this case 3.5–3.8 MHz.

If you have a frequency counter, connect it to the output of the VFO. If you haven't, read this part anyway so you understand the process, then another means of setting the VFO will be given especially for you! Rotate VC1 until the vanes are fully meshed. Very carefully, adjust the core of the VFO coil (L1) with a plastic trimming tool so that the frequency approaches and settles at 3.500 MHz. When you rotate VC1, the frequency should increase to **at least** 3.800 MHz at the far end of its travel.

In the absence of a frequency counter, borrow a communications receiver, set it for SSB reception (USB or LSB) on exactly 3.500 MHz. Set VC1 with the vanes fully meshed and turn the core of L1 in both directions until you hear a whistle in the communications receiver. Rotate the core so that the whistle reduces in frequency. It will eventually fade out at around 200 Hz;

Figure 4 Make sure that interconnections between the boards are correct, including cable screens

turn the core a little further and then leave it at that position. Rotate VC1 right to the other end of its travel, and search for the whistle with the tuning knob of the communications receiver. Check that the VFO frequency is at least 3.800 MHz.

Then, whichever method you are using for frequency measurement, mark the dial with frequency steps of 50 kHz. Setting and calibration are finished!

Setting the mixer

Again, there are various ways of doing this. If you have a signal generator, inject a signal at a frequency within the 80 m band, and adjust the cores of T1 and T2 sequentially for maximum output.

If you haven't a signal generator, connect an aerial to the mixer input, set the RF Gain to maximum (fully clockwise), and find a consistent signal. Adjust the volume control to a comfortable level. Rotating the core of T2 with your trimming tool, maximise the output. Then do the same with T1, although this will have much less effect. Find another station, and check that the positions of the cores aren't too different for a maximum signal.

You may find that your receiver benefits from the insertion of an aerial tuning unit (ATU) between the aerial and the input, to compensate for the impedance of your aerial not being 50 Ω. A design for such an ATU is presented in another part of this series. If the signals are still weak, connect the ATU to the junction of C1 and C2 via a 100 pF capacitor.

Try listening!

Remember that 80 m is a variable band. During daylight hours, your will hear Morse signals at the lower end of the band, and some British and closer continental stations between 3.7 and 3.8 MHz. In the evenings, stations up to 1000 miles away should be heard. Look for Novices around 3.7 MHz!

26 A two-way Morse practice system

Introduction

It is said that the pleasure of sending and receiving Morse code more than compensates for the learning effort needed. Transmitters for Morse code can be much simpler than those needed for any of the speech modes.

Many people choose to learn sending and receiving on their own. It can be much more fun if you have someone to learn with you, and it is for this reason that the following project arose. It comprises just one small circuit, and you build an identical circuit for each of the people who want to learn with you. All the individual circuits are connected with their output leads in *parallel*, as the two-way circuit of **Figure 1** shows.

A simple circuit

This diagram shows two identical circuits, as would be used if two people wanted to learn together. The circuit centres around our old friend the NE555 integrated circuit (IC). As it is connected here, it works as an *astable multivibrator*, a daunting name for what is essentially an oscillator. Each circuit is self-contained, having its own battery, Morse key, sounder and

STATION B

Figure 1 The circuit diagram shows two stations, but you could connect several more if needed

plastic box. The Morse key makes and breaks the power supply to the circuit, thus turning on and off the note emitted by the earpiece. The frequency of the note is controlled by the variable resistor RV1, resistors R1 and R2, and the capacitor C1. The range given by RV1 is approximately from 500 Hz to 2200 Hz.

R3 protects the output of the IC against accidental shorting either to the 0 V or to the 9 V supply rails. For best results, a crystal earpiece or high-impedance headphones should be used. You could try Walkman-type headphones, but the volume may be too low for you.

The units may be interconnected with thin twin cable (the sort used for wiring doorbells) and can be comfortably separated by 25 m, more than enough to communicate between rooms, or even with a neighbour!

In use

When an operator presses his key, the note is heard by himself and by everyone else who is connected. If more than one key is pressed at the same time, two or more notes are heard by everyone! It helps if each person adjusts his own potentiometer, RV1, to give a note which is different from the others. When one operator stops sending, the other can start immediately, without pausing to change from transmit to receive. In practice, this technique is known as *full break-in*.

The current drawn by the circuit is only 10 milli-amps (mA) when the key is down, meaning that the life of a typical PP3 battery will be virtually its shelf-life! No switch is needed, because the key acts as the switch. The current drain will be even less if the NE555 is replaced by an ICM7555 IC. It has exactly the same pin connections as the NE555, so no circuit modifications are needed.

The circuit board

The circuit is constructed easily on a small piece of Veroboard of the copper-strip type. **Figure 2** shows the layout of the prototype, the board measuring 18 holes by 10 strips. **Be aware that there is no row 'I' when you are transferring mental images of where the parts are to real positions on the board!** Break the copper tracks where shown with a 3 mm (⅛ inch) twist drill, rotated carefully between thumb and forefinger. Hold the board up to a bright light to make sure that the tracks are completely broken and that there are no fragments of copper swarf shorting adjacent tracks. Then, solder in the wire links shown in Figure 2, followed by the resistors, RV1, and the capacitors, C1 and C2. Solder the battery connector leads to tracks A and G, G being positive. Use insulated wire to connect from the board to the jack sockets used as connectors for the key and the earphones. If you use

different sized jack sockets (i.e. 2.5 mm and 3.5 mm) you won't plug the earphones into the key socket! A two-screw terminal strip is useful to connect the cable runs between operators.

The key

The circuit is designed to be used with a *straight key* (one that moves up and down). It is a requirement of the UK Morse test that a straight key is used, so it is very sensible to learn sending with a straight key before you try anything more complex! You will find many to choose from at rallies.

Parts list

For each board, you will need:		**Maplin order codes**

27 The Colt 80 m receiver – Part 4

Introduction

In Parts 1 to 3 of this series, the design of an 80 metre direct-conversion receiver has been described. In this final part, we are going to change the circuit to operate as a superheterodyne receiver, or *superhet*. Most radio receivers are superhets, and they change the incoming signal to another frequency, known as the *intermediate frequency*, or IF, before producing an audio signal. The use of a superhet in a good receiver is mandated by the requirements for good *sensitivity* and *selectivity.*

Sensitivity and selectivity

Figure 1 shows the block diagram of the receiver. If you look closely, you will see that it is two similar circuits, one after the other. The incoming

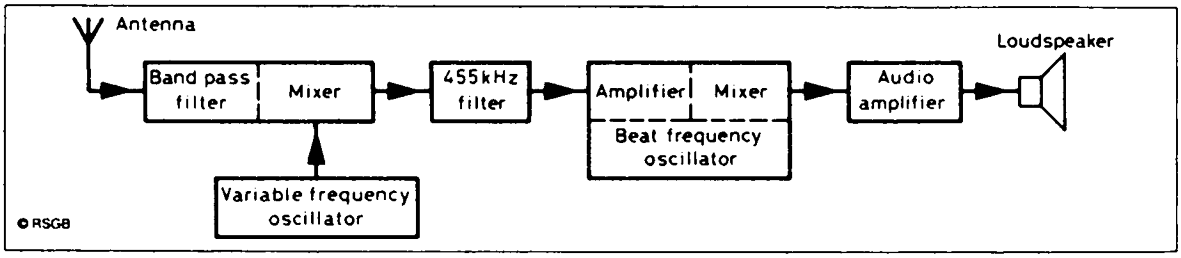

Figure 1 This is how the different stages of the Colt go together to make a superhet receiver

signal is filtered and fed to a mixer where it is combined (mixed) with the signal from the variable-frequency oscillator (VFO). This oscillator operates at a frequency which is 455 kHz higher than the incoming signal from the aerial, and the mixer output is therefore at a frequency of 455 kHz. If you are not sure about this, please refer to the section 'The direct conversion process' in Part 3 of this project. This new frequency is called the *intermediate frequency*, or IF. This frequency doesn't change; the tuning is accomplished by the VFO, and the mixer output is *always* at 455 kHz. The extraction of the audio signal from the IF signal is identical with the direct conversion process which is used in your existing receiver.

This may seem a long-winded way of doing things, but it has its advantages. A receiver must have a good *sensitivity*, or gain, so that it can receive very weak signals. In very general terms, it is easier to handle low-frequency signals than it is to handle high-frequency signals. We are changing our signal frequency from around 3.6 MHz down to 0.455 MHz (455 kHz), which is much lower and can be filtered and amplified relatively easily. A second advantage is that it is easier to provide gain at a fixed frequency than at a variable frequency. Remember that the IF is fixed, and providing gain is, again, relatively simple.

Our receiver also needs good *selectivity*, the ability to separate (or select) one station from another very close to it in frequency. This requirement is significantly simplified by the fact that the IF is fixed, and a good filter in the IF circuits can do wonders for the rejection of adjacent-frequency stations! Several stages of IF amplification and filtering are possible in more adventurous designs.

The filtered signal at 455 kHz passes to another mixer which has an associated oscillator, usually called a *beat frequency oscillator* (BFO). When receiving CW (Morse) signals, the BFO is usually tuned about 1 kHz above or below the IF (i.e. at 454 or 456 kHz) to produce a 1 kHz beat note as the audio signal. This signal is then amplified and fed to a loudspeaker or headphones.

The circuit

Figure 2 shows the circuit of the IF section shown in the photograph on p. 94; this section is added to the existing circuit to make it a superhet. The existing mixer board (described in Part 3) is used as the first mixer. Between it and the audio amplifier is connected the new IF board.

The signal output from the first mixer (at 455 kHz IF) is fed into a *crystal filter*, the most expensive part in the whole receiver. It provides the selectivity which makes the Colt such a good receiver. Another NE602 mixer/oscillator chip follows the filter. The oscillator section is controlled by the tuned circuit in T1, the frequency of which can be altered by rotating the core inside the coil. Once set, it remains fixed.

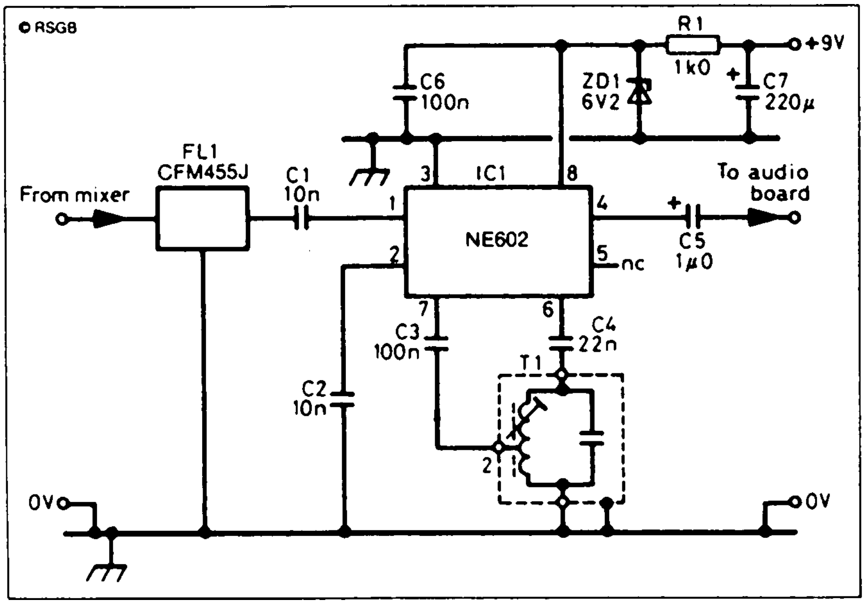

Figure 2 The IF board is connected between the mixer and audio amplifier

At this stage you should have built the first mixer and the audio amplifier, and proved that they *both* work by using the circuit as a direct-conversion receiver. When you have finished constructing and checking the IF board, you will need to add it to your existing circuits.

Adjusting and testing

There are three pairs of connections to the IF board – the 9 V supply leads, the input leads and the output leads. The IF board should be mounted on the metal baseplate, along with the other boards. **In making the following connections, make absolutely sure that the braid of each piece of coaxial**

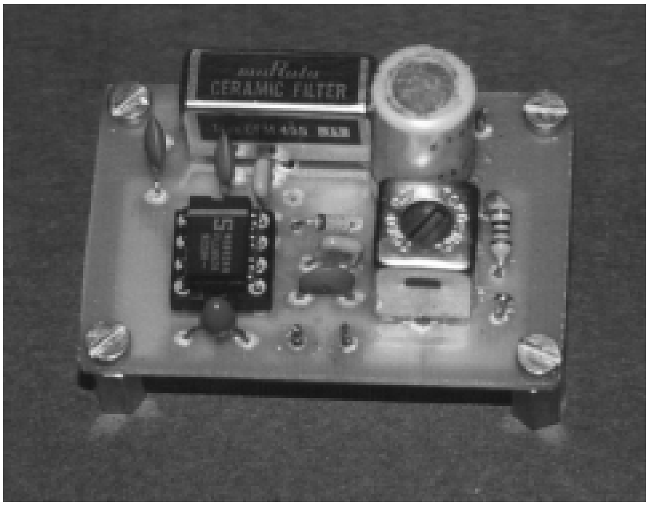
cable is soldered to the correct connection on each board. The same applies to the polarity of the 9 V leads. Disconnect the screened lead which presently goes from the first mixer board to the AF amplifier at the amplifier end. Connect it instead to the *input* of the IF board. Connect a new piece of screened cable from the IF output to the vacated AF input. Now connect the 9 V supply leads to the same points as the supply leads from the other boards. Check these newly made connections.

You should have confidence at this point that things should be right. After all, you *have* tested the direct-conversion process and you *know* it works. All that you are now testing is the IF board. This is the attraction of building a receiver in modules, working from the speaker backwards, and testing as you go!

The VFO and BFO need to be correctly adjusted. Mesh the vanes of the tuning capacitor and, using the same frequency measurement method as you did originally, set the VFO frequency to 3.955 MHz (which is 3.500 MHz + 0.455 MHz, if you hadn't guessed!). The BFO can be set using a frequency counter, but it is just as good to set it by listening to SSB or CW signals. A high-pitched hissing sound should be heard in the speaker. As you rotate the core, the pitch should reduce, go through a minimum, then increase again. Set the core at the minimum pitch position. You may want to readjust the two cores a little as your listening skills improve but, once you are happy, they will never need to be altered again!

In conclusion . . .

You should now have built a superhet receiver capable of excellent results. It uses the same type of circuit as that found in far more advanced receivers.



The superhet is far more sensitive than the direct-conversion type, and can weed out those elusive DX stations. You may have found that a station will appear at two places on the dial of the direct-conversion receiver; you will have no such problem with the superhet.

Parts list

Resistor

R1	1 kilohm (kΩ), 0.25 watt, 5% tolerance

Capacitors

C1, C2	10 nanofarads (nF) min. ceramic
C3, C6	100 nanofarads (nF) min. ceramic
C4	22 nanofarads (nF) min. ceramic
C5	1 microfarad (μF) 16 V electrolytic
C7	220 microfarad (μF) 16 V electrolytic

Integrated circuit

IC1	NE602

Additional items

ZD1	Zener, 6.2 V 0.5 watt
FL1	Crystal filter, Murata CFM455J
T1	Tuned inductor, Toko YHCS11100AC

28 A simple crystal set

Introduction

There are many designs of crystal set – they are all ‘simple’, and even the most seasoned radio amateur will build one of these every so often because it is something that never ceases to amaze! Although using modern components, the design is a period piece!

Design and construction

The circuit diagram of **Figure 1** shows the simplicity of the circuit. The prototype was constructed on a wooden baseboard with an aluminium front panel, although this could be made of wood if you prefer.

Winding the coil always causes the most groans but when finished, gives the most satisfaction. The construction of the coil is detailed in **Figure 2**. A discarded toilet roll centre is an ideal *former* on which to wind the coil. The coil will take up about 7 cm of the length of the tube, so assuming the tube is about 11 cm long, the ends of the coil will be about 2 cm in from each end of the tube.

The aerial coil, the *primary winding* of this radio-frequency (RF) transformer, is made from about 30 turns of 26 SWG enamelled copper wire, wound on the matchstick ribs. These ribs should be about 2 cm long, and are glued on **top** of the end of the secondary coil *after* the secondary coil has been wound. The *secondary winding* has 140 turns with *taps* every 10 turns for 70 turns. This coil covers most of the length of the cardboard tube. To make your coil-winding easier, here are some tips for completing the coil and still having some hair left at the end!

- Support the reel of wire on a dowel rod or pencil, clamped in a vice or held rigid in a vertical position by some other means. Don't leave it to trail around on the floor.
- Have a small piece of sandpaper handy to remove the enamel from the copper wire, starting with the end coming from the reel. Remove about 1 cm only, until the shiny copper is visible all round the end of the wire.

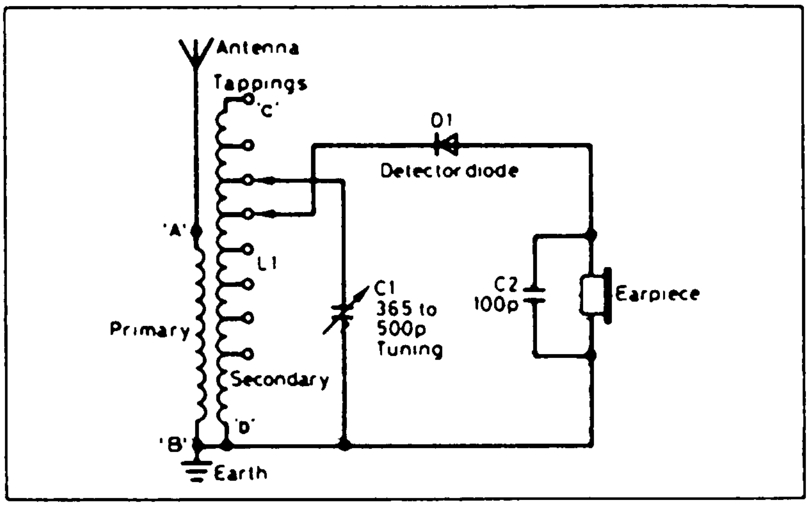


Figure 1 Circuit diagram of the crystal set

D
B

Figure 2 The coil is mounted on a cardboard tube as shown. Exact size is not too important. Try different taps for best results

- This part is the most difficult of all. Seasoned coil winders may have their own favourite ways of doing this, but for first-timers, play it safe and do it this way! Have a second bobbin (or a piece of stout card) ready, on which you will need to wind the wire loosely while you prepare the taps. Then, starting from the free end of the wire, measure 125 cm and, at this point, remove about 2 cm of the enamel with the sandpaper. Bend the wire firmly back on itself in the middle of the bared area, and *tin* (cover with solder) the exposed copper. This is your first tap. Then repeat this six more times at 125 cm intervals, thus giving you seven taps; wrap the wire as you go, on to the second bobbin or piece of card. After the seven taps, you are half-way down your coil so, to begin winding it in earnest, wind the wire carefully from the second bobbin or card **back** on to the original reel of wire.
- Looking at Figure 2, make two small holes about 3 mm apart, about 2 cm down from the top of the tube, where wire C will be entering. Poke the end of the wire into one hole, then bring it out again through the other; leave about 10 cm of wire on the free end. Loop this wire in and out once more, thus anchoring the wire firmly.
- Then, begin winding; keep the wire tight and make adjacent turns touch neatly. As you pass each tap, make sure it sticks outwards while avoiding flexing the wire too much; the wire is inherently weak at each tap.
- When you reach the last 10 cm of wire, stop. Put two more holes, like the first, beside your stopping point, and anchor the end, D, of the coil in the same way as you did with end C. The secondary winding is complete. Take a break *after* you have completed the next step!

- Prepare the six matchsticks for supporting the primary coil and glue these every 60 degrees around the end of the coil at D. Remove the enamel from the free end of the new copper wire on your reel and, using your favourite quick-drying cement, put a drop over the wire on one of the matchsticks, leaving 10 cm free as before. If you are using 26 SWG enamelled copper wire, its diameter is 0.46 mm, so 30 turns should occupy 14–15 mm of the 20 mm matchstick length. This will allow you to position the glued point such that the coil will be roughly in the centre of the matchsticks. When the glue has set, wind the 30 turns and anchor this end of the coil in the same way. Then remove the enamel at the end of the 10 cm lead.

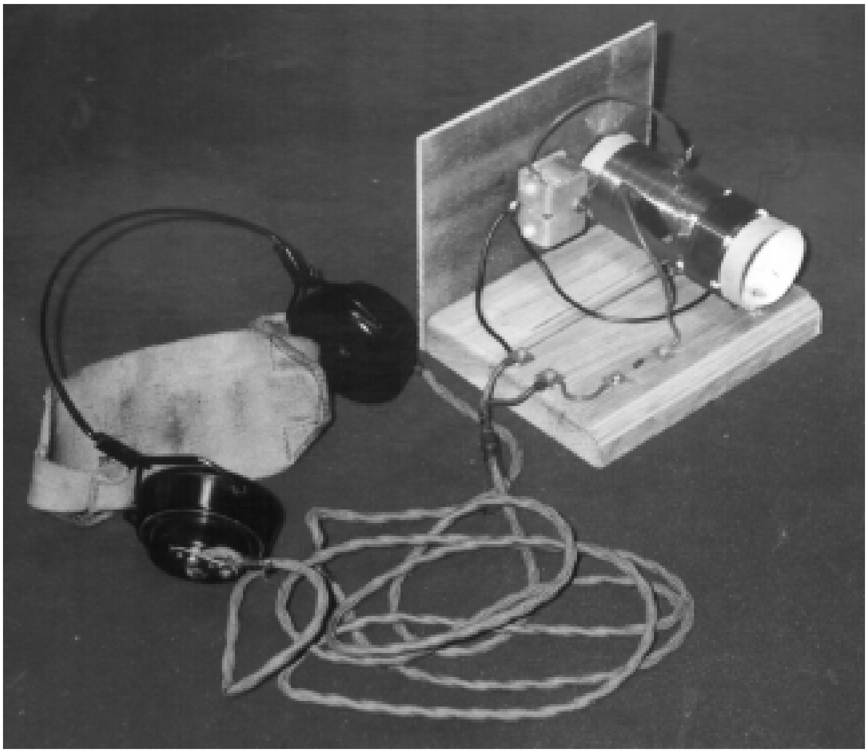
Assembly

The coil former can be screwed to the baseboard at each end, *before* the front panel is screwed to the baseboard! As the photograph on the next page shows, the tuning capacitor is mounted in the centre of the front panel. Five solder tags (or drawing pins as a last resort) should be screwed into the baseboard. The two to the left of the photograph are the connections to the earphones, the two along the rear edge have the diode, D1, soldered to them. One end of the diode (and, for once, you can connect the diode either way round!) is connected to one earphone tag. The other end has a flying lead of about 10 cm attached to it and terminated in a crocodile clip which is used to connect to one of the taps on the coil. The fifth tag secures the end, A, of the primary coil, to which you will attach the aerial. The earth tag on the tuning capacitor, C1, serves as an anchor point for the ground connections to B and D and to the other earphone tag.

Use

The longest piece of wire you have available to use as an aerial should be connected to the aerial tag just mentioned. If you can connect the earth tag of the tuning capacitor to a good electrical earth, this will help also. You should be able to hear something as you turn the tuning knob. Try adjusting the tapping connections on the coil – change only one at a time, or you will never find the optimum positions. You now have a fully operational crystal set!

Simple it may be, but this circuit illustrates some important principles which are used even in the most expensive receivers. Firstly, the coil, L1, and the capacitor, C1, form a *tuned circuit* which *resonates* at the frequency of the station you have tuned in. This *selects* the signal you want to hear. The *modulation* on this signal is removed by the *detector*, D1, and fed to the earphones, which act as *transducers*, turning the electrical energy into sound energy which you can hear. It doesn't need a battery or other power supply either!



Parts list

Capacitors

C1	Variable capacitor of between 200 and 500 picofarads (pF) maximum
C2	100 picofarads (pF) min. ceramic

Additional items

D1	Germanium, type OA47 or OA90
	High impedance crystal earphone (not Walkman type)
	Tuning knob
	Wooden base, approx. 110 mm square
	Aluminium (or wood) front panel, approx. 80 × 100 mm
	Cardboard tube (toilet roll centre), about 110 mm long, 40 mm diameter
	Reel of 26 SWG enamelled copper wire for both windings of L1

29 A crystal calibrator

Introduction

A crystal calibrator is a device that produces oscillations of a precise frequency which are rich in *harmonics*. A harmonic is an integer multiple of the fundamental frequency; for example, if our fundamental frequency was 100 kHz (as it is in this circuit), there would be harmonics of this frequency at 200 kHz, 300 kHz, 400 kHz, and so on. These harmonics can be used, when picked up by any receiver, to calibrate that receiver, as the harmonics are quite accurate in frequency (see later for an assessment of accuracy). However, a gap of 100 kHz between harmonics is rather wide for most purposes, so we reduce this frequency to 25 kHz, so that the harmonics are then 25 kHz apart, thus producing a much more useful set of *marker points*. A calibrator such as this is often called a *crystal marker*, producing these marker points from 25 kHz to beyond 30 MHz.

The circuit

The circuit diagram is shown in **Figure 1**. The circuit around TR1 is the fundamental oscillator, and its frequency is controlled by the quartz crystal, X1. Even crystal oscillators are not 100% accurate, and the small trimmer capacitor, TC1, is able to ‘pull’ the frequency to one which is nearer the

correct one. TR2 is a *buffer* stage, which isolates the oscillator from the rest of the circuit. It acts as a switch, and applies a good signal (switching between 0 and 5 V) to the input of IC1.

IC1 is an integrated circuit which can be connected to do several things. It is connected here to divide the incoming frequency by a factor of 4, producing on pin 9 an output frequency of 25 kHz.

The combination of R6, C4 and D1 produces a supply of 5 V for IC1; it would be damaged if the battery voltage were applied to it. You will no doubt be ready to assemble the circuit, so here is some information for you.

Construction

If possible, always build a circuit in individual stages, which you can test as you go along. It is not always easy in small projects like this, but even the crystal calibrator can be split into two for construction and testing.

It is an ideal project for assembly on Veroboard of the copper-strip type; the prototype layout is shown in **Figure 2**, on a board measuring 11 holes by 24 strips. First of all, remove the copper strip at the locations shown, using a 3 mm drill rotated between the fingers. Hold the board up to the light to ensure that there are no pieces of copper swarf bridging adjacent strips, and that the copper is completely removed where it should be! Assemble the circuit from left to right, but do not wire up anything around IC1. Be aware that the diagram shows the board *from the component side*. Although you

can use virtually any kind of crystal, you will need to mount it firmly. If you use a small one, it can be soldered directly in position on the board. With one in a valve envelope, you will need a B7G valveholder. Be prepared to mount the circuit in a **metal** container; the prototype used an (empty) tin of tuna! The valveholder mounts well on any metal case.

Disconnect the aerial of your receiver, and replace it with about 30 cm of wire laid near your oscillator circuit. Connect the battery and switch on. Tune the receiver around until you can hear a whistle on SSB. Rotate the tuning knob to reduce the frequency of the whistle and, as the whistle becomes too low to hear, you have reached one of the calibration markers, and your frequency will be an integer multiple of 100 kHz. If you are already using a calibrated receiver, you will be able to verify this. Going up or down in frequency should locate another marker 100 kHz away, and so on right through the receiver's tuning range. If the signals coming from the circuit are very weak, switch off the calibrator and connect another 30 cm piece of insulated wire to the collector of TR2, and lay it close to (but *not* touching) the wire from the aerial connector. Switch on an try again; you should not now have a problem! If you have access to a multimeter, check that the voltage at the collector of TR1 is very close to 5 V. If it is close to 9 V, you have connected the diode, D1, the wrong way round!

Having verified that the oscillator is working, you can now wire up the integrated circuit socket, being careful to put the notched end of the socket pointing towards R4, the collector resistor for TR2.

Check your connections around IC1, and when you are satisfied that they are correct, line up IC1 with its socket, making sure that the notched ends are together, and press down *gently* to insert the IC into its socket. Insert the 30 cm piece of insulated wire into the output socket, connect the battery and switch on. You should still hear whistles in your receiver, but now they should be 25 kHz apart, rather than 100 kHz apart.

All that now remains to be done is to mount the circuit rigidly inside whatever casing your have chosen. Make sure that none of the connections under the board touch the metal case, and secure the valveholder, on/off switch and output connector to the case. You now have a completed crystal calibrator.

Calibration

The simplest way to calibrate your circuit is with a frequency counter. Most clubs will have one of these and, if not, will know someone who has! Connect it to the collector of TR2, where the frequency should be 100 kHz. Do *not* connect it to any part of the circuit around TR1, or you may alter the frequency you are trying to measure! If the frequency is not exactly 100.000 kHz, rotate TC1 until it is (or is as close as you can get it). Now your calibrator is as accurate as the counter with which you have calibrated it.

Accuracy

Despite your best efforts at calibration, by whatever means, your crystal will *never* have a constant frequency. Such a thing is a scientific impossibility. It is usual to express the accuracy of a crystal in parts-per-million (ppm), and it is governed by many things, principally its temperature. You will be *very* fortunate if your circuit maintains an accuracy better than about ±10 ppm. Expressed in figures, it means that the true frequency can be anywhere between 99.999 kHz and 100.001 kHz, i.e. within 1 Hz of the correct frequency.

Although this may seem more than adequate, it is as well to remember that the accuracy degrades as the frequency increases. At 1 MHz the error will be ±10 Hz and at 10 MHz it will be ±100 Hz. At 30 MHz it will be 300 Hz. Even so, this should be acceptable for most non-critical applications.

30 A simple short-wave receiver – Part 1

Introduction

No apologies for yet another design of short-wave radio. This is the beauty of our hobby – there is always something new to try. Not all circuits operate in the same way; not all circuits work equally well; sometimes a simple design suits the operator better than a complicated design. So here is another one for your consideration; it's a good project for a novice, *and* a good one-evening project for someone more experienced.

A basic description

Figure 1 gives the block diagram of the receiver, which employs a *regenerative detector*, one of the earliest techniques by which excellent *selectivity* (the ability to separate two stations very close in frequency) could be combined with good *sensitivity* (the ability to pick up very weak stations) using a very simple circuit. The receiver falls into the category known as *tuned radio frequency* (TRF), meaning that the whole circuit (prior to the extraction of the modulation from the carrier) operates at the incoming radio frequency. In other words, it is *not* a superhet.

As you can see, the regenerative detector has what is called a *feedback loop*, which feeds a small amount of the output signal back to the input. You have heard the effects of feedback with a public address system, when the microphone gain is too great – everything becomes very loud and then bursts into a deafening squeal! This is exactly what the feedback does here, except that it is carefully controlled, thus providing both gain and selectivity. The resulting audio is then amplified for use with headphones.

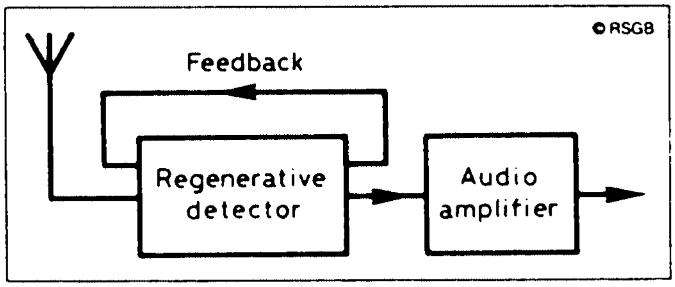

Figure 1 Just two simple stages make up the circuit

The circuit

The circuit of **Figure 2** shows the complete system. TR1 is an untuned *field-effect transistor* (FET) stage, and is used to match the aerial to the next stage. Occasionally, a regenerative detector produces unwanted signals, and TR1 also prevents them from reaching the aerial and being transmitted! The smaller of the two windings on T1 (the *primary* winding) will match a low-impedance aerial, the capacitor input matching a high-impedance aerial.

Ignore TR2 for the moment – the next stage in the signal path is TR3, the detector, using another FET. The tuned circuit is formed by T2, VC1 and VC2 (remember TR1 is untuned). The primary winding on T2 taking the output from TR1. The reason for having two variable tuning capacitors, one large, the other small, is that the large capacitor is the main tuning capacitor, while the small one is used as a *bandspread* control (for very fine tuning). The tuned signals are then detected (converted to audio frequencies) by TR3.

Figure 2 The circuit diagram showing the 10-turn potentiometer VR1. This is the regeneration control for the circuit

TR2 is a *Q-multiplier* stage. It is a Colpitts-type oscillator which uses C8 and C9 to give feedback and produce the oscillation. C7 couples the tuned circuit (and the input to TR3) to TR2. The tuned circuit thus controls the frequency of oscillation of TR2 and the signal passed on to TR3.

The secret of the ease of operation of this receiver is VR2, a 10-turn potentiometer (or *helipot*). The resistance wire is wound in the form of a helix, giving a much greater wire length than in a normal potentiometer, and the shaft must be turned ten times to cover the whole length. Helipots are very useful when very fine adjustments have to be made. Here, VR2 sets the regeneration (or *reaction*) level, depending on the type of signal you are receiving, as will be discussed in Part 2.

TR4 provides the first stage of audio amplification and, after the volume control, VR2, the audio amplifier integrated circuit, IC1, will drive a small loudspeaker or headphones.

In Part 2, the construction will be discussed, together with the choice of aerial, the parts list, and advice on using the receiver.

31 A fruit-powered medium-wave radio

Introduction

This is a one-evening project that will result in a working medium-wave (MW) radio, and will also teach you a little about the way electricity can be generated from the right metals and a little (safe) acid. All you need are three lemons or other citrus fruit, three pieces of copper and three pieces of zinc (or galvanised metal) for your power supply.

Construction

Figure 1 shows the circuit and **Figure 2** its layout on a simple ‘plug-in’ prototype board. The six pieces of metal are connected as shown, to wire the three lemons in series; use ordinary wire between each lemon and the next. If you have a meter to measure the total voltage, it should be about 1.8 V. Use a standard ferrite rod, and wind on it about 40 turns of single-conductor PVC-insulated wire.

Figure 2 Three lemons power the radio, which gives good results for such a simple circuit

Wire up the circuit on the board as illustrated in Figure 2. Soldering is not required with this type of board – just plug in the components and the wires. Only one transistor is needed. The tuning capacitor, VC1, selects the station you want to hear, and D1 helps to remove the carrier from the RF signal. The resulting audio signal is fed to TR1, a small transistor audio amplifier, which makes the signal big enough to drive a crystal earpiece comfortably. Walkman-type earphones will not work, so invest in a crystal earpiece which you can use in several other projects, too! If you use a smaller capacitor than that specified for VC1, you will need more turns on the aerial coil.

Tests on the prototype indicated that the radio will run for about a week on three lemons!

Parts list

Resistors: all 0.25 watt, 5% tolerance

R1	1 megohm (MΩ)
R2	10 kilohm (kΩ)

Capacitors

C1	1 nanofarad (nF) min. ceramic
VC1	250–500 picofarad (pF) variable

Semiconductors

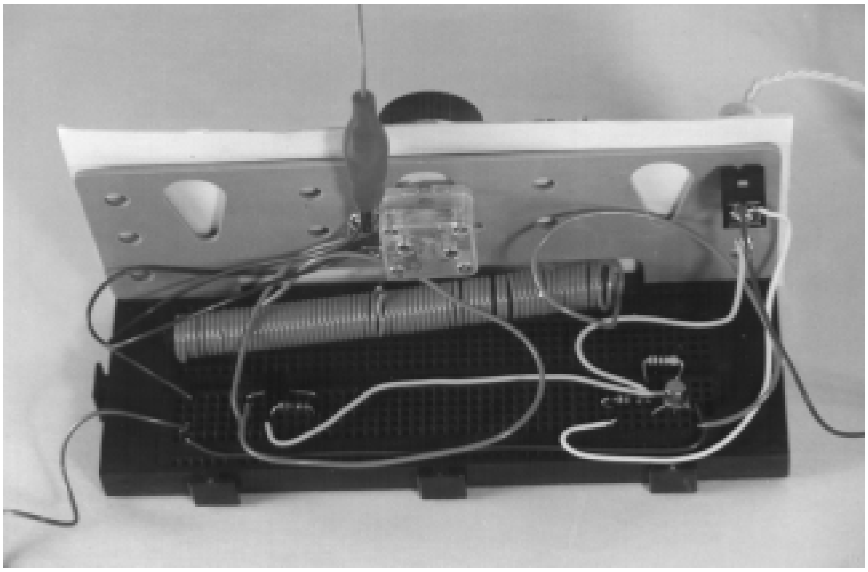
TR1	BC107 npn (or BC108, BC109C)
D1	OA90, OA91 germanium (not silicon)

Coil

L1	2 metres of single-conductor insulated wire on a standard ferrite rod

Additional items

- Plug-in prototype board, e.g. Maplin YR84F
- Wire aerial at least 3 m long
- Crystal earpiece
- Three juicy fruits



32 A capacitance bridge

Introduction

It is always valuable to have a means of measuring capacitors amongst your test gear. Universal LCR bridges (i.e. systems that can measure inductance, capacitance and resistance) can be found at most rallies, and you can work your way up to owning one of these. In the meantime, a piece of home-made equipment gives you experience as well as resulting in a useful measuring instrument.

The circuit described here is called a *capacitance bridge*, because it balances the effects of one resistor/capacitor pair against another; if one capacitor has an unknown value, then the other can be calculated. The basic bridge circuit is shown in **Figure 1**. To avoid having calculations to perform, this instrument will be calibrated by using capacitors of known values. The bridge is a useful way of performing measurements, because a knob is turned until there is a null in the signal from an earpiece or loudspeaker. The ear is very precise in being able to perceive nulls, which makes the bridge easy to use and reasonably accurate. At the null, the bridge is said to be *balanced*.

How does it work?

Figure 2 is the circuit diagram for this capacitance bridge. Transistors TR1 and TR2 form an oscillator. This is the audio oscillator shown in Figure 1, and produces an alternating voltage which is fed to the bridge. RV1 (in the collector lead of TR2) replaces both R1 and R2 in Figure 1 – that part of

Figure 2 Transistors TR1 and TR2 give an audio signal which is adjusted by variable resistor RV1

RV1 *above* the wiper represents R1, while that part *below* the wiper represents R2. The voltage on one side of the earpiece is determined by the ratio of these values, and is adjusted by rotating RV1. The voltage on the other side of the earpiece is determined by the ratio of C3 to Cx, where Cx is the unknown-valued capacitor. When these two voltages are the same, the bridge is balanced and there is no current through the earpiece.

Figure 3 shows the layout of the components on the matrix board of the prototype. It measures 10 holes by 14 holes, and is of the plain type, i.e. no copper strips. All earth connections are taken to a single solder tag. When

mounting the board inside a metal box, a long screw is used with extra nuts, to earth the board to the case while providing a stand-off, thus preventing any unwanted short-circuits between the board connections and the case. Be aware that a *crystal* earpiece must be used; low-impedance headphones of the Walkman type are not satisfactory. Solder two flying leads as shown in **Figure 4**, about 15 cm long, terminated in small crocodile clips for attaching to the unknown capacitor.

Calibration

After checking the circuit carefully, attach the battery and switch on; a buzzing noise should be heard in the earpiece. This is the first sign that everything should be OK. If there is no buzz, switch off and recheck the connections.

You will now need a range of close-tolerance (1%) silver-mica capacitors covering the range 10 to 1000 picofarads (pF). Arrange the capacitors in ascending order and connect them to your bridge in sequence. After having prepared a neat piece of card or paper mounted behind the knob on the front panel, mark the dial at the positions of the nulls for all the capacitors. You have now calibrated your capacitance bridge. If you are more likely to want to measure larger capacitors, replace C3 by a 1 nanofarad (nF) capacitor, and the bridge will measure up to 10 nF approximately.

Parts list

33 A simple short-wave receiver – Part 2

Introduction

In Part 1, the design of this receiver was discussed in some detail. Now we are going to put it all together and see how it works. The receiver is laid out on a printed-circuit board (PCB) or on a matrix board.

Construction

The layout of the components is shown in **Figure 1**. Identify each part separately, insert it into the holes in the board and solder carefully. Long leads may be cropped before or after soldering, depending on your skill and preference. All electrolytic capacitors, T1, T2 and IC1, must be connected correctly. The front-panel controls are connected to the PCB terminals shown in Figure 1.

The layout of the controls and the placing of the board inside the case are matters of personal preference. The size of the prototype front panel is shown in **Figure 2**. The prototype had a slow-motion drive fitted to VC2, the main tuning capacitor. This required the capacitor to be fitted on its own small panel. The bandspread control does not need any form of

Figure 1 Layout of the receiver circuit board

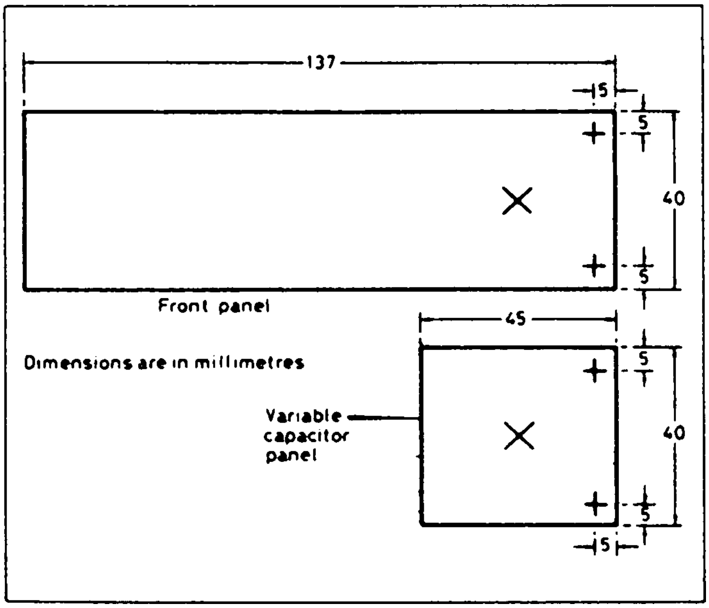

Figure 2 The case can be metal or made from PCB material

slow-motion drive. A tuning dial may be fitted behind the tuning knob on VC2 if required. The volume control, VR2, has its own on/off switch for the battery, which can be mounted behind the back panel, on which are mounted the aerial input sockets and the headphone/speaker socket. Check your soldering carefully, together with all the wiring between the board, the potentiometers and variable capacitors. When you are confident that everything is perfect, connect the battery and switch on.

The first tests

If you have a good aerial and are using an aerial tuning unit (ATU), use the low-impedance input. Excellent results are possible, though, with about 3 metres of wire connected to the high-impedance input. Set the volume control to give a gentle hiss in the headphones or speaker. Advance the reaction control to give a definite hiss. As you tune in an AM station, the hiss will change to a whistle; back off the reaction until the oscillation *just* stops. The receiver is now correctly set for AM reception.

On the amateur bands, the stations will be SSB or CW, and the reaction needs to be set *just above* the oscillation point, and will need slight adjustment from time to time for different qualities of signal. Juggling with the volume, reaction and tuning is part of the pleasure of using regenerative receivers!

In action

Practice is needed for best results. The regenerative receiver is renowned for its versatility in being able to be set up *exactly* for all types and strengths of signal. The basic receiver tunes from 6.5 MHz to 11 MHz approximately; this includes two amateur bands at 7.0 MHz and 10.1 MHz and two broadcast bands.

34 A basic continuity tester

Introduction

This little device can be built on a plug-in breadboard, and is ideal for testing fuses and cables, as well as doubling as a signal source for testing amplifiers, etc. It can even be used for testing npn transistors by replacing either of the transistors in the circuit, and seeing if the circuit still works!

Simple and quick to build

Using a plug-in breadboard, this circuit is so simple it could almost be built when you need it, and then dismantled again! If you want the circuit to make a different sound, the components to change are R2, R3, C1 and C2. Always make sure that R2 = R3 and C1 = C2, or the sound may be excessively 'edgy' and lacking in volume.

Basically, the circuit is an oscillator which drives a little loudspeaker directly. The fuse or cable you are testing is connected between the crocodile clips. If there is a current path between the two clips, the current also flows through the circuit, thus operating the oscillator and producing a sound from the loudspeaker.

Figure 1 The circuit diagram of the continuity tester

If you want to use the circuit to produce a signal to test an amplifier, for instance, connect the croc clip which comes directly from the battery to the junction of R1, R2, R3 and R4. This supplies current to the circuit while, at the same time, bypassing the loudspeaker. Use the two components R5 and C3 between the oscillator and your amplifier. The loudspeaker is bypassed because you will want to listen to the output from your amplifier, *not* from the oscillator!

Remember, NEVER test any equipment which is still connected to the mains electricity supply. Avoid testing anything which is switched on and has its own power supply. You may damage both your tester ***and*** the circuit you are 'testing'!

35 A charger for NiCad batteries

Introduction

The cost of replacing dry batteries can be alleviated to a great extent by the use of rechargeable batteries such as those containing nickel and cadmium (called *NiCads*). They are more expensive than the batteries they replace, but they can be charged hundreds of times and thus prove cheaper in the long run.

NiCads produce only 1.2 V per cell, compared with the 1.5 V of ordinary cells, so before you rush out and buy lots of these, please make sure that the equipment on which you plan to use them will work on the reduced voltage! For example, if you are using four cells to give you a 6 V supply, NiCads will give you only 4.8 V, which is quite a reduction. Using six cells to replace a 9 V battery will give you only 7.2 V. Not all equipment is happy with these reductions!

However, we all use them when we can, and they save substantial amounts of money. Here is the circuit of a charger to keep them in prime condition.

Charging NiCads – the ampère-hour

NiCads require charging at constant current, which means that connecting one across a normal power supply (constant *voltage*) is useless and can destroy it. They need pampering to the extent of needing a long charge (around 16 hours) at a rate dependent upon the *capacity* of the battery. By the capacity of a battery, we mean how much energy it can store. You will probably know that energy is measured in joules. For the purposes of storing energy in batteries, the joule is *not* the ideal unit, so we use one that is! This unit is the ampère-hour (Ah), and must be interpreted with some realism. For example, if the battery is rated at 2 Ah, it will deliver a current of 0.5 amp for 4 hours, or 0.25 amp for 8 hours. Provided the current is not too high, the product of the current (in amps) and the time for which it will flow (in hours) before the battery is flat will always be around 2 Ah. A workable ‘rule of thumb’ for calculating the charging current is that its value should be around one-tenth of the numerical value of the capacity; so, for our 2 Ah battery, a charging current of around 200 mA (2 ÷ 10 = 0.2 A or 200 mA) would be used.

Constant voltage to constant current

Many integrated circuit (IC) chips are available for use as voltage regulators, i.e. they supply a constant voltage. Most of these can be persuaded to become constant current supplies with one external resistor!

The voltage regulator IC usually has only three connections – ‘input’, ‘output’ and ‘common’. It is designed (in the case of the LM7805) to produce a constant 5 V output between the ‘output’ and the ‘common’ connections, at currents of up to 1 A. If a resistor is connected between these, the IC will maintain 5 V across it. If you look at **Figure 1**, you will see the circuit performing this conversion.

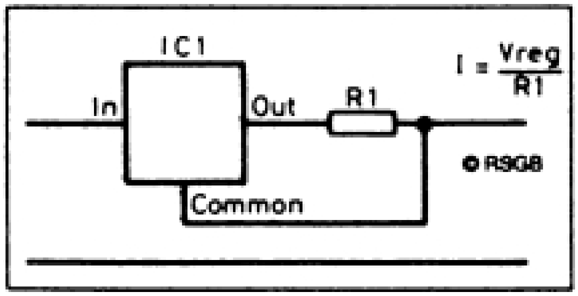

Figure 1 Voltage regulator arranged to produce a constant current

For the previous example, we derived a charging current of 200 mA, so we now need to calculate the value of resistor that will produce this current. Using the equation which is derived from Ohm’s law:

$$I = \frac{V}{R}, \text{ from which } R = \frac{V}{I},$$

where R = R1, the resistance in ohms that we are calculating,
V is the voltage across R1 (5 V), and
I is the current flowing (200 mA).

So,

$$\text{R1} = \frac{5}{0.2} = 25\,\Omega.$$

25 ohms is not a ‘common’ or ‘preferred’ resistor value, so we must choose the next *largest* value, which is 27 Ω. This reduces the current, but only slightly – it is now 185 mA. When calculating resistor values in power supply circuits, we must *always* check the power that they dissipate and make sure we specify and fit a suitable resistor.

Power (in watts) is the product of the voltage across and the current through a device, so in this case it is given by:

$$\text{Power} = V \times I = 5 \times 0.185 = 0.925\,\text{W}.$$

Rather than use a 1 watt resistor operating very near its limit, it is safer to use a 2 watt resistor operating well within its limits.

Looking again at Figure 1, we now have a constant-current source producing 185 mA, when R1 is a 27 Ω, 2 W resistor. For use with NiCads requiring charging currents other than 200 mA, you will need to repeat the two equations above, using a new value for *I*.

The full circuit and its assembly

This is shown in **Figure 2**, and can be broken down into two parts. The first is the AC to DC conversion produced by the mains transformer, T1, the bridge rectifier, BR1, and the smoothing capacitor, C1. The second is the constant-current section already discussed.

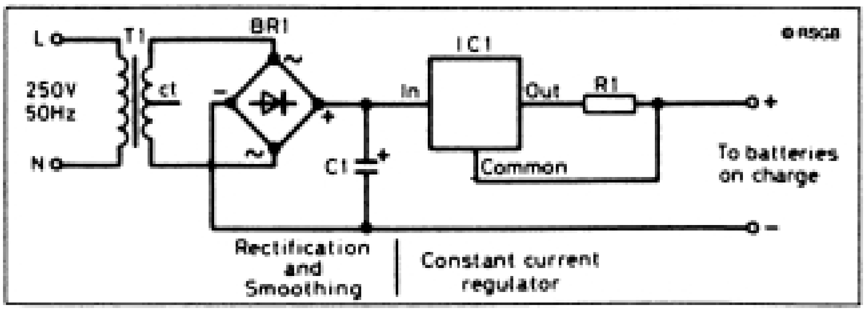

Figure 2 The complete circuit including mains components

The prototype was assembled on matrix board measuring 18 holes by 12 strips, although, as **Figure 3** shows, this is much larger than is strictly necessary. No strip cutting is needed, but make sure that IC1 and C1 are inserted correctly.

Warning! Before you attempt to wire up the transformer and the bridge rectifier, be aware that you will eventually be connecting the circuit to the mains supply, so there are three possibilities for you: (1) get a qualified friend to supervise your completion and testing of the circuit; (2) get your qualified friend to complete and test the circuit for you; (3) replace the transformer and bridge rectifier with a mains adapter.

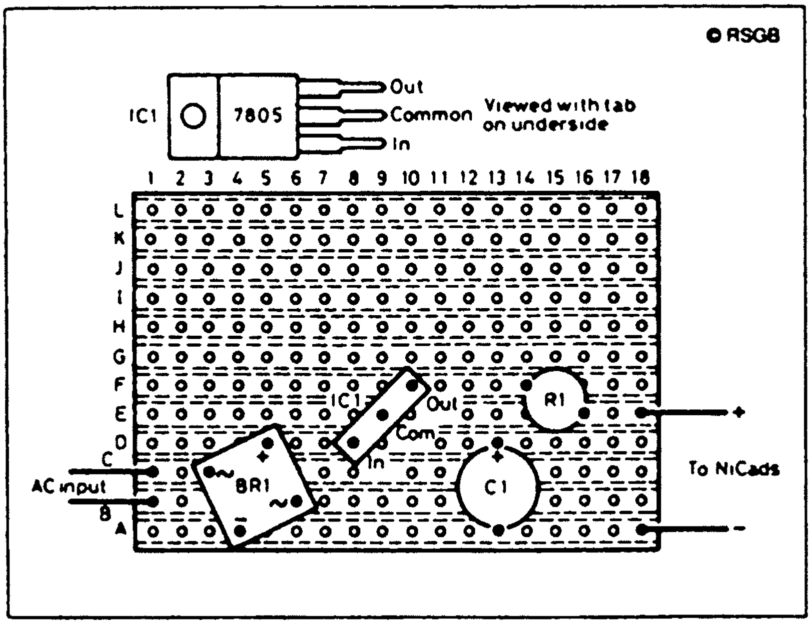

Figure 3 The charger can be built on Veroboard

If you decide to use the mains adapter, its output is connected directly across C1, because T1 and BR1 are now no longer needed. Make sure the polarity (positive and negative) is correct and that the adapter output is set to 12 V.

A quick test

If you have built the mains version, make sure all connections are correct, and that there are no soldered joints which will touch other parts of the circuit. The box must be securely closed before tests begin. The RSGB cannot be held responsible for damage to equipment or batteries! The version using the mains adapter need not be closed during tests.

Switch on. With nothing connected to the output, the unit should run cold. If this is not the case, switch off and recheck your circuit. If all is well, switch on again and connect a DC multimeter (on the current range) across the output. It should indicate only a slight difference from the calculated value of 185 mA. You can now charge your NiCads!

Other charging currents can be set by having different values for R1, perhaps selectable by a rotary switch. Remember to make sure that the values of both resistance *and* power dissipation are correct, and don't exceed the 250 mA rating of the transformer (or the 1 amp rating of the IC if you are using a bigger transformer).

36 An 80 metre crystal-controlled CW transmitter

Introduction

A simple transmitter is ideally suited to anyone venturing into our marvellous hobby for the first time. If you are put off by the complexities and prices of the 'black boxes' then this is the transmitter you've been looking for!

The circuit

The complete circuit is shown in **Figure 1**. It is a single-transistor crystal oscillator which is *keyed* (switched on and off) by the Morse key in the +12 V supply rail. The circuit first appeared in *QST* (the American equivalent of *RadCom*) in 1982, and has since appeared in a modified form in the *ARRL Handbook*. The circuit can produce about 2 watts on 80 m, and can be constructed on a piece of plain matrix board; the prototype board measured 7 cm by 3 cm, and its layout is shown in **Figure 2**.

Note that a bare copper wire runs along the bottom edge of the board to act as an earth wire for the relevant components. The only 'difficult' part of the construction is the winding and wiring of T1. The main winding is 38 turns of 26 SWG enamelled copper wire, and there are two link windings of four turns each. Make sure that all windings are wound the correct way round the toroid – Figure 1 shows this and should be studied carefully. If the windings do not have the correct *sense* (i.e. a clockwise coil has been wound anticlockwise, or vice versa), or have been connected incorrectly to the rest of the circuit, the oscillator will not work!

When putting components on the board, wire in the crystal socket *without the crystal in it*. Crystals do not like to be subjected to the horrors of a soldering iron, so keep your crystal to one side during the construction process!

Figure 2 Component layout is straightforward on a 'matrix board' (it has holes but no copper strips). The dotted lines are the connecting wires. The lower part shows the connections for the transmit/receive switch

The output filter, which comprises C7, C8 and L1, is a *low-pass* filter, which helps reduce any *harmonics* present in your signal. Harmonics are integral multiples of your transmitter frequency, so if you are transmitting on a frequency, *f*, harmonics will be present at frequencies 2*f*, 3*f*, 4*f*, . . . and so on. L2 is another inductance using 22 SWG enamelled copper on a ferrite toroid. The changeover switch is external to the transmitter board, and is used to switch your aerial between the transmitter and the receiver; its wiring is shown in Figure 2.

Use a dummy load

A dummy load enables you to test your circuit without actually transmitting a signal. If you haven't such a thing already, it is easy to construct one to use with this transmitter. Don't use it for transmitters of more than 2 watts output, though. Use two 100 ohm, 1 watt resistors, connected in parallel across the end of a short piece of coaxial cable, terminated in a BNC, PL259 or N-type free plug, as shown in **Figure 3**. Plug this into the aerial socket on your transmitter, plug in your crystal and connect the transmitter to a 12 V supply. Have another receiver switched on and tuned to the crystal frequency. Although the radiation from your dummy load is minimal, it will

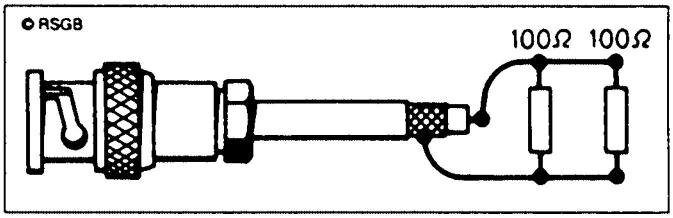

Figure 3 A simple 2 W dummy load can be made from two 100 Ω (ohm) resistors in parallel. The plug should match the socket on your transmitter

be enough to be picked up by a receiver in the same room. Send dashes with the Morse key, and adjust VC1 until the received note is *clean*. It should not sound rough, or have a *chirp* (change its frequency during a dash or dot). Avoid tuning for maximum power; this is seldom the correct setting!

You will need to put your completed transmitter in a metal box, using sockets for the power supply, aerial, receiver and Morse key. The sockets can be chosen to match your existing equipment.

Figures 4–7 are taken from the RSGB book *Practical Antennas for Novices*, and may give you some ideas on the type of aerial to be used with your transmitter.

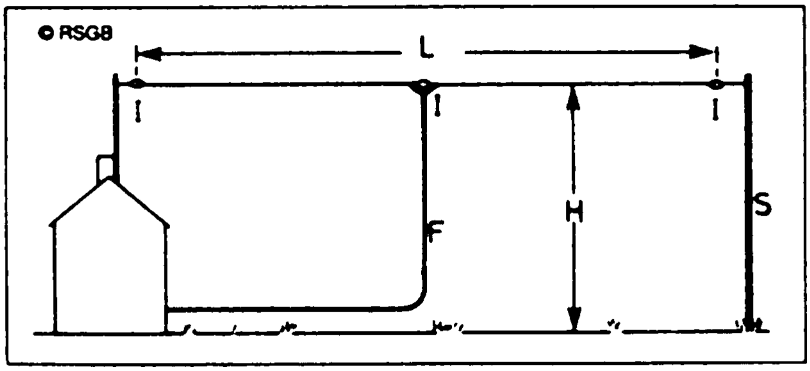

Figure 4 A simple dipole can be very effective. For the 3.5 MHz band, length L is 40 metres and height H should be as large as possible. The far support S can be a tree, pole or building. Insulators I may be home made from strong plastic and the feeder F should be 50 Ω (ohm) coax cable

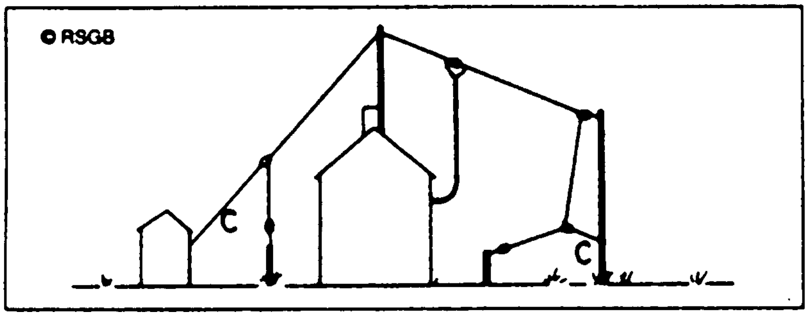

Figure 5 Your signal is radiated mostly from the centre of the dipole so the ends can droop or even be bent but the length may need shortening by a few centimetres because the ground and the bends will detune the dipole. Cords C are best made from strong plastic rope from a sailing or camping shop

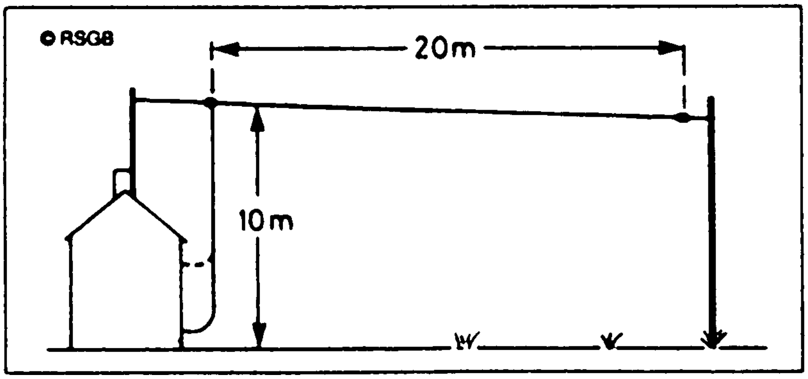

© RSGB
20m
10m

Figure 6 An ‘inverted-L’ takes up less space than a dipole and doesn’t need coax cable. Like the dipole, the end can droop or be bent to save space as in this case most of the radiation comes from the area around the top of the vertical part

37 A solar-powered MW radio

Introduction

What could be more ecologically friendly than a radio powered by the sun's energy? This design is quite standard, and if you have built any of the other medium-wave radios in this series, then this one should present few problems.

The solar panel

The solar panel is to the solar cell as the battery is to the cell; in other words a solar panel is several solar cells connected in series. The solar panel quoted for this radio will generate about 9 V at a current of around 30 mA on a sunny day. The circuit will operate on a supply of around 2 V, so bright sunshine is *not* necessary for satisfactory operation. The volume will be less, of course.

The circuit

The radio uses the ZN415E integrated circuit (IC), connected as shown in **Figure 1**, the complete circuit diagram. The signal is tuned in by the combination of L1 and VC1. L1 is made by winding about 35 turns of 24 SWG enamelled copper wire on a ferrite rod. A standard ferrite rod of 10 cm length and 1 cm diameter is used.

Signals selected by the tuned circuit are passed to IC1, which amplifies the signals and removes the audio component, which is then amplified further by IC2 for driving a small loudspeaker. The removal of the audio component is the process we call *detection*. In addition to this, IC1 provides *automatic gain control* (AGC), which helps to keep the audio signal constant, even when the incoming RF signal may vary due to fading.

The prototype board

Veroboard (also known as matrix board or stripboard) is ideal for the construction of the radio. The layout is shown in **Figure 2**. The board size is 11 strips by 30 holes (**please note that there is no row 'I', so take care with your counting!**). Using a 3 mm ($\frac{1}{8}$ inch) twist drill rotated between

your thumb and forefinger, break the strips at the points marked with a cross inside a circle. Hold the board up to the light to ensure that the tracks *have* been broken and that there is no copper swarf shorting tracks together.

Firstly, solder in the 8-pin DIL sockets for the ICs, making sure that the notches in the sockets are facing upwards, as shown on the diagram. Then, solder in the wire links, resistors, capacitors and diodes, making sure that the electrolytic capacitors (C2, C6 and C7) and the diodes (D1 and D2) are connected the correct way round. Use different colours of wire for the connections to the volume control, VR1, to avoid incorrect connections. Note the wiring of the tuning capacitor (VC1) shown in Figure 2; a two-section type is used, and both sections are wired in parallel to give twice the capacitance of a single section.

There is no on/off switch – just turn the volume down when you are finished using the set! The solar panel can be mounted parallel to the top of the case, or angled to receive the maximum energy from the sun, as shown in the photograph. You could have a battery available as a standby source to use the radio after dark; any battery of between 6 V and 9 V will do. Wire it with a simple changeover switch, so you can switch between solar and battery power. Ask a friend for help with this if you are not sure how to do it.

You may need to adjust the number of turns on L1 to get the best results, but it should be possible to receive at least five stations at good volume with your sun-powered radio!

38 A receiver for the 7 MHz amateur band

Introduction

Listening on the 40 metre band (from 7.0 to 7.1 MHz) can be very rewarding – it is a popular haunt for HF Special Event stations, and at night there are signals to be heard from all over Europe. This receiver is designed purely for the 40 m band, and is ideal for those who have built the simpler receivers and are looking for something a little more challenging. The more experienced constructor may prefer to build this on prototype board.

The circuit and its construction

Figure 1 shows the circuit diagram. The receiver will work well with headphones or loudspeaker. Walkman-type headphones and speakers are ideal for use here.

Figure 1 The receiver gives good performance on the 7 MHz amateur band as well as being simple to construct and align

Signals arriving at the aerial are coupled into IC1 via gain control VR1, which also functions as the on/off switch. Tuning is provided by varying the voltage on the *varactor diode* (or varicap), D1. VR3 is the main tuning control, and VR2 is the *bandspread* (fine tuning) control. The varactor diode is supplied as a dual device, which must be cut down the middle *carefully* with a sharp knife; with the lettering upwards, the ground lead (0 V) is on the left-hand side, as Figure 1 illustrates.

Solder in the IC sockets first, followed by the coils. After this come the links, resistors, capacitors and varactor diode. Ensure that IC3, the voltage regulator, is wired correctly, and check the polarity of the electrolytics. The crystal, X1, is very fragile, so take extra care with it. The wiring of the three controls is shown in **Figure 2**.

Before putting the ICs in their sockets, connect up the battery and check the following voltages with the negative voltmeter lead connected to the negative terminal of the battery:

Pin 8	IC1	5 V
Pin 8	IC2	5 V
Pin 8	IC4	9 V
Pin 1	IC5	9 V

When all these have been found to be correct, switch off and put the ICs carefully into their sockets. Use wire of different-coloured insulation to wire up the front-panel controls.

The case can be a small plastic box of size 22 cm by 15 cm by 8 cm, with three 10.5 mm holes drilled in the front and two 8 mm holes in the side for the aerial and earth connections. On one side are a 6 mm hole for the speaker socket and an 11 mm hole for the optional external power supply.

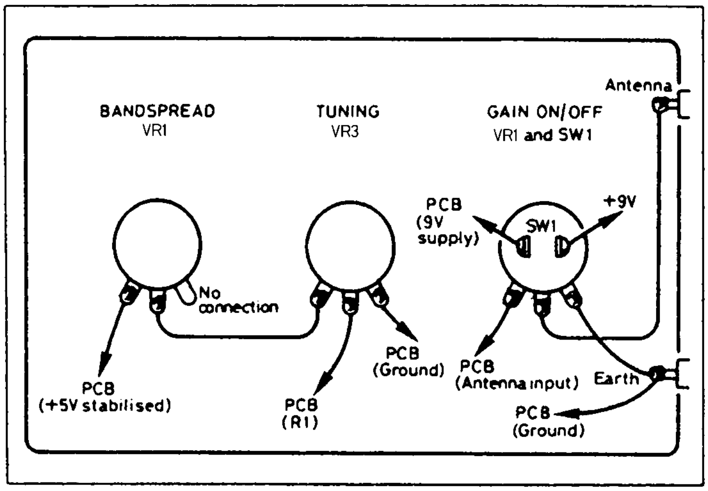

Figure 2 Rear view of the variable resistors. Check the connections carefully to make sure the wires are fitted correctly

Testing and tuning

The aerial for the receiver should be between 30 and 70 feet of wire, mounted as high as you can make it, away from trees and buildings if possible. Connect the battery and switch on. Adjust L1 and L2 for the best results. Tune slowly with VR3; you should find CW stations at the lower end of the band (anticlockwise) and SSB stations at the upper end (clockwise). You may find that it is easiest to make these adjustments *before* mounting the board in the case with double-sided sticky tape or pads. If you are planning to use an external DC supply, make sure it is a safety approved stabilised 9 V type, and **disconnect the battery before you use such a supply!**

If you suspect that the tuning doesn't quite cover the lower CW end of the band, try increasing C9 to 1200 pF. If it is the upper SSB end which is missing, decrease C9 to 820 pF.

It is always advisable to use an aerial tuning unit (ATU) between your aerial and the receiver. A suitable design of ATU is included as a project in this book.

39 Diodes for protection

Introduction

Many semiconductor devices can be destroyed in an instant if their supply is reversed. With the use of batteries as power sources, it is quite common for the battery to be connected ‘the wrong way round’, and the scope for damaging equipment is significant and very real. Diodes can protect equipment in several ways, and you may do worse than to consider one of these approaches to protect your next expensive project.

Choose wisely!

All the diode circuits given here are so simple as to invite calamity. The circuits are not foolproof but, with a little care, will work first time. Remember that a semiconductor diode has a forward voltage drop of between 0.5 V and 0.7 V, depending on its type and the current flowing. This will be mentioned later.

The first thing you need to do is to insert a good multimeter *in series* with the circuit you want to protect; set the range to Amps DC, and switch on. Check that the circuit works properly. Then, decrease the current range on the meter until a good reading is indicated. Make a note of this current, as it is the normal running current of your circuit.

To choose a diode, you must consult the catalogues or data sheets and find one where the quoted *maximum forward current* exceeds the current you have measured; preferably it should be at least twice your measured current. Secondly, the diode will have a *peak inverse voltage* (PIV); this is the maximum voltage it can withstand when the cathode is made positive with respect to the anode, i.e when it is *reverse-biased* and not conducting. This voltage must be greater than your battery voltage, again by a factor of about 2. Except in the case of the bridge rectifier (see later), these criteria will enable the selection of a suitable diode to be made easily.

The series diode

The simplest and most obvious way to protect equipment is to insert a diode in the positive supply lead, as shown in **Figure 1**, with the diode passing current *only* when the supply is of the correct polarity. Because of the 0.6 V that exists across the diode, your equipment will normally operate on a

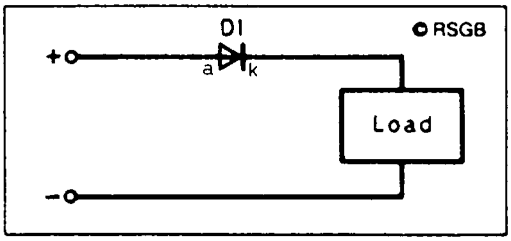

Figure 1 Series diode protection

slightly lower voltage. If you imagine reversing the supply to this circuit, you will see that the negative terminal of the battery is connected to the anode of the diode; the diode becomes reverse-biased and will not conduct any current, thus protecting the load. Your equipment will not operate when the battery connections are reversed.

The parallel diode

The circuit of **Figure 2** overcomes this voltage drop. It places the diode in parallel with the load (your equipment) but in a normally reverse-biased condition so that it draws no current when the battery is correctly connected. Reverse the battery connections, however, and a very large current will flow through the diode, thus blowing the fuse! For this technique to work successfully, the current drawn by the diode when the battery connections are reversed *must* be much greater than the maximum current drawn by the equipment, in order to blow the fuse. This is usually not a problem, however.

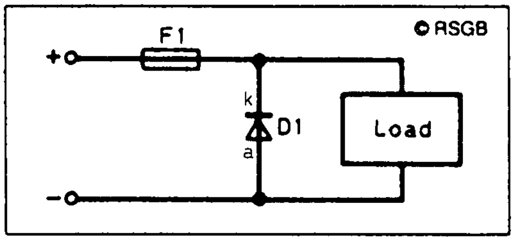

Figure 2 Parallel diode and fuse

The diode bridge

For sheer elegance, the circuit of **Figure 3** takes the biscuit! It uses four diodes connected in the form known as a *bridge rectifier*. Such rectifiers exist, and do not have to be made up from four discrete diodes.

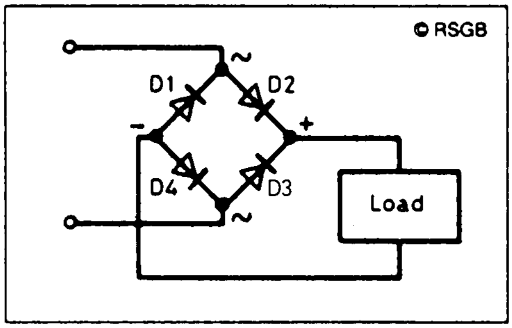

Figure 3 The diode bridge

Follow the current round the circuit from the supply, assuming initially that the top wire is positive and the bottom wire negative. It flows from the positive supply

(a) through D2
(b) through the load (top to bottom)
(c) through D4

and back to the negative of the supply.

Now assume that the bottom supply lead is positive and the top lead negative. The current flows from the positive supply

(a) through D3
(b) through the load (top to bottom)
(c) through D1

and back to the negative of the supply.

So, whichever way round the battery is connected, the current will *always* flow the same way through your equipment!

The circuit does have a drawback, however. Whichever way round the battery is connected, there are always **two** diodes conducting the current at any time. In the first case it is D2 and D4; in the second case, D1 and D3. This means that there is a total voltage drop of about 1.2 V. If your equipment can tolerate that reduction in voltage, then you will not have a problem.

Decoupling

Whenever the supply rail to a piece of equipment, or even to an individual stage of a circuit, is broken for the insertion of a device that will drop voltage, strange things can happen. This is because the supply for any circuit is assumed to have a low resistance to DC and a low *impedance* to AC. (Impedance is the AC equivalent of DC resistance.) These two are not the same, and the insertion of a diode or diodes is certain to make a big difference to them both. To overcome any irregularities in the operation of the circuit you are protecting in any of the ways described previously, the protected supply needs to be *decoupled* with a capacitor.

If the circuit handles audio frequencies only, placing an electrolytic capacitor directly across the load in all three circuits should solve the problem. The parallel circuit of Figure 2 is less at risk than the other circuits. The size of the capacitor will be determined by the current taken by the circuit, and may need to be chosen within the range 100 µF to 10 000 µF, with a working voltage greater than the supply voltage.

If the circuit is mainly handling RF currents, placing a capacitor of 0.01µF across the load should prevent any problems. A second capacitor, also across the load, of between 10 µF and 100 µF may be needed. Again, the parallel circuit of Figure 2 is less at risk than the other two.

Don't be afraid to experiment, but confine your experimenting (at first) to small equipment and low currents, until you get a 'feel' for the technique.

40 An RF signal probe

Introduction

A radio-frequency (RF) diode probe is a simple device which, when used with a conventional multimeter, enables the measurement of RF voltages in a circuit. When constructed, this will be one of the most useful pieces of test equipment for the experimenter who revels in the construction of transmitters and receivers.

The circuit

Figure 1 shows the simple circuit diagram. It is *almost* the same as a common diode rectifier circuit, but with a simple change to make it more sensitive. The circuit is known as a *voltage-doubler*, and is often found in high-voltage supplies, with beefier capacitors and diodes, of course! Because we are dealing with high frequencies and smaller voltages, the diodes and capacitors can be physically very small. The diode circuit of D1 and D2 *rectifies* or *detects* the RF from the probe, and any remaining AC is removed (short-circuited to ground) by C2. This produces, at the output, a constant voltage proportional to the peak-to-peak RF voltage present at the input; the output voltage is fed to an ordinary multimeter (on a voltage range).

D1 and D2 are germanium diodes
C1 and C2 are 10nF ceramic capacitors
© RSGB

Figure 1 The diode probe can be made from four electronic components

Construction

Although the circuit layout is not critical, a description of the prototype is given here for your information. **Figure 2** has the details. The components are soldered to square pieces of copper-clad printed-circuit board (PCB) glued to a larger piece of PCB. The larger piece serves as a ground connection. Use a stiff copper wire as the probe, and an insulated flexible wire with a crocodile clip to connect the probe to the ground of the circuit under test.

Cut a piece of plain PCB, 30 mm by 45 mm and another of 15 mm by 45 mm. Cut the smaller piece into three measuring about 15 mm square. Stick the three small pieces to the larger piece, ensuring that there are small gaps between each, as Figure 2 shows. Solder the components in place. The connection to the multimeter should be thin coaxial cable or screened microphone cable. If you use unscreened cable, there may be RF pickup here which can lead to false readings.

Simple to use

Using the probe is simple. Connect it to the multimeter and set the meter to around 10 V DC – you may need to reduce this, depending upon the magnitude of the RF voltage you are trying to measure. Hold the probe by

41 An RF changeover circuit

Introduction

The simplest entry route to operating an HF station is to buy or build a receiver, and to add a simple CW (Morse) transmitter. In theory, this sounds so simple, yet in practice there is one significant hurdle to be overcome. How can they both share the same aerial? A manually operated changeover switch is the obvious solution, but it takes time to perform the switching operation, by which time someone else has squeezed in before you and contacted the DX station! This small circuit accomplishes the changeover automatically, as soon as the transmitter is keyed.

How it’s done

The circuit is shown in **Figure 1**, and uses the signal from the transmitter to operate a relay. A relay is a switch which is operated electrically in the following way. A coil of wire with an iron core is used as an electromagnet. When current flows through the coil, it produces a magnetic field which, in turn, is used to pull a set of switch contacts. These contacts will be used to switch the aerial from transmitter to receiver and vice versa. The relay used here has a double-pole changeover (or DPDT, or DPCO) switch. If you are confused by the different types of switch, look at the basic descriptions elsewhere in this book. The *pole* of a switch is the part that doesn’t move; in Figure 1, one pole is connected to L1 and the other to the aerial output. In a circuit diagram, the switch contacts are always shown in their *normal* state, i.e. when *no* current flows in the relay coil. The changeover switch is normally in the receive position, so we say the receive switch is *normally closed*, and the transmit switch is *normally open*. We choose to have the circuit in the receive position normally, because everyone spends a lot more time receiving than transmitting. The relay is energised only when you are transmitting.

There are three RF sockets – one for the transmitter, one for the aerial, and one for the receiver. When the transmitter is not in use, there is a direct connection (via the Rx normally closed contacts of the relay) between the aerial and the receiver. The transmitter (which is not keyed at this time) is connected to a 50 ohm dummy load, R1.

When the transmitter is activated by pressing the Morse key, an RF signal appears at the transmitter socket. The wire carrying the signal to the relay

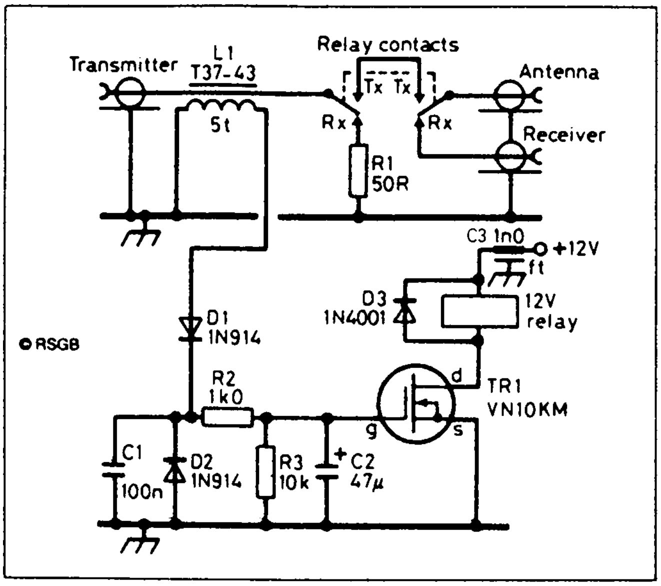

Figure 1 RF activated relay

Tx contacts passes through a toroid (a ferrite coil former, looking like a black Polo mint), which has a five-turn coil wrapped around it. This five-turn coil picks up the signal, which is then detected by D1 and D2, and converted to a steady voltage. C1 removes any remaining RF and C2 provides *hang*. Without it, the circuit would detect the gaps between every dot and dash being sent, and switch the aerial over very rapidly and very frequently! This is *not* what we want. We need the relay to remain in the transmit condition at normal Morse keying speeds, and then return to receive when the sending is complete. The combination of C2 and R3 achieves this.

The voltage appearing across C2 is fed to a VMOS field-effect transistor (FET), TR1, which acts as an electronic switch. When a voltage appears across C2, the FET switches on and passes a current through the relay coil, changing the contacts from receive to transmit. The diode, D3, across the relay winding protects the FET from being damaged by the large reverse-voltage spike which occurs across the coil when the FET switches off.

Construction

This is very simple – a circuit board is not required. The prototype was built into an old 50 g tobacco tin. All ground leads are soldered directly to the tin, thus supporting the components automatically. Phono sockets were used for the aerial, receiver and transmitter; you could use whatever connectors matched the rest of your station. The 12 V supply is fed through the tin using a 1000 pF feed-through capacitor, C3.

The 'dummy load', R1, must be able to withstand the RF output power of the transmitter. For novice use, 4 watts is adequate. Two suggestions for making up R2 from standard resistors are shown in **Figure 2**. Six 330 ohm, 1 watt resistors in parallel have a combined resistance of 330/6 = 55 Ω at 6 W. Two 100 ohm, 2 watt resistors in parallel have a combined resistance of 100/2 = 50 Ω at 4 W.

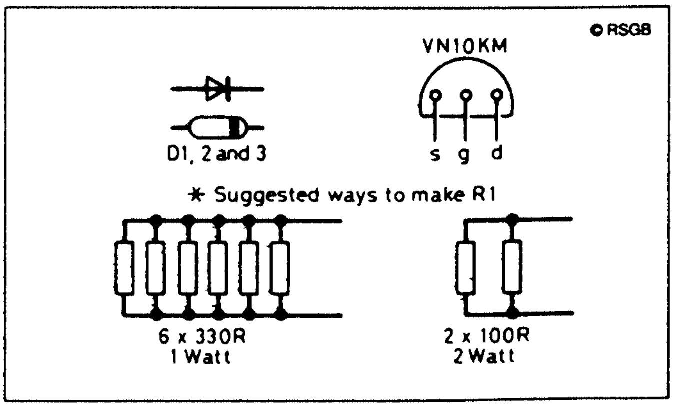

Figure 2 Component details

Make sure all the contacts to the relay are correct; also ensure that TR1, C2, D1, D2 and D3 are correctly wired.

Winding the toroid, L1, is very simple. It is made from PVC-insulated hook-up wire. Each time the wire passes through the centre of the toroid counts as one turn. The wire from the transmit socket to the relay simply passes through the centre! Use thin 50 Ω coax for the leads to the three sockets.

What happens to the receiver?

On transmit, the receiver is not connected to the aerial, but is only the separation of the switch contacts (about 0.5 mm!) away from the transmit lead. The receiver *will* pick up the transmitted signal, and there is a possibility that this signal will be enough to damage the receiver's sensitive input circuits. This can be prevented with the simple addition shown in **Figure 3**. Two diodes are connected back to back across the receiver socket. These act as a *limiter*, reducing the amount of signal that can enter the receiver. Solder these directly between the receiver socket and the tin.

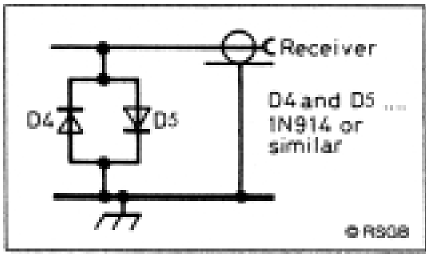

Figure 3 Receiver input protection

Warning

The wiring **must** be thoroughly checked. If the relay switch connections are wrong, there is a **great probability** that the full RF power will be applied to your receiver! You can check these connections as follows. With the 12 V supply connected, check that the relay energises (clicking sound heard) when the FET drain (d) is shorted to earth. Check the aerial and receiver connections with an ohmmeter or continuity tester. Disconnect the 12 V supply, and check that there is continuity between the centre pins of the aerial and receiver sockets. Reconnect the 12 V supply, short the FET drain to earth again (this will not damage the FET) and check that there is continuity between the centre pins of the aerial and transmitter sockets. If these tests show correct operation, disconnect the drain shorting wire (*most* important!) and your aerial auto-changeover is ready for use! Avoid using the device without the lid fitted.

42 A low-light indicator

Introduction

This is a simple one-evening project that can be built for the pure fun of it, or to use as the basis of a more complex project to switch your shack lights on when it gets dark! In its prototype form, it simply flashes an LED when the ambient light level drops to a preset point.

Operation

The heart of the circuit shown in **Figure 1** is a *photo-conductive cell*, also called a *light-dependent resistor* (LDR), a device whose resistance changes according to the amount of light falling on it. In bright light, the resistance is low (about 1 kΩ), whereas in the dark, its resistance is very high (up to 10 MΩ). The cell is made from a semiconducting material known as cadmium sulphide (CdS), and is enclosed in a small plastic container. The semiconductor is laid on a flat insulating surface in the form of a small flat ribbon. The ribbon construction gives a good area of surface for a given

length of ribbon, and the length of the ribbon is maximised by laying it out in a zig-zag pattern, as can be seen diagrammatically in **Figure 2**. In the dark, CdS is an insulator; when light falls on it, electrons are released inside the CdS, making it conduct. The more light there is, the more electrons there are, and the resistance falls.

In this circuit, the LDR is connected across the 9 V supply in series with a variable resistor, VR1. In this arrangement, the voltage that exists across the LDR will be determined by the light level. As the light intensity increases, the resistance of the LDR falls, dropping a smaller voltage across it. The

Figure 2 Component layout on tagstrip

©RSGB DY108

reverse happens when the light intensity falls – the voltage across the LDR increases. This voltage is used to drive an npn transistor, TR1, connected as an electronic switch. As the voltage on the base (B) rises, it will reach a point where TR1 will suddenly start to pass current, just as an ordinary switch does when pressed. The current flowing through TR1 also flows through a flashing light-emitting diode (LED), D1 and its series resistor, R1. D1 can be a steadily glowing type, if preferred. If you want to make the circuit switch the LED on at a different ambient light level, adjust VR1.

Construction

The prototype was made on an eight-tag tagboard (Figure 2). The resistors R1 and R2 can be laid on the tagboard for soldering, the rest of the components lying above or to the side of the board. Check the circuit after you have soldered everything on, then connect the battery. The LED should flash if you put your hand over the LDR, and VR1 can be adjusted to vary the point at which the LED lights. The project can be housed in a small plastic box with holes provided for the LDR and LED and an on/off switch if you want one.

Parts list

43 A J-pole aerial for 50 MHz

Introduction

For FM communication (i.e. voice and data) on the VHF bands, a vertical aerial is used to give all-round (non-directional) coverage. This is a half-wave aerial which can be fed at the end, thus removing the principal problem with the conventional vertical centre-fed half-wave dipole, which is that the feeder should leave the dipole at right angles. This is no problem when the dipole is horizontal, but can be difficult for the vertical dipole.

Basic facts

A feeder must be connected to an aerial at a point where the *impedance* (AC 'resistance') of the aerial closely matches that of the feeder. The difference between the two impedances gives rise to the voltage standing-wave ratio (VSWR), which is unity only when the two impedances are the same. With 50 Ω feeders, the feed point of a half-wave aerial is at the centre, where the aerial impedance is around the same value. At the end of a half-wave aerial, the impedance is high, so it is *not* a suitable point to connect a 50 Ω feeder.

Connection at this point can be effected using an RF transformer. RF transformers act in the same way as ordinary transformers, except that they are much smaller, and usually comprise wires of particular lengths adjacent to each other. **Figure 1** is a good starting point. It shows the aerial in its diagrammatic form. Notice that the aerial is in the form of an elongated letter 'J'; this shape gives rise to its nickname – the *J-pole*. The quarter-wave RF transformer is the lower 'U' section below the half-wave element. At the bottom of the U section, the impedance is zero (this may become clearer later) and at the top of the U section it is high, thus matching the aerial impedance. The coaxial feeder cable is connected part-way up the U section, where the impedance is around 50 Ω.

The practicalities

Figure 2 shows the aerial as constructed. As it is about 4.5 metres high, it may be too high for the average house loft, but is ideal for mounting outside, supported by a non-metallic pole or hung from a tree branch. The upper half-wave section is made from 1.5 mm insulated copper wire, as used in domestic mains wiring. The quarter-wave transformer below the half-wave section is made from 300 Ω balanced line ('ribbon cable'). The

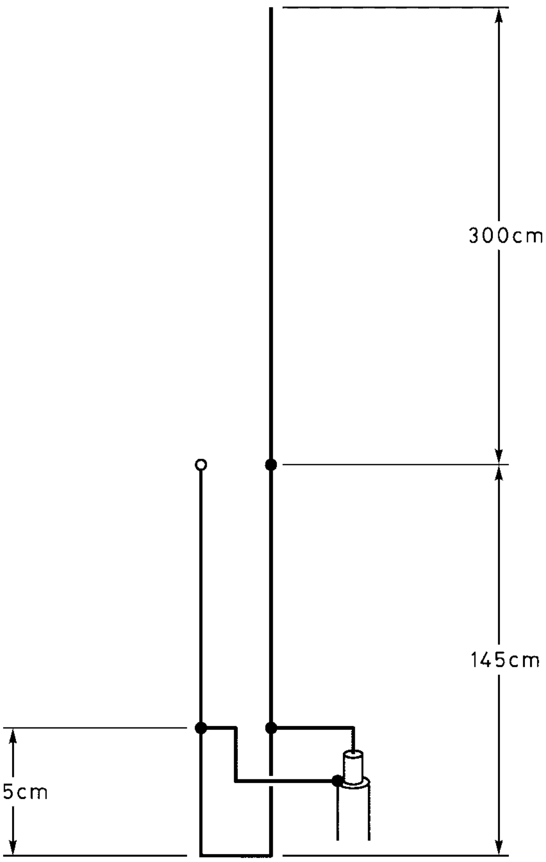

Figure 1 Overall dimensions of the 6 metre J-antenna

wires at the bottom of the transformer section are stripped of their insulation, twisted and soldered. At the upper end, only one wire of the balanced line is soldered to the bottom of the half-wave section. The other wire of the pair is not connected and is left insulated.

At the feed point of the transformer, the insulation needs to be carefully stripped from the balanced line. You will need a standing-wave meter (VSWR meter) in the coaxial line between your transmitter and the aerial, and you will need to adjust the position of the feed point. 45 cm from the bottom was the best point on the prototype, but this position is dependent upon the immediate surroundings of the aerial, and *must* be done when the aerial is in its final operating position. **Warning: *Never* make adjustments to the feed point when the transmitter is on. Make a VSWR measurement, switch off, move the feed point, switch on again, make another measurement, and so on.** You will need to aim for the lowest VSWR you can – certainly better than 2:1. Having found the best position, wrap all the exposed wires with self-amalgamating tape, to seal them against the ingress of moisture.

Figure 2 Construction details

How it performs

Figure 3 shows a computer prediction of how the J-pole radiates. It is called a *polar diagram*, and shows the distribution of your transmitted power when viewed 'from the end of your garden'. Most of your signal is sent at a fairly small angle to the horizontal; very little signal goes upwards, which is a good thing, of course. This also shows why the J-pole (or any other vertical aerial) should not be called 'omnidirectional', which means it radiates in all directions. It is omnidirectional *only* in the horizontal plane.

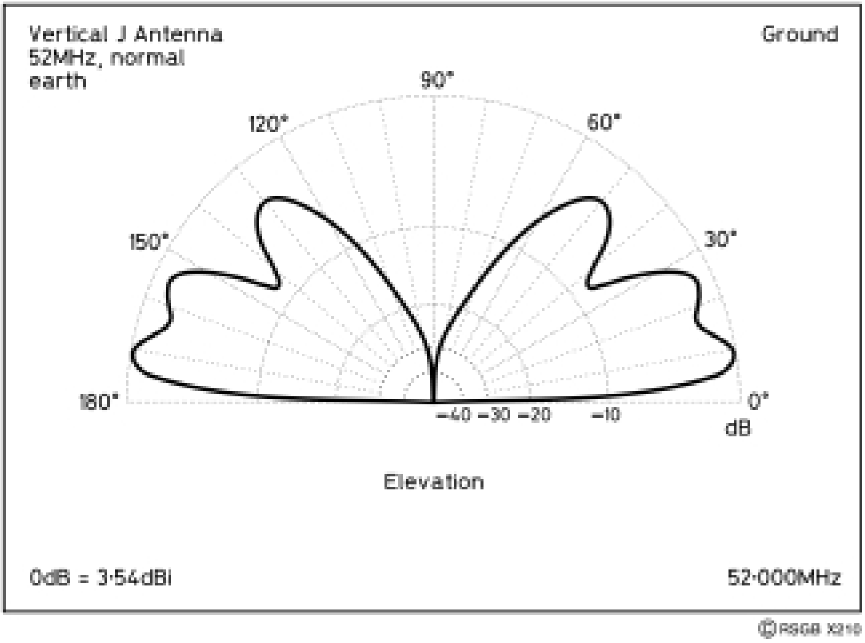

Figure 3 This polar diagram computed for the J-pole

Safety

Where you mount your aerial is a matter of personal preference and the restrictions of height and space, but the following safety rules *must* be applied.

1. Never fix an aerial where it may come into contact with power lines or telephone lines.
2. When climbing a ladder to put up an aerial outside, make sure the ladder is safe and that it is secured.
3. Don't do this alone. Preferably have someone with you. If this is not possible, make sure someone knows where you are.

Parts list

3.00 metres	1.5 mm insulated copper wire
1.50 metres	300 ohm balanced line
As required	50 ohm coaxial cable
As required	Self-amalgamating tape

44 Measuring light intensity – the photometer

Introduction

Before the days of automatic 'point-and-shoot' cameras, a photographer would use a light meter or *photometer* to measure the light level, then manually convert this reading into shutter speed and lens aperture settings to ensure a correctly exposed negative. Modern cameras have quite sophisticated photometers, which control the shutter speed and iris settings automatically.

A short explanation

A simple photometer circuit is shown in **Figure 1**, and is based on a device called a *light-dependent resistor*, or LDR. As its name tells us, its resistance depends upon the amount of light falling on it. In bright light, the resistance is relatively low (about 1 kΩ), whereas in the dark, its resistance is very high (up to 10 MΩ). The cell is made from a semiconducting substance known as cadmium sulphide (CdS), and is enclosed in a small plastic container. The semiconductor is laid on a flat insulating surface in the form of a small flat ribbon. The ribbon construction gives a good area of surface for a given length of ribbon, and the length of the ribbon is maximised by laying it out in a zig-zag pattern. In the dark, CdS is an insulator; when light falls on it, electrons are released inside the CdS, making it conduct. The more light there is, the more electrons there are, and the resistance falls.

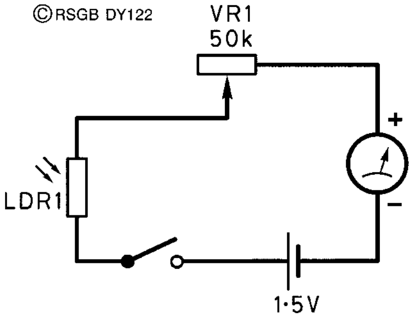

Figure 1 Circuit diagram of photometer

The photometer circuit

The circuit is simply a series connection of four things – the battery, the LDR, a variable resistor and a meter. A switch is also provided. The combination of the LDR resistance and that of VR1 determines the current flowing, which is indicated on the meter. Altering the resistance of VR1 sets the *sensitivity* of the photometer – you may want full-scale deflection of the meter needle for a bright light, or for a dim light.

It is simple to make, and a plug-in type matrix board is ideal to test the circuit, so that you can decide if you want to make a permanent version. Connect all the components in series; the only change you may want to make is the connection to VR1. If you find that the sensitivity control seems to work 'backwards', simply unsolder the wire from the end tag of VR1 and solder it to the opposite end tag. Problem solved!

In use

As soon as you connect up the battery, you will probably have a meter reading because of the daylight falling on the LDR. Shading it with your hand should reduce the reading. If the meter needle is hard over against the end-stop, turn VR1 until it indicates about half-scale. The LDR is very sensitive, and will read zero only in a dark room. If you put on a torch to see what the meter reading is, the LDR will detect the torch light, and will give a reading!

Here is a simple project where you can use the photometer in an experiment which has an analogy in radio. Draw a circle on a large (A3 or bigger) sheet of paper and divide it up into 30-degree sectors, as shown in **Figure 2**. Draw a series of smaller circles which divide the maximum radius into five. Look at the figure if you're not sure about this. Bring the LDR away from the circuit by using two long, flexible wires. The experiment must be performed in a darkened room (preferably in total darkness). Prepare a table with two columns, the left-hand one headed 'Angle (degrees)' and the right-hand one 'Meter reading'. Fill in the left-hand column 0, 30, 60 . . . and so on up to 360°.

Place the torch in the position shown, with its lens at the centre of the circle and pointing along the 0° line; switch it on. Place the LDR facing the torch and adjust VR1 until you have full-scale deflection of the meter needle. Suppose the meter indicates 10 units at this point. Enter this into your table in the 0° row. Keeping the torch the same distance from the circle centre, and pointing at it, move the LDR round all 30° positions and record the meter readings. Switch off the torch and take the sheet of paper and your tabulated results into daylight!

Lay the large sheet of paper on a table with your results beside it; then, at each 30° interval, plot the point along the radius corresponding to the meter

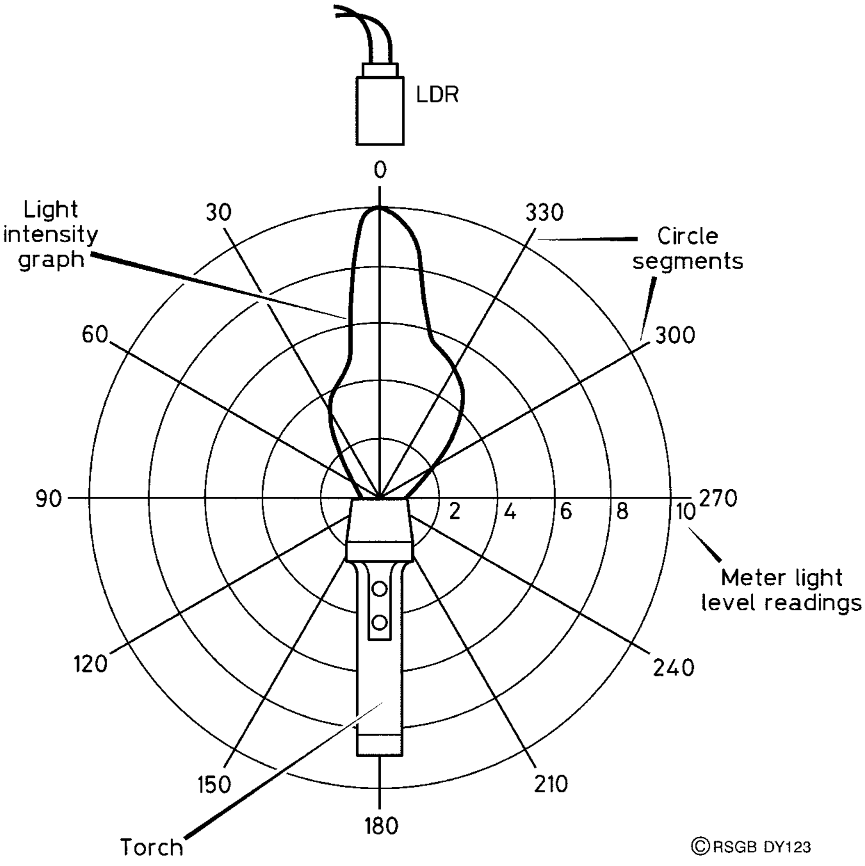

Figure 2 Torch light intensity pattern plotted at RSGB HQ

reading. Then, join up all the points and you have what is called a *polar diagram* of light intensity. The use of the word 'polar' implies that the readings have been taken in a circle and plotted that way.

Light waves and radio waves are both examples of *electromagnetic radiation*. The torch is designed to 'beam' its radiation in a particular direction, just like an aerial does. Hence the use of the word 'beam' for a directional aerial. If a similar polar diagram is drawn for a Yagi-type aerial, it will show the same general characteristics as does Figure 2, namely a main direction (or 'lobe') where most of the energy is concentrated, with evidence of *sidelobes*, indicated by 'lumps' on the otherwise smooth main lobe.

Also in this book you will find a project for the construction of a UHF field-strength meter, which you could use to carry out a measurement of the polar diagram of a UHF aerial.

45 A 70 cm Quad loop aerial

Introduction

This is a description of how to make an aerial for the 70 cm band which has gain compared with the 'rubber duck' or the dipole aerial. It can easily be dismantled and reassembled, making it ideal for contest use.

The principles

Most aerials which comprise several similar *elements* arranged along a *boom* are variations of the design originated by Yagi and Uda, and which takes the name (for historical reasons) of the former, and is know as the Yagi array. Let us suppose we have a Yagi aerial beaming left to right in front of us. The elements get progressively shorter from the left (look at almost any TV aerial to see this). All the elements on a Yagi aerial are classified as follows:

- The *reflector* – the leftmost element as we look at the array. It is the longest. Next to it is:
- The *driven element* – this is the element connected to the feeder, which in turn runs down to the transceiver. It is slightly shorter than the reflector.
- All the elements beyond the driven element are called *parasitic elements*, or *directors*. They are shorter than the driven element and usually get progressively shorter as we progress to the right along the boom. The directors are mainly responsible for the *directivity* (or *beamwidth*) of the array.

The progression from a simple dipole (a driven element in isolation) to a Yagi array is simple, but is nevertheless important. To make an aerial of two elements, a reflector (*not* a director) is added to the driven element. For three or more elements, directors are added to the two-element design. Adding more and more directors soon becomes impractical, the reduction in beamwidth (such as it is) does not warrant the extra expense, weight and wind resistance that is incurred.

Instead of using linear (straight) elements, as in the generic Yagi, this design uses loops. Designs using squares of wire instead of loops are known as *Quad* aerials, and HF designs require large X-shape frames to support the large squares of wire. At 70 cm, however, the use of wire loops is easier, and they are self-supporting.

Construction

This is quite simple. Any type of material (metal, plastic, wood) can be used for the *boom* (the support for the elements) and for the mast. The elements are made from 14 SWG enamelled copper wire. 16 SWG hard-drawn aerial wire, which is not enamelled, has also been used with success. Thinner wire might result in a rather ‘floppy’ aerial! The separate parts of the aerial are held together with *jubilee clips* (hose clips).

The driven element is secured to the boom with a jubilee clip and a three-connector plastic connector block as shown in detail in **Figure 1**, and in the photograph. Cut the wire for the driven element 70 mm longer than the 700 mm indicated in Figure 1. Then, using sandpaper, remove the enamel from one end to a distance of 20 mm, and from the other to a distance of 50 mm. After forming the loop of the driven element, bend both stripped ends through 90°, and insert them into the first to holes of the plastic connector block (Figure 1). Do not tighten the screws yet. Push both ends into the block as far as they will go, then bend the 50 mm end back on itself and pull the ends back through the connector block so that the end you have just bent goes into the third hole in the block. Now tighten the screws in the block and in the jubilee clip.

Each director and the reflector should be made 40 mm longer than the circumferences shown in Figure 1. Strip the enamel, as before, from the last 20 mm at each end. Form the wire into the loop, slip the ends under the jubilee clip (Figure 1) and tighten it. You may find that it helps to solder the stripped ends together before securing the jubilee clip.

The boom is fixed to the mast using jubilee clips and wire, as shown in Figure 1. Solder the feeder cable to the driven element, with the braid soldered to the end of the driven element which is connected to the boom (this applies to metal booms; with plastic or wooden designs, the feeder connections are not critical).

Figure 1 70 cm 4 element quad construction, with detail of how hose clamps are used in the construction

You will need a plug on the shack end of your feeder to suit the transceiver, aerial tuning unit (ATU) or the standing-wave meter (SWM) you are using. Always connect these in the order: transceiver – SWM – ATU – aerial.

Testing

Always test aerials outside and away from buildings (if possible!). This avoids getting misleading results.

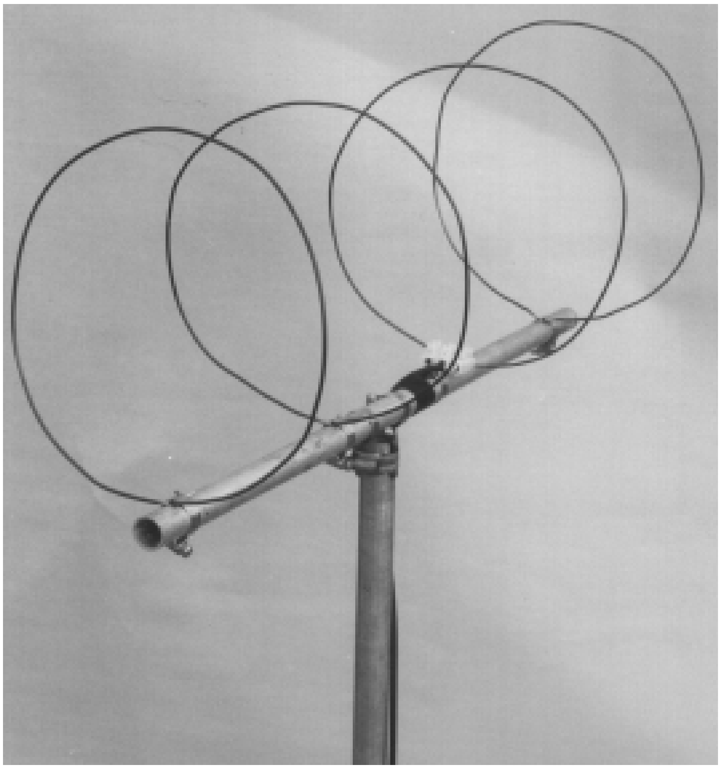
Use a rubber duck, or whatever aerial you usually use, and tune around to find a repeater or beacon signal which is consistent. Note the reading on the S-meter. Then, connect your new Quad loop. Rotate it to give the strongest S-meter reading (don't forget it is directional). Verify that the meter reading varies as you rotate it. How does the S-meter reading compare with the original reading? Much depends on the siting of your original aerial; if you are comparing your Quad loop at ground level with a vertical on the chimney, you wouldn't expect your new aerial, even with its gain, to outperform a vertical which is well elevated!

Now a test on transmit is called for. The use of an SWR meter is essential here. Find a clear frequency and check that it *really is clear* before announcing your presence and carrying out the test. A reading of 1:1 is excellent, but any value less than about 1.8:1 would be acceptable. You can measure the directivity of your aerial using the field strength meter, also described in this series.

Materials

4 metres of 14 SWG enamelled copper wire
Material for boom and mast
15 amp connector block
7 Jubilee clips

The enamelled copper wire is available from AA&A Ltd, Sycamore House, Northwood, Wem, Shropshire SY4 5NN. Everything else is available from most hardware stores.



46 A UHF field strength meter

Introduction

It is always interesting, and often useful, to know just *where* the radiation is going from your aerial. How much of your radiated energy is going in the general direction of the station you are in contact with, and how much is being effectively wasted? Some of these questions can be answered with the use of a *field strength meter.* A field strength meter is simply a receiver, stripped down to its bare essentials, such that it responds only to the magnitude of the carrier. The use of a field strength meter assumes that the aerial under test is radiating a continuous carrier. Don't forget to find a clear frequency and identify your transmissions at least every quarter-hour, in order to comply with the terms of your licence.

Description

Two types of field strength meter are shown in **Figure 1**. You will recognise both circuits (Figure 1b particularly) as being types of 'crystal set' with a meter replacing the headphones. Figure 1a is a broad-band HF design (there is no tuning provision) and Figure 1b is tuned in the same way as the crystal set; with a loop of wire as an aerial, it will perform well in the VHF/UHF range.

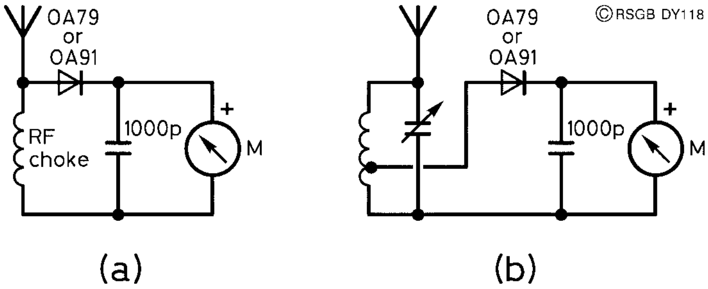


Figure 1 Construction of the UHF field strength meter

A tuned field strength meter also doubles as an *absorption wavemeter* if it is well calibrated. Such devices are useful for detecting transmitter harmonics also. This design is intended for use in the UHF band, so it will have to be sensitive around 432 MHz.

Construction

The field strength meter comprises a loop of wire, 600 mm long, which acts both as aerial and as the tuning inductance, a diode, a capacitor, a connector block, a meter and a length of twin wire. All the components, with the exception of the meter, are fixed to a pole with a jubilee clip, as shown in **Figure 2**. The meter should have a sensitivity of between 50 µA and 100 µA, or a multimeter can be used. The multimeter is more flexible, as you can select different current ranges, giving you a range of sensitivities.

Using the field strength meter

Connect your meter to the ends of the twin wire from the pole. Place a hand-held transceiver about 2 metres away, and press Transmit. If there is no meter reading switch off the transmitter and check the wiring. If the needle attempts to go negative, simply reverse the wires to the meter. If the reading is too high, either move the transmitter further away, or increase the current range on the multimeter. Try changing the orientation of the transmitter aerial, and note how the signal varies.

Figure 2 Assembly of the field strength meter

To measure the *polar diagram* (a graph of the signal strength against the angle between the aerial boom and the field strength meter, plotted on polar axes) of a beam aerial, mount the loop as far away from the aerial as you can, preferably at the same height, and rotate the aerial, say 15 degrees at a time, and record the signal strength, until the aerial has been turned through 360 degrees. If you need help plotting the graph, enlist the help of a friend who has done it before, or one who knows about polar graphs! If you have already built the Photometer project, you will have measured and plotted the polar diagram of the light intensity from a torch. Now you will see the great similarity!

Parts list

Capacitor	100 picofarads (pF)
Diode	Germanium, OA79 or OA91
Connector block	10 A, 3-way
Wire	600 mm of 16 SWG enamelled copper Length of twin cable for meter connection
Clip	Jubilee (hose) clip

47 Christmas tree LEDs

Introduction

A novelty ideal for the festive season, this circuit causes one LED at a time to light up around a small cardboard Christmas tree.

Warning

This circuit uses members of the integrated circuit family known as CMOS (complementary metal-oxide semiconductor). These use very little current and can be completed destroyed if they come into contact with the magnitudes of static electricity that most of us carry about when we walk on carpets and wear rubber shoes. You will never know if this wanton destruction has happened – all you will discover is that your circuit doesn't work and that you have tested *everything*. To avoid this problem do the following things:

1. **Before you open the little packet in which each IC is supplied, touch something which you *know* to be earthed – the metalwork of any equipment which is mains-earthed, for example. Then open the packet.**
2. **Let the IC fall gently on the bench – don't pick it out with your fingers. Touch your earthed metalwork again. Pick up the IC and insert it gently into its holder.**
3. **Repeat the process with the second IC.**

The circuit is safe from destruction while it is connected to the battery. However, when the battery is removed, the same care should be exercised with its handling, because there are no supply decoupling capacitors across each IC.

Description

Figure 1 shows the layout, and how the wires are connected from the circuit board to the LEDs around the tree. The circuit, shown in **Figure 2**, is quite complicated, so you need to be confident in your logical approach to circuit-building before you attempt this one! It uses two common integrated circuits (ICs). IC1 is simply an oscillator which provides timing pulses for IC2, which 'counts' up to a maximum of 10. The outputs of the counter are indicated by light-emitting diodes (LEDs); red, orange, yellow and green are common colours which you can use.

The circuit is built on a single piece of Veroboard measuring 29 holes by 12 strips. **Be aware that there is no strip labelled 'I', so don't make mistakes in your counting!**

First of all, cut the tracks in the positions shown in Figure 1 using a 3 mm ($\frac{1}{8}$ inch) twist drill rotated between thumb and forefinger. Then, solder in the IC sockets, the notches facing row M. Wire up and solder in the links and then the Veropins for the connections to the LEDs and battery. Having done this, the resistors and the capacitor should be fitted. When wiring the LEDs, each cathode (the lead adjacent to the 'flat' on the LED encapsulation) is connected to R4, and the anodes go to separate pins on IC2.

Testing

Hold up your circuit board to the light and check carefully for solder bridges between adjacent tracks. Then check again that the wiring is correct. Place the ICs in their holders, with the notched ends lining up with those on the holders. Connect the battery, and the LEDs should illuminate in sequence.

If you have no success, you are now wishing you had checked the circuit more carefully! Learn something from your mistake and it will not have

been in vain! The first thing to check is that the LEDs are the correct way round. If that is OK, then check the positions where the tracks are broken (intentionally!). After that, are the wire links in the right places – had you forgotten there is no row ‘I’? Check *all* the wiring, then check *again* for solder bridges, and switch on again. One of these tests should have revealed a fault. If it *still* refuses to work, perhaps one (or both) of your ICs were damaged by static electricity, despite your precautions – or did you choose to ignore them?

48 An audio signal injector

Introduction

An audio signal injector is a device used to test audio frequency circuits. It is simply an oscillator running at a frequency in the audio range, so that when its output is fed to the input of an amplifier, it will produce a sound in the loudspeaker if the amplifier is working. The oscillation is so rich in harmonics that the signal can also be heard (sounding rather different) when injected into an RF circuit.

The design

The circuit is shown in **Figure 1**, and is a basic *astable multivibrator*, a free-running oscillator producing a roughly rectangular-wave output. The two transistors, TR1 and TR2, operating as switches, switch on and off alternately at a frequency around 500 Hz. The prototype was constructed on plain matrix board (no copper strips), as illustrated in **Figure 2**.

Both transistors are type BC108, which are only a few pence each new, and can be found at almost any rally. You can add an on/off switch, or simply disconnect the battery when you are finished using it. To make the unit in one piece, the battery can be taped to the board, as the diagram shows.

The probe itself is made from a short piece of stiff insulated wire, soldered to a tag on the board; an earth lead is also soldered to the board, and terminated in a crocodile clip to attach to the ground lead of the equipment under test.

------ Wires under board

Figure 2 Component layout of the signal injector

Using it

After checking the wiring of the circuit, connect the battery. Find a transistor radio that is known to work. Carefully remove the case, switch on and apply the probe to the centre tag of the volume control. A *very* loud buzz should be heard from the speaker, indicating that the audio circuits of the radio are working. Using the injector to fault-find equipment you have made yourself is rather more instructive and rewarding, because you *know* where to inject the signal, and you should *know* what to expect when you do.

Warning

Do *not* work on any equipment connected to the AC mains. Work only on battery-powered circuits, for your own safety.

Parts list

Resistors: all 0.25 watt, 5% tolerance

R1, R4	10 kilohms (kΩ)
R2, R3	330 kilohms (kΩ)

Capacitors

C1, C2, C3	10 nanofarads (nF) or 0.01 microfarad (µF) ceramic

Semiconductors
TR1, TR2 BC108

49 Standing waves

Introduction

Everyone has, or *should* have, a standing-wave ratio (SWR) meter as part of his/her array of test gear. Most people know how to use it, but what does it really do?

Before attempting to answer that question, we need to look at some aerial fundamentals. An aerial is a *transducer*, the word meaning 'to lead across'. We use it whenever one form of energy is converted into another form. A bulb is a transducer; it converts electrical energy in the filament to radiated heat and light energy. **Figure 1** shows the situation.

An aerial, or antenna, is also a transducer; it converts radio-frequency (RF) energy in the feeder (or *transmission line*, to give it its proper name) into radiated electromagnetic energy, in the manner shown in **Figure 2**. The aerial has resistance, just like the bulb filament, and if the filament had zero resistance, there would be no radiated energy. In the same way, if the aerial had no resistance, there would be no radiation from it.

Transmission lines should convey RF energy from transmitter to aerial with the minimum power loss. A common form of transmission line is the *coaxial*

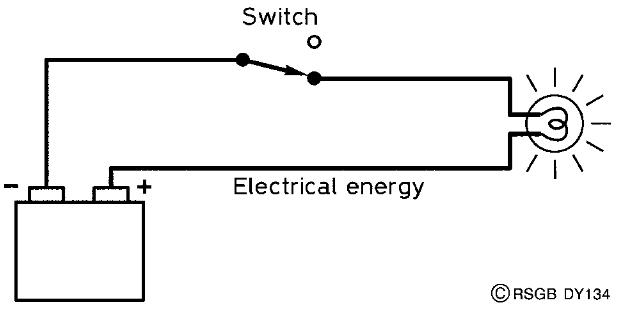

Figure 1 The light bulb converts electrical energy to electromagnetic light energy

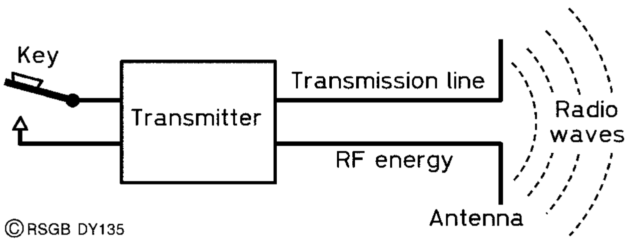

Figure 2 The antenna converts RF current to electromagnetic radio waves

cable. As you might expect, any feeder cable has a DC resistance caused by the resistance of the copper wire from which it is made. It also has an AC resistance, caused by the capacitance between the centre conductor and the braid, and by the inductance of the cable itself. This means that the feeder has an *impedance*, which is constant for the particular type of cable. This is what we call the *characteristic impedance* and, for the cables used in most amateur radio applications, it is 50 Ω.

If this impedance can be made the same as that of the aerial (it is already the same as the impedance of the transmitter output), then the transfer of energy will occur with minimum loss. If the aerial and cable impedances are *not* the same, then there is a *mismatch*, which causes some of the RF energy to be reflected back towards the transmitter. We now have a situation where RF energy is flowing along the cable from the transmitter to the aerial (the *forward* wave) and, at the same time, flowing from the aerial to the transmitter (the *reflected* wave). The two waves interact along the cable and form a stationary pattern of voltage and current. The pattern is known as a *standing wave*, and can be visualised from the waveforms in **Figure 3**. The ratio of the maximum voltage to the minimum voltage on a given wave defines the *voltage standing-wave ratio* (VSWR), or just *standing-wave ratio* (SWR) for short.

The SWR meter is easy to use. It is positioned in the feeder between the transmitter and the aerial tuning unit (ATU) if there is one, or between the transmitter at the aerial otherwise. Most meters have a single meter and a four-position switch. The transmitter is first keyed and, with the switch in

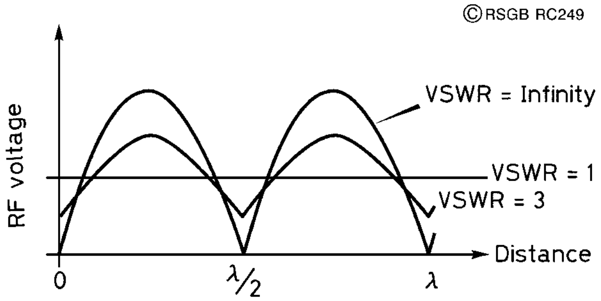

Figure 3 Standing waves on a transmission line

the 'calibrate' position, the sensitivity control is adjusted to give full-scale deflection on the meter. The switch is then changed to 'forward' to read the forward power, to 'reflected' to read the reflected power, and to 'SWR' to read the value of the standing-wave ratio. When there is no reflection (see Figure 3), the meter should read 1:1 or, simply, 1.

Most SWR meters remain in the feeder line while the transmitter is operating, so the condition of the aerial and feeder can be constantly monitored. Problems with the aerial (such as water entering the feeder at its junction with the driven element) are immediately shown up. Without the use of the SWR meter, the situation would slowly deteriorate over several months and you would be left wondering why so few stations were answering your calls!

50 A standing-wave indicator for HF

Introduction

The standing-wave ratio (SWR) meter shows how well the aerial system, including the feeder, is *matched* to the output of the transmitter. This design does not *measure* SWR, but it gives an indication of when the SWR is minimum for a given system of aerial and feeder. The design is usable on the HF bands from 1.8 to 28 MHz, and can be used at 50 MHz with reduced sensitivity.

How it works

There are two types of wave in any feeder: the *forward* wave, which travels from the transmitter to the aerial; the *reflected* wave, which travels back to the transmitter from the aerial. The presence of a reflected wave is evidence that some of your transmitted power is not being radiated, but is being returned to the transmitter to be lost as excess heat. When aerial and feeder are perfectly matched, there is *no* reflected wave, and all the power from the transmitter is radiated.

Referring to the circuit of **Figure 1**, a tiny fraction of the signal is removed by the transformer, T1, and by the capacitors, VC1 and C1. It is then detected by the germanium diodes, D1 and D2, and any residual RF removed by the capacitors, C2 and C3. The currents through the diode and meter (depending on the position of switch, S1) represent the forward and reflected signals. VR1 acts as a sensitivity control for the meter.

It pays to shop around for a suitable meter. Surplus types from tape recorders and hi-fi equipment are usually ideal for this purpose. A new one would cost several pounds. The more sensitive the meter, the more sensitive your indicator will be. Meter sensitivity is given by the current required to give full-scale deflection (FSD) of the pointer. One with an FSD of between 50 and 200 micro-amps (μA) is suitable for this circuit. The higher the FSD, the less sensitive the circuit.

Construction

The meter circuit and the sampling transformer (see **Figure 2**) are built and mounted on Veroboard of the copper-strip variety. It simplifies construction

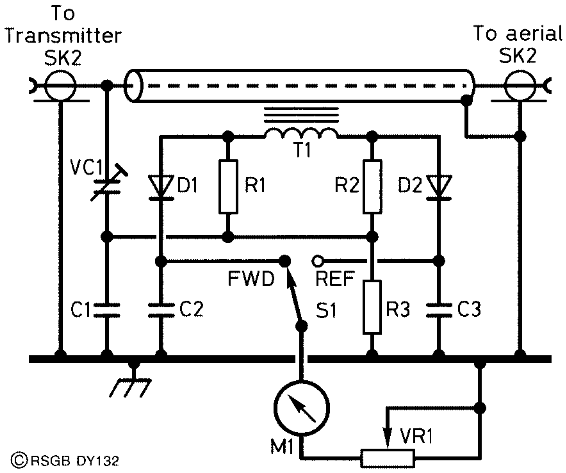

Figure 1 Circuit diagram of the SWR meter

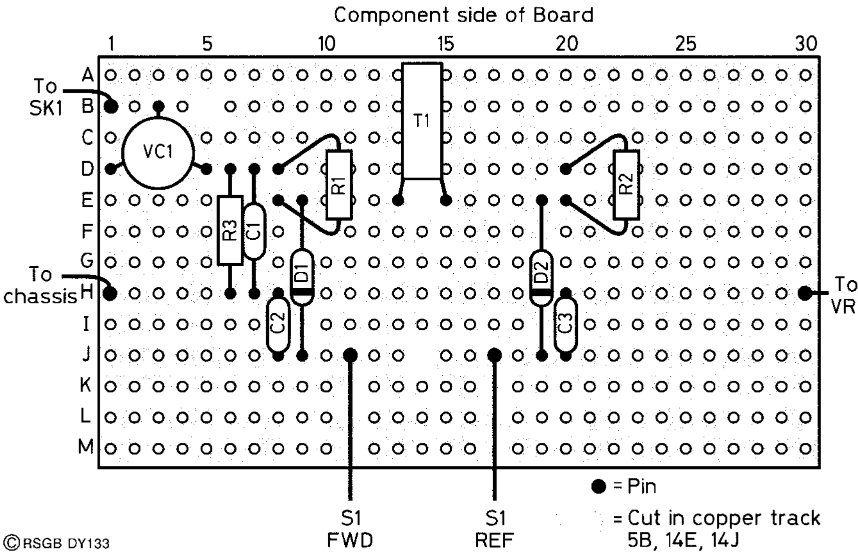

Figure 2 Component layout of the SWR meter

but reduces the operational range of the meter to below 30 MHz because of the capacitive coupling between strips. The board has 13 strips by 30 holes, although you can reduce this if you have a smaller case.

Firstly, cut the tracks at the three points shown. Then insert and solder Veropins for connections to the external components, the switch, variable resistor and the meter. Solder in the components starting with the resistors and followed by the capacitors and the diodes, ensuring that the diodes are inserted correctly.

Now you have to wind the transformer, T1, on a small toroidal ferrite core. Wind the secondary with 15 turns of 36 SWG enamelled copper wire, spaced evenly over about two-thirds of the former. The turns should not overlap, and considerable care must be taken; the wire is very thin, will kink easily and will break if you apply too much tension. The 'primary' is an 8 cm length of 50 Ω coaxial cable which passes through the toroid on its way between the input and output connectors. The braid of the cable is connected to the case at only *one* of the connectors (see Figure 1); this prevents the screen and the metal case between the two sockets forming a single, shorted turn.

The ends of the secondary winding must be carefully stripped of their enamel with sandpaper, before attaching the toroid to the board with cotton or nylon fishing line. On no account must wire be used for this!

Solder the secondary connections of T1 to the board and thread through the coaxial cable ready for soldering to the connectors.

The case used was an aluminium box (Maplin LF02C), but any suitable metal box could be used. Aluminium is preferable, as it is easily drilled with simple tools. Use standoff insulators to mount the board in the case. Once this has been done, the leads from the board to the chassis-mounted components can be soldered. So can the coaxial cable passing through the toroid. Make the lead from the input socket to VC1 as short as possible.

Setting up

You will need a 50 Ω dummy load and a transmitter to set up your indicator. Connect the transmitter to SK1 and the dummy load to SK2. Set the toggle switch, S1, to *forward* and the sensitivity control, VR1, to mid-travel. Switch on the transmitter, and set VR1 for maximum meter deflection. Switch to *reflected* and adjust VC1 until the reading is minimum (ideally zero). This completes the setting up!

Using the indicator

For setting up an aerial, connect your circuit between the transmitter and the cable leading to the aerial. With S1 in the *forward* position, key the transmitter and adjust VR1 for maximum reading on the meter. Switch to *reflected*, and then adjust your ATU to give minimum reflected power. If your adjustments are to be made to the aerial itself, to give minimum reflected power, you must make a note of the reflected reading, switch off the transmitter, make a change to the aerial, key the transmitter, and note whether the reflected power is greater or less than before. Then, make more changes to the aerial. **Never adjust your aerial with the transmitter on**. Make your adjustments on an unused frequency, and do it as quickly as possible, thus avoiding (or minimising) interference to other stations.

Parts list

Resistors: all 0.25 watt, carbon 5% tolerance
(or Maplin 0.6 watt metal film)

R1, R2	27 ohms (Ω)
R3	2.2 kilohms (kΩ)
VR1	10 kilohms (kΩ) linear

Capacitors

C1	220 picofarad (pF) disc ceramic 50 VDC
C2, C3	0.1 microfarad (μF) disc ceramic 50 VDC
VC1	20 picofarad (pF) trimmer

S1	Single-pole changeover (SPDT or SPCO)
SK1, SK2	Coaxial sockets to suit station standards
	Veroboard – 13 strips by 30 holes
	Veropins (7 off)
	Amidon FT 50–43 ferrite toroid
	Meter, less than 200 μA FSD
	36 SWG enamelled copper wire
	Short length of UR43 or RG58 coaxial cable
	Insulated stranded wire
	Aluminium box
	Standoff insulators for mounting the board
	Knob for the sensitivity control

51 A moisture meter

Introduction

Dry rot (*Merulius Lacrymans*) can strike havoc in buildings, causing the timbers to decay and crumble to dust – hence the term *dry rot*. Wood is attacked only if its moisture content rises above 20%.

Construction

The circuit of the moisture meter is shown in **Figure 1**. The two probes touch the wood, and the current that flows between them depends on the moisture content of the wood. If the moisture is sufficiently high, the current, after amplification, will be enough to light the LED.

The meter can be made on a piece of plain matrix board (no copper strips), as **Figure 2** shows. The board is big enough (10 cm by 2.5 cm) to accommodate the PP3 battery, taped on. No case is needed, unless you want

Figure 2 Moisture meter, component layout

to leave the meter in a damp location for a protracted period! Make sure that the transistors and LED are mounted correctly. In Figure 2, the connections as shown to TR1 and TR2 are illustrated as if the transistors were transparent. An on/off switch is not really necessary, as only a very small current flows when the probes do not touch anything. Use solder tags, screwed to the board, to act as probes.

After the assembly is completed, check your circuit one final time, and then connect the battery. Nothing should happen at first. If you lick your forefinger and hold it across the probes, the LED should light.

Using it

The prototype was compared with a commercial moisture meter, and the LED lit when the moisture was around 20%. This was quite fortuitous, as the point at which the LED lights depends both on the separation of the probes and on the gain of the two transistors.

In addition to searching for dry rot, the instrument may be used to monitor the moisture in the soil of household plants. In this case, probes made of 16 SWG copper (*not* enamelled) should be soldered on to the two tags, and should penetrate the soil to a depth of several centimetres, and R1 may require adjusting so that the LED extinguishes if the soil is too dry, and lights if the soil is sufficiently moist. If you wanted to leave the meter with the probes in the soil, an on/off switch *would* be necessary.

52 Simple aerials

Introduction

The performance of *any* receiver or transceiver, no matter how expensive it is, is limited by the aerial that feeds it. Two of the most frequently asked questions are:

- Which is the best sort of aerial to use?
- Where is the best place to locate an amateur radio aerial?

To answer these questions, you must ask yourself what sort of operation you want to do. Are you interested in local, chatty contacts on the lower bands or VHF, or are you more disposed towards long-distance (DX) contacts, and on what band?

A house with a moderately sized garden is assumed in the diagrams here, to illustrate the configurations of some simple aerials. You would not need all these aerials festooned around your house, because one or two would be sufficient for your needs. The problems incurred by properties with more restricted space will be covered later.

VHF aerials

For VHF operation, the aerial should be mounted as high as possible, either on a mast or on a chimney. For all-round coverage on FM and the local repeaters, a vertical colinear is a good choice. For SSB and CW DX operation, a horizontal rotatable beam is needed. If satellite working is envisaged, you will need to contemplate mounting an elevator on top of your rotator, so that your beam can point in *any* direction, including vertically upwards! An advantage of satellite working is that the aerials do not *necessarily* have to be up in the air, provided you have a relatively uncluttered site. Your rotator and elevator can be at ground level, which is good!

If the VHF aerial is mounted on the chimney, use a double mounting bracket, particularly if you have a beam and rotator. Keep the TV, broadcast FM and amateur aerials as far apart as possible, and keeping the feeders separated is also a good plan.

The dipole aerial

One of the simplest types of aerial for single-band operation is the half-wave dipole. (The name ‘dipole’ simply means ‘two poles’ or ‘two elements’, and

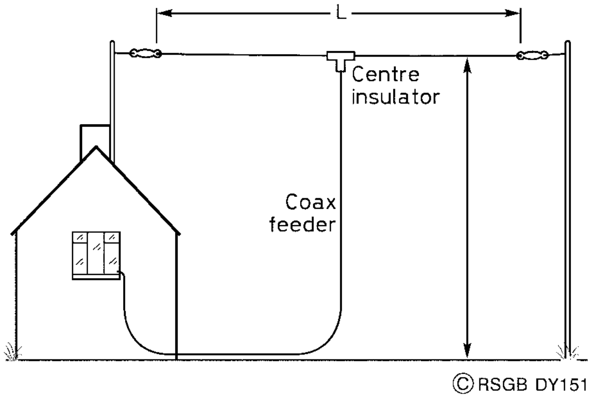

Figure 1 Layout for a dipole aerial

in this case the total length of the dipole is approximately half a wavelength at the operating frequency.) It is usually fed in the centre by coaxial cable as shown in **Figure 1**. The length of the dipole for the lowest frequency in each band is shown in **Table 1**. Normally, the length of the aerial will be 'trimmed' to be tuned to the centre frequency of the part of the band in which you will operate. This is done using the data in the right-hand column of Table 1. As an example, suppose you wanted your aerial to be resonant at 3.7 MHz. The table gives an overall dipole length of 42.86 m for 3.5 MHz. To resonate the aerial 200 kHz *higher*, then this length must be shortened by 2 × 0.595 m = 1.190 m. Your dipole would thus be 41.67 m long. Remember to allow extra wire for fixing the dipole ends to the insulators.

Table 1 Dipole lengths for lowest frequency of each band and the length to be trimmed from each to raise the resonant frequency by 100 kHz

Band (MHz)	*Dipole length (m)*	*Trim each end (mm/10 kHz)*
1.8	83.33	2190
3.5	42.86	595
7	21.43	150
10	14.85	70
14	10.71	35
18	8.33	20
21	7.14	15
24	6.03	12
28	5.36	10
50	3.00	6

On the lower-frequency bands, the lengths become rather large. In this case, you can 'bend' your dipole, as illustrated in **Figure 2**. The length of wire required to give an acceptable value of SWR (less than 2:1 on transmit) may need to be different from the calculated value, so be prepared to experiment!

Dipoles are single-band aerials, although they will often work acceptably on the third harmonic of their design frequency: a 7 MHz dipole often operates reasonably well on 21 MHz. It is possible to operate several dipoles in parallel, as **Figure 3** shows. Interaction between the elements can occur if the spacing between them is less than about 10 cm. A multi-band dipole, as shown in Figure 3, has the elements separated with plastic spacers, and drooping ends to produce maximum spacing between the elements' ends.

The long-wire aerial

This aerial is simple, cheap, easy to erect, and suits most houses and gardens, as **Figure 4** shows. Using an aerial tuning unit (ATU), an end-fed long wire can function on several bands when used with a set of radials or a counterpoise. **Figure 5** illustrates the setup. The length of the aerial will determine the bands which will be covered.

¼-wave counterpoise wires for each band

Figure 5 How to connect a radio to a long-wire aerial

A wire length of 10.5 m will work on the 40, 30, 17, 15 and 12 m bands.

A wire length of 15.5 m will work (with an ATU) on the 80, 40, 20 and 12 m bands and possibly (depending on your ATU) on the 17 and 15 m bands.

A wire length of 26.5 m will operate on all bands, but may be difficult to load on 10 m.

The wire lengths given here may need some adjustment because of the geometry of your particular house and garden. For receive-only purposes, the lengths are far less critical.

In general, you cannot get a good radio-frequency (RF) earth from a first-floor (or higher) shack. Unless a good RF earth exists within a small fraction of a wavelength of the transceiver, an *artificial ground* comprising a single $\frac{\lambda}{4}$ radial or counterpoise will be needed. You will need one counterpoise for each band you intend to use, and the wire can be concealed around the skirting-board of the shack, or under the carpet. Make sure that the free end

Table 2 Lengths of elements for vertical antennas, radials for verticals and counter-poises for end-fed long wire antennas

Band (MHz)	*Element length (m)*
1.8	39.66
3.5	20.40
7	10.20
10	7.14
14	5.1
18	3.96
21	3.4
24	2.95
28	2.55

of each counterpoise is well insulated; this point can carry a *very high voltage* when you transmit; anyone coming into contact with this can suffer very severe RF burns. Counterpoise lengths can be read from **Table 2**.

The vertical aerial

The single-band vertical aerial is sometimes used by DX operators because it has a low angle of radiation, which favours long-distance propagation. However, it must be sited clear of obstructions and must have a *good* counterpoise or radial system. Illustrations of the vertical aerial are shown, and the lengths of the vertical and radial sections are given in Table 2. The centre of the coaxial feeder is connected to the vertical section, and the braid to the counterpoise or radial system, which is made up of four or more wires buried just below the surface and joined together near the base of the aerial.

Cable entry to the house

Bringing coaxial cable into the house by an open window must be regarded as a temporary measure. Wooden window frames can be drilled, one hole for each feeder. Make the holes slope downwards from inside to out to prevent rain entering, and treat these with wood preservative. Leads from long-wire and inverted-L aerials should be kept separate from other cables.

Alternatively, a plastic pipe large enough to take all your feeders could be fitted into the brickwork (again, sloping downwards towards the outside). You may want to let a friendly builder do this for you.

53 A breadboard 80 m CW transmitter

Introduction

In the early days of radio, many circuits were built on a wooden baseboard, the parts being screwed down on the board. This was called breadboard construction, because it was a breadboard that was frequently commandeered for the process! Wives have always been generous in this respect, it appears!

This circuit was originally designed by GM3OXX, and became known as the *Oner*, because it was built on a circuit board one inch square! The circuit appeared in the G QRP Club journal *Sprat* and, since that time, many hundreds of *Oner* circuits have been built and used on the air. It is a well-proven circuit.

The transmitter has no tuned circuits in the power amplifier (PA) and thus has a rather high *harmonic* content. It **must** be used with the ***low-pass filter*** described elsewhere in this book. Without the low-pass filter, interference will be caused to other stations.

Simple aerial changeover switching is provided, which allows this circuit to be used with any of the 80 m receivers, such as the *Colt*, described in this book. It can also be used with any kit or commercial receiver for the 80 metre band.

The circuit

The transmitter circuit is shown in **Figure 1**. TR1 is a crystal oscillator, the frequency of which is controlled by crystal X1. A small trimmer capacitor, TC1, is added to allow the frequency of X1 to be varied by a small amount. If adjustment of this trimmer is made possible from the front panel, it is useful to adjust the transmit frequency to avoid other stations already on the crystal frequency. The collector load resistor, R2, of the oscillator transistor, TR1, determines the power output; a value of 3.3 kΩ seems to work well in producing an output of 3 watts.

TR1 is directly coupled to TR3, a VMOS transistor (a type of field-effect transistor (FET)). This acts as the power amplifier (PA) stage. TR3 should

give about 3 W output, which is then coupled to the output by C3. The radio-frequency choke (RFC) providing the drain load of TR3 is simply a few turns of wire on a ferrite bead.

TR2 is an interesting addition to the circuit. It is used as a switch to ‘key’ the PA, TR3. The transmitter *could* be built without TR2, just placing the Morse key between the top of the RFC and the 12 volt supply. Adding TR2 is helpful, because it means that one side of the Morse key can be grounded (always a good thing), and some degree of *shaping* of the output RF waveform is provided by R3 and C1. This makes the transmission sound a little better and reduces the possibility of spurious frequencies being generated and transmitted. TR2 is a pnp transistor; note that it is the *emitter* of this transistor which is connected to the positive side of the supply.

Some form of changeover switching is needed for the aerial. A double-pole changeover toggle switch can be used. See the chapter on switches, later on in this book. One pole is used to switch the aerial between transmitter and receiver; the other pole is connected in the 12 volt supply line, and is labelled RECEIVE/TRANSMIT – NETTING. Its use will be described later. In this simple circuit, the PA cannot work when the key is open, because the key breaks its supply (via the RFC). When the key closes, TR2 switches on and applies the 12 volt supply to the top of the RFC. C2 is a *decoupling* capacitor, which prevents any residual RF signals at the top of the RFC reaching TR2.

Building

The prototype was put together as follows. Take a piece of plain printed-circuit board (PCB) measuring 5 cm by 4 cm. Then, with a *new*, *sharp blade* in a junior hacksaw, draw the blade horizontally across the surface of the copper in order to make a pattern of 6 squares along the 5 cm side and 5 squares along the 4 cm side. No more pressure should be applied than is necessary to cut through the copper! All the parts will be soldered on these pads in a form of surface-mount construction. To do this, each active pad (i.e. one that is going to have a component soldered to it) needs to be *tinned*. This means coating the pad's surface with solder, and is carried out as follows. Place the hot tip of the soldering iron on to the pad, and hold it there for a second or so. Then, with the tip still in place, touch the end of your reel of solder *on the pad*, not the tip of the iron. The solder should flow evenly all over the pad, and you can remove the iron. The solder should solidify in a rounded, shiny blob! This provides a good surface for making soldered joints.

To join component leads to the pads, cut each lead about 1 cm long, and then bend the last 2 mm at right angles to the rest of the lead. As you did before, tin the 2 mm length of each lead. Place the tinned portion on to the pad, and place the tip of your iron *on the pad*, close to the lead. The solder on the pad and on the lead will melt and run together; remove the iron and *hold the component still* until the solder solidifies. When the joint has cooled, give the lead a gentle tug to make sure you have a good joint (a good *mechanical* joint is usually a good *electrical* joint, too!). Each transistor straddles three pads, so the centre lead will need to be shorter than the other two. Take care here to get the lead lengths right – if you do, you will be surprised how much more firmly the transistor is held than if you just botched the lead lengths by bending them to fit! Make sure the connections to the transistors are correct.

Winding the RFC is quite simple. Seven (or more) turns of thin (32 SWG) enamelled copper wire are threaded through a small ferrite bead. This requires care, because the bead is small and the wire is thin. Trim the ends to within about 1 cm of the bead, remove the enamel carefully with sandpaper and tin the bare ends, prior to soldering the choke to the board.

After completion of the wiring, check the circuit against Figure 1. Bread-boarding a circuit like this has its advantages, but it can have disadvantages, too. One of these disadvantages is that it can make circuit checking difficult. For a simple circuit like this, it is not too bad! Check that no solder has run between the pads. Plug in your crystal for the 80 m band, and connect up the 12 V power supply. Do not connect the Morse key yet and do not switch on the power.

Testing and operating

Clear your workbench of all metallic objects, slivers of copper, bits of wire, etc., switch on your power supply. With an external receiver, listen on and around your crystal's frequency for a signal. Remember that the oscillator runs all the time and, because you haven't yet connected the Morse key, your receiver is close enough to pick up the signal from the oscillator. This confirms that your oscillator is running. Switch off.

Connect the station aerial to the transmitter's aerial socket, and the receiver to the transmitter's receiver socket. Connect the Morse key, put the Receive/Transmit–Netting switch in the receive position and switch on. You should be able to hear stations in the normal way. Now put the switch in the Transmit–Netting position. Signals in the receiver should almost disappear, as the circuit has disconnected the receiver's aerial.

Tune the receiver until you can hear your own crystal oscillator signal. This is known as *netting*, tuning your receiver and transmitter to the same frequency. Pressing the key will now transmit your signals when the switch is in the Transmit–Netting position; switch back to the receive position to listen for stations answering your call. As soon as you are happy that your circuit is functioning properly, **you must build the low-pass filter circuit** before using the transmitter regularly.

54 A 7-element low-pass filter for transmitters

Introduction

The simpler the transmitter, the more likely it is to radiate *harmonics* of its fundamental frequency. Harmonics are integral multiples of the frequency on which the transmitter is *designed* to operate. If you think you are transmitting on a frequency, *f*, for instance, you will also be radiating the harmonics of *2f*, *3f*, *4f*, . . . and so on. This results in your signals being heard on *several frequencies*, spread over a very wide frequency range. You are also contravening the terms of your licence. To avoid this, it is always advisable to use a *low-pass* filter between your transmitter and aerial. This is a filter which will *pass* your signal frequency, *f*, and all frequencies *below* it, but will *not pass* (attenuate) frequencies above *f* to any significant extent. The value of *f* is known as the *cutoff frequency* of the filter.

A design of 7-element low-pass filter

A 7-element low-pass filter (LPF) is so called because it has seven components, as the circuit diagram of **Figure 1** shows. Filters containing any odd number of elements are possible: a 3-element filter would

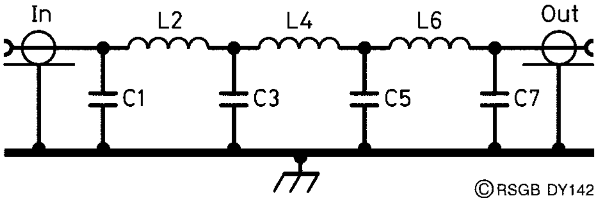

Figure 1 Circuit diagram of filter

comprise C1, L2 and C3 only, and is sometimes called a pi-network because the element disposition resembles the Greek letter pi (π); a 5-element filter would comprise C1, L2, C3, L4 and C5 only, and so on. In general, the more elements the filter has, the more effectively it attenuates signals above *f*.

The circuit of Figure 1 is designed to have an input and an output impedance of 50 Ω, which means that it can be placed in the aerial feed of any common transmitter. Filter design is a very complex business, and is best left to the experts. One such expert is W3NQN, who produced a number of computer designs of LPF using commonly available (*preferred value*) capacitors, and aimed specifically for use on amateur frequencies. The results of this work are condensed into **Table 1**. The inductors are wound on standard toroidal cores, and their details are included in the table.

Table 1 Filter component values for each brand

40	270	680	19	21	T37-2	26
30	270	560	19	20	T37-6	26
20	180	390	16	17	T37-6	24
15	82	220	12	14	T37-6	24
10	56	150	10	11	T37-6	22

Making the filter

The filter was made originally as an adjunct to the *Breadboard 80 m CW transmitter*, which you will also find in this book. It uses the same constructional technique, based on a single piece of plain, copper-clad

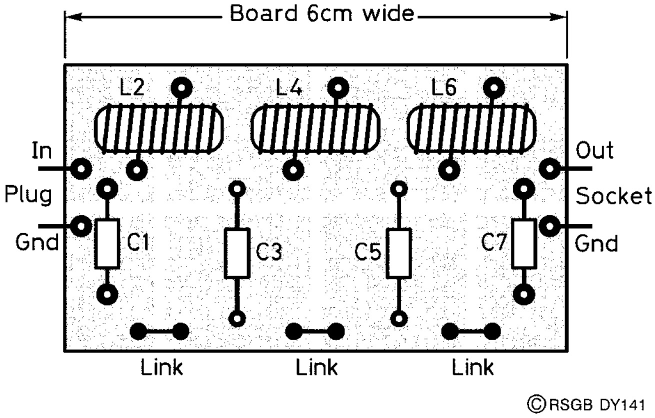

Figure 2 Layout and construction of filter

PCB, with 'pads' created by using a sharp blade in a junior hacksaw. The cuts in the copper are shown in the layout diagram of **Figure 2**. There are two ways of mounting the components: the first way is to drill small holes in each pad, as shown in Figure 2, and mount the components through the holes in the normal PCB manner; the second way is to solder the components directly to the pads, in the way that was described for the *Breadboard transmitter.*

Winding the inductors is quite simple. All you need to remember is that each time the wire passes through the core counts as one turn. Cut off the spare wire at each end of each coil to about 1 cm, scrape off the enamel with sandpaper, and tin the exposed copper. See the transmitter description if you are unsure of how to do this. Note the wire links between each of the lower pads, forming a solid 'ground' for the elements. The prototype had a plug and socket on the ends, to match the transmitter and aerial terminations.

The type of capacitor used in the design is not critical; the polystyrene type works well.

55 Radio-frequency mixing explained

Introduction

Mixers find widespread use in electronic circuitry. Many of the projects in this book, together with every TV set and radio in the home, contain mixer circuits – a good indication of their usefulness.

Confused?

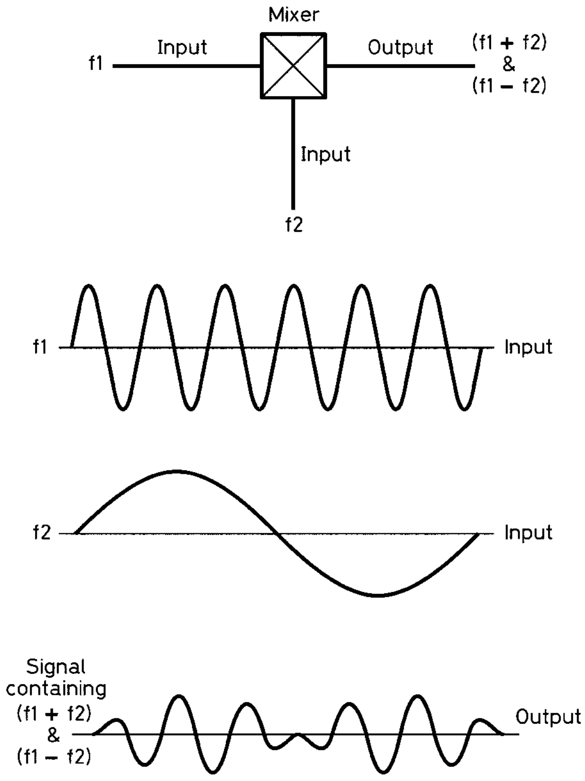
Audio mixers (as used in recording studios and radio broadcast stations) are used to **add** or ‘balance’ the signals from various sources such as microphones, CD players, etc. These have nothing whatsoever to do with radio-frequency (RF) mixers, and should never be confused with them.

RF mixers and beat frequencies

Instead of **adding** signals (as in the audio mixer), the RF mixer **multiples them together.** As you might expect, this has an entirely different effect. The two signals entering the mixer *beat* or *heterodyne* with each other to produce *signals on other frequencies*. One example of this occurs in sound, when two musical notes of almost the same frequency are heard together. Instead of hearing two separate notes, the listener hears one note whose *intensity* (*loudness*) appears to increase and decrease. This intensity variation is called a *beat*, and its frequency is equal to the difference in the frequencies of the two original notes. The technique is used by musicians to tune their instruments. If one note is known to be a correct frequency, the other can be tuned to it by making the beat frequency as close to zero as is possible.

Multiplying together

The process of mixing presupposes that we have a device which will automatically multiply two signals together. Fortunately, this is easy; so easy, in fact, that it often occurs when we do not want it! Multiplying is achieved by any device which is *non-linear*; this means a device whose output is not a constant factor larger than its input, something that can be achieved by many electronic devices and circuits.



©RSGB DY145

Figure 1 The effect of multiplying (or mixing) two signals together

Let us look now at what a mixer does in concrete terms. Suppose two signals, of frequencies *f*1 and *f*2 go into our mixer. These signals are shown in **Figure 1**. Putting numbers in, to make the situation clearer, suppose *f*1 is 1.000 MHz and *f*2 is 160 kHz. The beat frequency is the *difference* of these: 1.000 MHz – 0.160 MHz = 0.840 MHz, or 840 kHz. A mixer *also* produces an output at the *sum* of these frequencies; in this case the new frequency would be 1.000 MHz + 0.160 MHz = 1.160 MHz.

Suppose you fed the output of your mixer, operating with these input frequencies, into a receiver and tuned around to find what frequencies were present. You would find two signals, one at 840 kHz and one at 1.160 MHz, showing that the two 'new' frequencies were very real!

In addition to drawing out the waveform of the resultant signal, as in Figure 1, we can draw the inputs and outputs on a frequency axis, to form a *spectrum* of the signal components. This is done in **Figure 2**. The top two diagrams show the input signals at *f*1 and *f*2. The bottom diagram shows the output signals in relation to the input signals. Depending on the type of mixer used, one or both of the input signals would be removed.

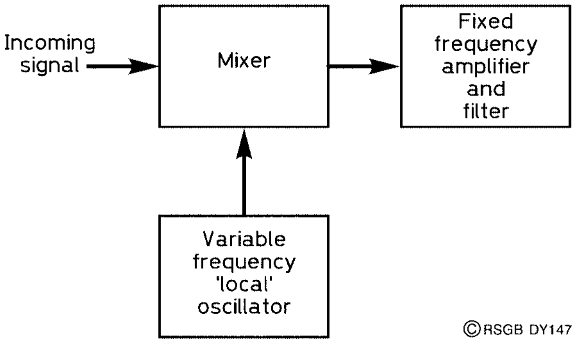
Figure 2 The result of multiplying or mixing two signals together as seen on a spectrum analyser

A mixer in every radio

Basically, a mixer is used to change a signal from one frequency to another, something it does without altering the characteristics of the incoming signal. If the incoming signal is amplitude modulated (AM), then the frequency-changed signal would be AM also. The same applies to FM, SSB, CW, and all other modulation forms you can think of. This explains why mixers are often called *frequency changers*.

Frequency changing is the key process in the type of radio known as a *superheterodyne* (or *superhet*). By mixing the incoming signal with a variable-frequency *local oscillator* as **Figure 3**, shows, the signal can be converted to the fixed frequency of a filter and amplifier. This is useful



Incoming signal
Mixer
Fixed frequency amplifier and filter
Variable frequency 'local' oscillator
©RSGB DY147

Figure 3 The basic idea of a superhet receiver

because it is easier to make a very high-quality filter and amplifier at a single fixed frequency, than at a variable frequency.

All TV receivers and virtually all radio receivers (and transmitters) use mixers. Both the *Yearling* and *Colt* receivers (see the relevant projects) are superhets, and use mixers.

56 A voltage monitor for a 12 V power supply

Introduction

If for any reason, the stabilisation of your main 12 volt power supply unit (PSU) breaks down, it is possible that a voltage much higher then the nominal 13.8 V will be applied to your precious equipment. If you would like to know the instant that this occurred, and hence be able to switch things off before it was too late, then this circuit is what you need. It will give audible *and* visual indications if the voltage rises above 14.4 V, and a visual indication only if the voltage is reduced.

The circuit

The circuit uses three ICs and is shown in **Figure 1**. The circuit is powered by the PSU whose output is being monitored, and the circuit's immunity to supply line variations is secured by the 6 volt regulator, IC1. The heart of the circuit is IC2, an LM3914; it is a *bargraph driver*, which operates ten LEDs in a display resembling a thermometer – the string of lit LEDs increases in length as the voltage on pin 5 increases.

The input voltage range on pin 5 is 1.2 V maximum, making each LED correspond to one-tenth of this, which is 0.12 V, the *step size*. R1 and R2 act as a voltage divider, so that voltages of up to the maximum of 14.4 V may be applied to R1 without exceeding 1.2 V at pin 5. R3 sets the brightness of the LEDs and R4 determines the step size.

IC3 is an *opto-isolator*, a device containing an LED and a phototransistor in one package. This enables the piezoelectric sounder to operate without affecting the operation of the bargraph driver. The input to IC3 is provided by the voltage on D8, so that if any of the LEDs at or above D8 are lit, the

sounder will operate, indicating overvoltage. Despite the fact that some of your other equipment might be damaged by this overvoltage, the monitor circuit itself is unaffected.

Construction

The prototype was built on two pieces of Veroboard of the copper-strip variety. The main (circuit) board measured 15 strips by 25 holes, and the display (LED) board measured 4 strips by 30 holes. Track cuts are necessary in each board. The correct places are shown for the main board in **Figure 2**, but there is sufficient flexibility in the layout of the display board for a prescriptive layout not to be needed. All the anodes of the LEDs are connected to the same strip, which makes things comparatively simple!

For the main board, insert the Veropins and the wire links first, and solder them to the copper strips. Then fit the IC holders and the resistors. Fit the IC holders with their notches towards the top of the board. When fitting the voltage regulator, IC1, note than the centre lead (the 'common' lead in Figure 1) does *not* go to position A3; the track should be cut at A3, and the common lead soldered at B3. This is indicated in Figure 2.

Wire up the LED board with its ten LEDs and 11 connecting wires, each about 10 cm long. This length depends on how far away from the main

Figure 2 PSU monitor, PCB layout

board you are planning to mount the display. The LEDs should have different colours: three orange, four green and three red, to indicate 'low', 'medium' and 'high' voltage.

Now solder the other ends of these leads to the Veropins on the main board, making sure that the order is correct. Finally, connect the piezoelectric sounder to the main board; the polarity is important, so make sure the red lead goes to pin 4 of IC3 and the black lead to the ground rail. If you were careful to fit the IC holders with their notches in the correct positions, match these up with the notches on the ICs before pushing home the ICs *gently*. Check your circuit for solder bridges and unwanted pieces of copper swarf before screwing the small heat sink to the voltage regulator, IC1.

Testing

(a) **With a variable-voltage PSU**. Set the PSU for 10 V, connect the circuit and switch on. Increase the voltage slowly, and check that each LED lights up after the one before it. As the voltage exceeds about 14.4 V, the first red LED should light and the sounder should operate. If an LED does not illuminate, you should immediately suspect either a dry joint or an incorrect LED polarity. The voltage at which the first red LED lights can be adjusted by varying R1; increase R1 if the LED comes on too early; decrease R1 if the LED comes on too late.

(b) **Without a variable-voltage PSU**. For your ‘variable supply’, you can use several AA-type 1.5 V cells (or 1.2 V NiCad cells) in series. The voltages produced by a range of cells is shown in **Table 1** – because of the lower voltage of NiCad cells, more of them are needed to produce a given voltage.

Once the operation of the circuit has been checked, it can be fitted into a plastic or metal box. Only two connections are needed for the PSU. You may want to drill some holes in the case to increase the apparent loudness of the sounder.

57 A 1750 Hz toneburst for repeater access

Introduction

Repeaters across the UK and much of Europe need an access tone to switch the transmitter from standby ready for use. Commonly, this is a 1750 Hz tone of duration no greater than half a second. Although many UK repeaters may now be accessed using the *continuous tone-coded squelch system* (CTCSS – see the *RSGB Yearbook*), you may wish to access a repeater whose CTCSS frequency you don't know; in this case, using the universal 1750 Hz tone will gain you access. Commercial transceivers are usually fitted with an automatic toneburst, but if you are using a home-made design, then you may want to incorporate this little circuit.

Warning

This circuit uses a member of the integrated circuit family known as CMOS (complementary metal-oxide semiconductor). These use very little current

and can be completed destroyed if they come into contact with the magnitudes of static electricity that most of us carry about when we walk on carpets and wear rubber shoes. You will never know if this wanton destruction has happened – all you will discover is that your circuit doesn't work and that you have tested *everything*. To avoid this problem do the following things:

1. **Before you open the little packet in which the IC is supplied, touch something which you *know* to be earthed – the metalwork of any equipment which is mains earthed, for example. Then open the packet.**
2. **Let the IC fall gently on the bench – don't pick it out with your fingers. Touch your earthed metalwork again. Pick up the IC and insert it gently into its holder.**

The circuit is safe from destruction while it is connected to the battery.

Circuit description

The circuit is shown in **Figure 1**. The tone is generated by an integrated circuit oscillator (IC1), whose frequency is controlled by a *ceramic resonator*, XL1. Its frequency is very high, and is divided down to the 1750 Hz needed by the same chip. The ceramic resonator is designed to operate at 455 kHz, the intermediate frequency of many receivers. Because all divider circuits use powers of 2, we need the oscillator to run at 448 kHz so that when it is divided by 256 ($256 = 2^8$), we end up with 1750 Hz. Try it on your calculator:

$$\frac{448\ 000}{256} = 1750.$$

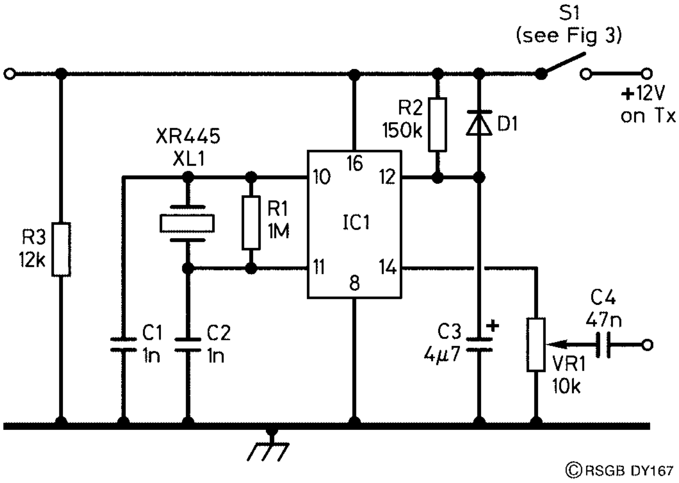

Figure 1 Toneburst module, circuit diagram

We use C1, C2 and R1 to *pull* the frequency of the oscillator away from 455 kHz to 448 kHz. The divider chain has eight *counters* in it, and each counter divides the frequency of the signal it sees by two, giving the final division of 256.

This counting process can be stopped at any time by taking the voltage on the *reset* pin (pin 12) up to the supply voltage. When the circuit is switched on by closing S1, pin 12 is at 0 V because C3 is discharged. The oscillator runs, producing the output frequency of 1750 Hz. As time progresses, C3 charges up through R2 and the voltage on pin 12 rises. When this has risen sufficiently, and in a time determined by the values of C3 and R2, the counter resets and stays in the reset state; no division takes place and there is no output. The duration of the toneburst is thus governed by C3 and R2.

When S1 is opened, the circuit is switched off, and C3 is discharged through D1 and R3, ready for the next toneburst. If you have used a repeater, you will know that a toneburst is needed **only** to activate a repeater in the standby condition; it is not needed once a contact has been established.

VR1 adjusts the amplitude of the tone fed to the microphone, and C4 prevents any voltage that may be present on your microphone connector from damaging the integrated circuit.

Construction

The prototype circuit was built on Veroboard of the copper-strip variety, measuring 20 holes by 14 strips. The layout is shown in **Figure 2**. Make the track cuts first, and check that there are no slivers of copper wedged between adjacent tracks. Then, solder in the IC socket (with the notched end

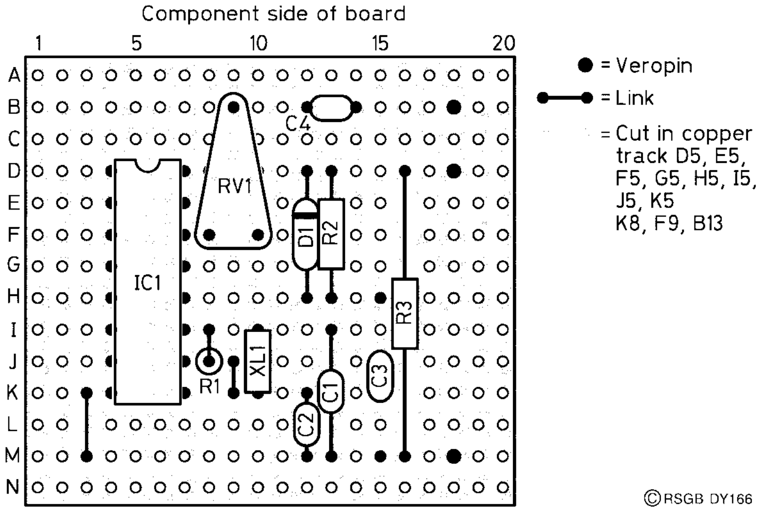

Figure 2 Veroboard component layout

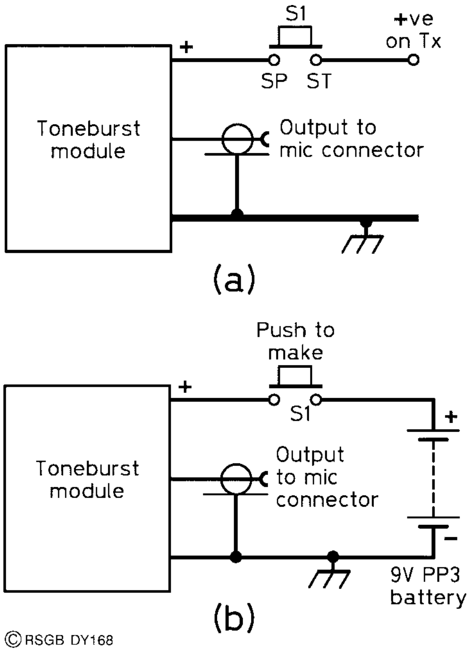
facing towards track A), the wire links and the three Veropins. Having done this, solder in the resistors, capacitors and diode, making sure that D1 and C3 are the right way round! Using your best soldering technique, solder in the ceramic resonator quickly, to prevent heat damage. Recheck your circuit, check for solder splashes and bridges, and then gently insert IC1 into its socket, matching up its notch with that of the socket.

Testing

Set VR1 to half-way and connect a crystal earpiece to the output; apply power to the circuit. You should hear the tone, lasting for about half a second. If there is no tone, disconnect your circuit from the power supply, and check for dry joints in the vicinity of pin 12. Is the diode, D1, the correct way round? Is C3 the correct way round? Did you choose to ignore the CMOS safety precautions given earlier?

Once the circuit is working, you need to decide how you are going to connect it to your transmitter. Two options are shown in **Figure 3**. If you have access to a point in your transmitter circuit that has between 9 V and 12 V positive on it during transmit, you can use this to power your circuit. As the toneburst is needed only for repeaters, the switch, S1, disconnects it when not needed, as shown in Figure 3a. If you want the circuit to be self-powered, then a 9 volt PP3 battery may be used; Figure 3b shows this configuration.



©RSGB DY168

Figure 3 Toneburst module: two alternative switching arrangements

The output from the circuit board is fed directly into the microphone socket, in parallel with the microphone itself; use thin coaxial or screened cable for this lead, or you may induce hum into the microphone circuit and suffer from RF breakthrough into the audio circuits. To adjust the setting of VR1, start with it at the zero output position and connect a dummy load to your transmitter. Slowly, increase the output while monitoring your transmitted signal on another nearby receiver. Make sure you do **not** increase the output so far that the signal sounds distorted. If you would prefer that the tone was on continuously while you made this adjustment, simply connect a wire across C3 remembering, of course, to remove it as soon as you have completed the test!

58 A circuit for flashing LEDs

Introduction

There are many occasions when one's attention needs drawing to the fact that something important has happened. A single red light coming on is seldom sufficient to attract attention, particularly if it is surrounded by other lights and indicators. The eye is known to be very sensitive to *changes* in its peripheral vision; such changes can be brought about by movement or by differences in light level – a flashing light, for example. So, a circuit that flashes a single LED or a pair of LEDs finds plenty of uses in the amateur station.

Warning

This circuit uses a member of the integrated circuit family known as CMOS (complementary metal-oxide semiconductor). These use very little current and can be completed destroyed if they come into contact with the magnitudes of static electricity that most of us carry about when we walk on carpets and wear rubber shoes. You will never know if this wanton

destruction has happened – all you will discover is that your circuit doesn't work and that you have tested *everything*. To avoid this problem do the following things:

1. **Before you open the little packet in which the IC is supplied, touch something which you *know* to be earthed – the metalwork of any equipment which is mains earthed, for example. Then open the packet.**
2. **Let the IC fall gently on the bench – don't pick it out with your fingers. Touch your earthed metalwork again. Pick up the IC and insert it gently into its holder.**

The circuit is safe from destruction while it is connected to the battery. However, when the battery is removed, the same care should be exercised with its handling, because there is no supply decoupling capacitor across the IC.

Basic description

LEDs can be made to flash (switch on and off) by driving them from sources that switch on and off. Such a source is an *astable multivibrator*. If you have built or read about *A basic continuity tester*, elsewhere in this book, you will have come across such a beast before. That circuit used an astable multivibrator made from two transistors. This new circuit achieves the same behaviour from a single integrated circuit, the CMOS 4011. To give it its full description, the 4011 is a *quad 2-input NAND gate*. Quite a mouthful, but all it means is that inside the chip are four NAND gates, each with two inputs.

A NAND gate needs a positive voltage (known as a *logic 1*) on *both* inputs in order to produce zero volts (known as *logic 0*) at the output. Two NAND gates can be connected, as are A and B in **Figure 1**, to make our astable multivibrator. The combination of A and B has been described as the most perverse circuit in electronics; as soon as the output goes to logic 1, the circuit decides that it would prefer to have a logic 0 there, and switches over. With logic 0 at the output, the circuit now prefers to have logic 1 there, and so it goes on! We are going to use this continuous switching backwards and forwards to flash two LEDs. The rate at which A and B 'change their minds' is the frequency at which our LEDs will flash, and is controlled by the charging and discharging times of C1 through R2 and C2 through R1. As the values of R1 and R2 are the same, and those of C1 and C2 are the same, the ON and OFF states of the circuit are the same.

Gates C and D do not contribute to the flashing action; they act as *buffers* to isolate the LEDs from the multivibrator circuit itself. You will find in electronics that an oscillator is seldom used to drive another device *directly*; there is usually a buffer between it and the stage it drives.

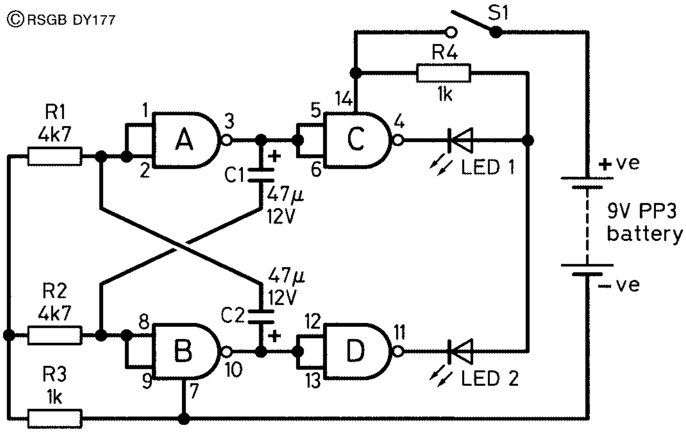

Figure 1 Flashing LEDs, circuit diagram

A characteristic of all multivibrators, astable or not, is that they have two outputs. In this case, those outputs are at pins 3 and 10, which are then buffered and appear at pins 4 and 11, respectively. When one output is at logic 1, the other is at logic 0, and vice versa. This means that LED1 is off when LED2 is on, and LED1 is on when LED2 is off, the two states switching backwards and forwards at the frequency of the oscillator.

Construction

Read the warning at the beginning of this article again. It is not intended to scare you off from building this, but is a genuine piece of advice which can save you time and irritation when all your labours result in a circuit that doesn't work! That extra bit of care can make all the difference!

Veroboard (the copper strip type) is used for the layout, shown in **Figure 2**. It measures 20 holes by 12 strips. **Be aware that there is no row 'I' in the layout, so don't miscount when you are placing components on the board!**

Firstly, cut the tracks using a 3 mm (⅛ inch) twist drill held between thumb and forefinger; check that there are no slivers of copper bridging any of the tracks, and that the tracks have been completely cut by the drill. Solder in the components carefully. Leave the IC in its carrier for the time being, and solder in the IC socket, with the notched end facing row A. On completion, check the circuit carefully. If you are happy that it is correct, follow the instructions given earlier and fit IC1 into its socket, matching up the two notches. Connect the battery and switch on. The two LEDs should flash on and off alternately. If only one LED flashes, you have probably connected the other one the wrong way round. Switch off, check and correct if necessary. If neither LED flashes, you must have a significant error in your circuit, which will need checking *again*! Or did you choose to ignore the handling precautions for the CMOS chip?

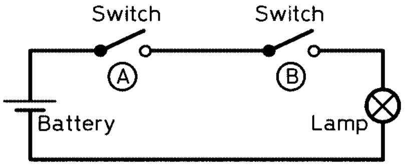
59 Digital logic circuits

Introduction

Logic circuits form the backbone of even the most advanced computer, yet their basic operation can be demonstrated by a couple of switches, a battery and a bulb.

Logic using switches

Everyone reading this article will look at **Figure 1** and know immediately how it works and be able to write down something like 'When switch A and switch B are closed, the light will come on'. Without knowing it, you have written down a logic statement involving the so-called **AND** operation; the light comes on only when switches A **AND** B are ON. Below the circuit in Figure 1, is a table showing the only possible positions of the two switches and the state of the bulb for each position. This is called a *truth table*, and is frequently used in logic analysis.



A	B	Lamp
Off	Off	Off
On	Off	Off
Off	On	Off
On	On	On

©RSGB DY182

Figure 1 Switches and lamp AND gate

Figure 2 shows a different circuit. Here, the two switches are in parallel rather than in series, as was the case in Figure 1. Again, if you analyse the circuit in words, you would say that the light will be on when switch A **OR** switch B is ON. This is an example of the **OR** operation, and its truth table is shown in Figure 2. The statement above is not complete, however; can you see why? The truth table will show you. The light comes on if A is ON, **OR** if B is ON, ***OR*** if A **AND** B are both ON. That third condition is easy to miss, but don't worry about it!

©RSGB DY184

Believe it or not, some very complicated logic is possible (in theory) using switches and lights, but it is highly impractical and would be very slow. This is where electronic logic circuits come in.

Switches with no moving parts

You may have come across projects in this book where a statement is made such as '. . . the transistor is being used as a switch . . .'. Transistors *can* be used as switches, as were thermionic valves in the world's first programmable computer *Colossus*, at Bletchley Park. However, technology has moved on from valves, through transistors to *logic gates*, combinations of electronic switches designed specifically to perform logic functions.

These act on voltage levels as their inputs and produce changes in voltage levels as their outputs. A positive voltage is called *logic 1*, and corresponds to a switch being ON in our previous descriptions; a zero voltage is called *logic 0*, and corresponds to a switch being OFF. The output from a logic gate (normally labelled Q) is also logic 1 or logic 0, corresponding to our light being ON or OFF, respectively, in our switch analogy.

Many logic devices operate from a stabilised 5 V supply, and this determines the *ideal* voltages corresponding to the two logic states:

logic 0 ≡ 0 V,

logic 1 ≡ 5 V.

The world isn't an ideal place, so the *real* voltage ranges used by the logic gates are:

logic 0 ≡ 0.0 to 0.4 V,

logic 1 ≡ 3.0 to 5.0 V.

The **AND** circuit of Figure 1 is now called an **AND gate**, and requires logic 1 inputs on A **AND** B to produce a logic 1 at the output. **Figure 3** shows this. The truth table is identical with that of Figure 1 – logic 1 replaces ON and logic 0 replaces OFF. Now compare Figure 2 with **Figure 4** – circuits and truth tables for the **OR** function. Again, we have exact similarity.

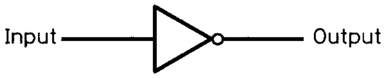
Figure 4 Electronic OR gate

There is another very common logic gate, which performs the **NOT** function. It is easy to understand. Just ask yourself the question 'What is **NOT** logic 0?', and the answer is obviously 'logic 1'. Similarly, logic 0 is **NOT** logic 1. A **NOT** gate simply changes the logic state of the input; it is also known (because of this behaviour) as an *inverter*. Its symbol and truth table can be found in **Fig 5**. Note the little circle on the output of the gate in Figure 5. In logic circuits, this symbol always implies inversion, or the presence of a **NOT** gate. Keep an eye open for it!

So far, the logic functions we have discussed have all been words which we use in everyday language, which has made the electronic interpretation of them relatively easy. Now we must introduce a function for which there is *no* analogy in normal speech – the **NAND** function. This means a



Input	Output
1	0
0	1

©RSGB DY185

Figure 5 Electronic NOT gate

combination of an **AND** gate and a **NOT** gate, and the sharp-eyed reader will have spotted the little circle added on to the normal **AND** gate symbol in **Figure 6**!

To make things easier to understand, the truth table in Figure 6 has four columns, not three as in previous tables. The third column is the standard **AND** output – compare it with the third column in Figure 3. That is the output from the **AND** gate *before* it encounters the little circle that inverts it, so the final output from the **NAND** gate is the output of the **AND** gate, inverted! The third and fourth columns are the inverse of each other.

Figure 7 Electronic NOR gate

We can add the inverting operation to the output of an **OR** gate also, producing a **NOR** gate! The symbol and its truth table are shown in **Figure 7**. Again, notice that the final output is that of the ordinary **OR** gate, inverted!

These new functions of **NAND** and **NOR** are used more than the **AND** and **OR** functions because it makes other circuits easier to design using combinations of these gates.

A taste of Boolean algebra

The design of circuits using combinations of logic gates usually begins with a little mathematics, where the functions to be implemented are analysed. The mathematics used is surprisingly simple, and is a slightly changed version of ordinary algebra called *Boolean algebra*, which allows manipulation of logic functions to be made. Normal algebra has operations in it such as addition, subtraction and multiplication and division. The mathematician Boole found that the logical **AND** operation could be handled by the algebraic operation of *multiplication* (symbols × or •), and the **OR** operation by the algebraic operation of *addition* (symbol +). The **NOT** operation involved a new symbol, that of a bar over the input being inverted, such as $\overline{A}$.

So, our five basic logic operators can now be written in a mathematical form:

AND	$Q = A \times B$
OR	$Q = A + B$
NOT	$Q = \overline{A}$
NAND	$Q = \overline{A \times B}$
NOR	$Q = \overline{A + B}$.

Using logic operations in a mathematical form enables the most complex logic to be designed, simplified and converted into circuit diagram form in a very efficient and rapid way. There are more logic operators than the five we have considered here but, in general, they can all be broken down into combinations of these gates alone!

60 A resistive SWR indicator

Introduction

When a transmitter produces some output power, we want to make sure that as much as possible of this power is radiated by the aerial. This often requires the use of an *aerial tuning unit* (ATU), which matches the aerial impedance to that of the transmitter.

How do you know when this matching has been achieved? The most usual way is to use a *standing-wave ratio* (SWR) indicator. If the impedance of the aerial does not match that of the transmitter output, some of your transmitter power (also known as the *forward* power) is reflected back along the aerial feeder and back into the transmitter, where it causes excess heating. The forward and reflected waves interact along the feeder to produce a wave whose position remains constant, and which is therefore called a *standing wave* or a *stationary wave*. An SWR meter simply indicates forward power and reflected power, and adjustments are made to your ATU until the reflected power is as small as possible (ideally zero, of course). If there is no reflected power then, by a process of elimination, all your forward power is reaching the aerial!

Sampling the RF

Whatever type of SWR indicator you use, it must use some sort of sampling circuit to pick up the forward and reflected waves. The project *A standing-wave indicator for HF*, elsewhere in this book, uses a toroidal transformer to separate the readings for the forward and reverse waves. This design differs in that it measures the voltages across resistors through which the RF current is passing. Its advantages are:

(a) it uses cheap parts – four resistors, two capacitors and a diode, together with a rotary switch, a surplus meter, a preset potentiometer and two sockets;

(b) within this SWR indicator, there is always a resistive path for the RF current from the transmitter, formed by R1, R2 and R3; this can prevent damage to simpler home-made transmitters, which may be damaged during adjustment of the ATU when using more conventional SWR indicators.

The only disadvantage of this form of indicator is that it must be switched out of circuit once the ATU has been adjusted for a particular band.

Construction

The SWR indicator is very simple to build, as most of the components can be mounted on the back of the 3-way rotary switch. This is shown in **Figure 1**. The switch is a 4-pole, 3-way rotary type, of which only two poles are used.

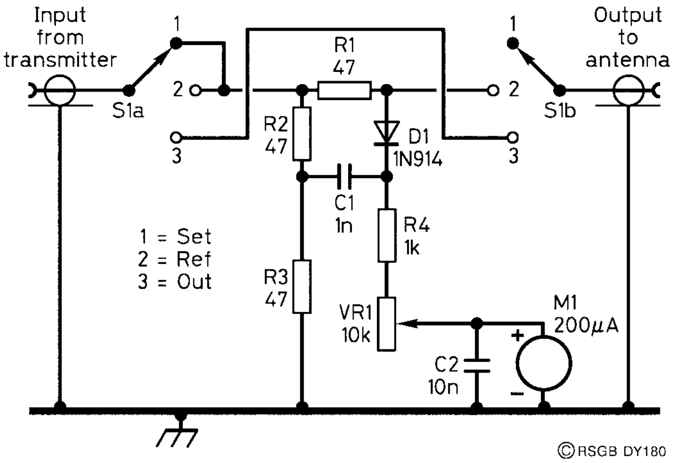

Figure 1 Resistive SWR meter, circuit diagram

Because the other switch contacts are not being used, they can be employed as support tags for other components. The ground wires are all soldered on to the metal frame of the switch. If your switch frame is of all-plastic construction, then a 12 SWG copper wire run around the switch will make a good earth connection to the metal case for the leads shown in Figure 1. The preset potentiometer used to control the sensitivity of the circuit can be mounted directly on the meter tag.

Resistors R1, R2 and R3 handle the RF power during the tuning-up process. If you have them, use 1 watt resistors; otherwise, you can use two 100 ohm half-watt resistors in parallel for each of R1, R2 and R3. The meter, M1, can be any DC type of sensitivity around 200 µA.

In use

First, find a clear frequency, and without the indicator in circuit, check that the frequency really *is* clear by asking and identifying yourself. If it is, connect the indicator between the transmitter and the ATU which, in turn, is connected to your aerial. Turn SW1 to the SET position and key the transmitter. Adjust VR1 until the meter reads full scale. Switch off the transmitter. Turn SW1 to the REF position and key the transmitter again. Adjust the ATU until the lowest reading is obtained on the meter. Switch off the transmitter. For the chosen frequency, you have adjusted your ATU for minimum reflected power and hence the lowest SWR. You will need to repeat the process when you change bands, and possibly when you change frequency within the same band. Switching SW1 to the OUT position, you are ready to transmit. You may have noticed that it is good practice to switch the transmitter off when operating SW1. Get into that habit!

61 An audio filter for CW

Introduction

This is a simple passive circuit (it has no power supply) that adds some audio selectivity for Morse code reception and also includes a very simple noise limiter that gives a visual indication of when noise spikes are being removed!

The circuit

Figure 1 shows the complete circuit. The tuned circuit of C1 and L1 resonates very close to 800 Hz, so initially you will have to tune a signal in carefully until it sounds loudest – you will soon be able to do this without thinking. The two LEDs connected back to back across the signal path act as a noise limiter, reducing the amplitudes of static crashes and noise from car ignition systems, etc. The LEDs blink when they conduct – this is not necessary to the operation of the circuit, but adds a little colour to your listening! The noise limiter *does* make listening more comfortable, though.

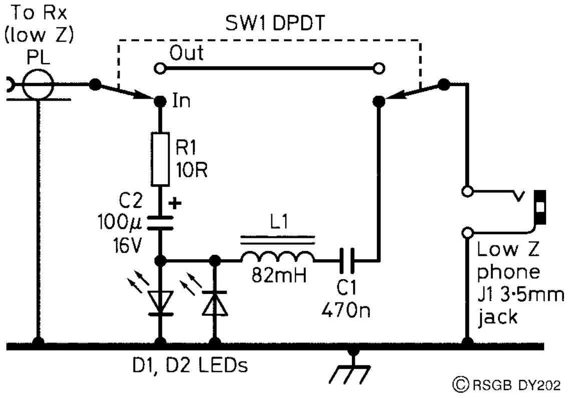

Figure 1 CW filter, circuit diagram

Construction

The circuit layout is shown in **Figure 2**. Point-to-point wiring is used, with a small tag-strip being the only item used for the extra support of C2 and R1. The LEDs and SW1 support the other components. An aluminium box (**Figure 3**) is used to make the circuit tidy and usable.

You must use low-impedance headphones for the circuit to perform properly. Plug the completed unit into the headphone socket of your receiver and adjust the volume so that the LEDs are just *not* blinking on normal audio. The unit should be switched out of circuit for speech listening; this is the purpose of the toggle switch, SW1.

Parts list

Resistor

62 An electronic die

Introduction

Throwing a die is a venerable way of generating a 'random' number between 1 and 6. A die is easy to lose, so here is an electronic die-throwing circuit which brings the technique up to date and serves as another application of logic circuits. If you need a reminder of the basics of logic, refer to *Digital logic circuits*.

Warning

This circuit uses members of the integrated circuit family known as CMOS (complementary metal-oxide semiconductor). These use very little current and can be completed destroyed if they come into contact with the

magnitudes of static electricity that most of us carry about when we walk on carpets and wear rubber shoes. You will never know if this wanton destruction has happened – all you will discover is that your circuit doesn't work and that you have tested *everything*. To avoid this problem do the following things:

1. **Before you open the little packet in which the IC is supplied, touch something which you *know* to be earthed – the metalwork of any equipment which is mains-earthed, for example. Then open the packet.**
2. **Let the IC fall gently on the bench – don't pick it out with your fingers. Touch your earthed metalwork again. Pick up the IC and insert it gently into its holder.**

The circuit is safe from damage while it is connected to the battery.

Description

The circuit is shown in **Figure 1**. IC1a and IC1b form an *astable multivibrator*, similar to that used in 'An LED Flasher' also in this book. It runs constantly, and its output is fed to IC2 via a single NAND gate, IC1c. The other input of IC1c is held at 0 V by R3 and C3. Whenever one input of a NAND gate is logic 0 (or 0 V), there can be *no output* from the gate, irrespective of what is happening at other inputs. So, despite the fact that the oscillator (or *clock*) is running all the time, its square-wave output never

Figure 1 Electronic dice, circuit diagram

reaches IC2 until the ‘other’ input of IC1c is brought away from logic 0. This happens when SW2 is pressed. Pressing SW2 momentarily, as is normally done, charges up C3 to 9 V, putting a logic 1 on the second input of IC1c and allowing the clock signal through to IC2. As the switch is released, C3 begins to discharge through R3, gradually lowering the voltage on pin 8 of IC1c. As this voltage crosses 4.5 V (half the supply voltage), IC1c then treats this input as logic 0, which cuts off the clock signal from IC2 again. Thus, when SW2 is momentarily pressed, the clock signal is fed to IC2 for a short interval of time, before being blocked again.

IC2 is a binary counter, and the outputs that concern us are from pins 14, 11 and 6. Pin 14 is the *most significant bit* and pin 6 the *least significant bit*. See the panel for an explanation of what happens here.

To understand these outputs, you should be able to count in binary, using three bits. At the start of the counting process, all the bits have zero values, i.e. 000. The left-most bit is called the *most significant bit*, and the right-most bit is called the *least significant bit*. (When we write numbers normally, a number 1 in the left-hand position represents one hundred, 1 in the middle column represents ten, while the number 1 in the right-hand position means one. One hundred is a more significant number than one, hence the nomenclature.)

The three bits of our binary number have values, from left to right, of 4 ($=2^2$), 2 ($=2^1$) and 1 ($=2^0$). This means that a number 1 in the left-hand column signifies the normal number four, in the middle column it would represent two, and in the right-hand column, it would represent one. This should help you understand the patterns of bits which emerge as the clock waveform is counted, as the next paragraph explains.

As each cycle of the clock enters IC2, it increments its internal counter and the values of that counter are shown by the states of pins 14, 11 and 6. After the first pulse, these three pins would have states corresponding to 001; after the second, 010; after the third, 011; after the fourth, 100; after the fifth, 101; after the sixth, 110. This sequence of 3-bit numbers represents a binary count from 1 to 6 in ‘normal’ parlance. These six states are used to illuminate the conventional pattern of dots on a die, using LEDs.

As the clock cycles are counted, the LEDs flicker as the die is ‘rolled’. Resistors R4 to R7 are used to limit the current through the LEDs. When the counter stops, it can be in any of the positions shown in **Table 1**. Because of

Table 1 Dice number relative to counter output

Step	*Pins*			*Dice number*
	14	*11*	*6*	
1	0	0	1	4
2	0	1	0	2
3	0	1	1	6
4	1	0	0	1
5	1	0	1	5
6	1	1	0	3

the way in which the dots are grouped on the faces of a die, the wiring of the LEDs is simpler than it might otherwise be. You can see from Figure 1 that there are really only three sets of connections to the LEDs – one from each bit of the counter output. When pin 14 is at logic 1, four LEDs are lit, corresponding to the number four. For the number five, pins 14 and 6 will be at logic 1. For the number one, only pin 6 is at logic 1. For three, pins 11 and 6 are at logic 1, for six, pins 14 and 11 are at logic 1, and for two, only pin 11 is at logic 1. These conditions are summarised in Table 1.

Construction

Two pieces of Veroboard (of the strip type) are needed – one for the main circuit (**Figure 2**) and the other for the display LEDs (**Figure 3**). The display board is easier to build, so we will do that first. It measures 20 holes by 18 strips.

Cut the tracks as shown in Figure 3, using a 3 mm (1⁄inch) twist drill rotated between thumb and forefinger. Insert and solder the Veropins, resistors and the wire links. Then solder the LEDs in place, making sure their polarities are correct. The LEDs are mounted proud of the board (**Figure 4**, which will help when you come to fix the board into a case.

The main board measures 32 holes by 18 strips. As before, remove the tracks in the places shown in Figure 2. Note that track 'L' is *not* broken under the position for IC2. Solder in the IC holders and the links. Solder in R1 and R2 vertically, and R3 horizontally. Then solder in C1, C2 and C3; these all being electrolytics, check their polarities. Solder in the Veropins and prepare the connections to those components not on the main board, using stranded, insulated wire. Check the circuit carefully, and read the handling precautions given earlier before carefully inserting the two ICs.

Figure 3 Board for the six LEDs

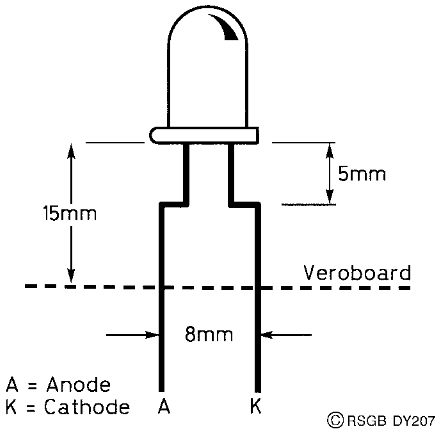

Figure 4 D7 lead bending

Testing and use

When the circuit is switched on, it is likely that the centre LED only will be lit. Press SW2, the 'throw' switch. All the LEDs should flicker, even after the switch is released, but only for a second or so. Then a standard pattern should show, signifying numbers between one and six. If this does not happen, switch off and check your circuit again. Are there any missing links? Are there any obvious dry joints (usually dull instead of shiny)? Can you see any solder bridges between tracks? Did you choose to ignore the handling precautions? If none of these results in a working circuit, try some fault-finding.

- Disconnect the lead to D7 on the main board (marked 'to pin F1' on Figure 2). Touch the lead on to the positive supply rail. D7 should light. Now transfer this lead on to pin 4 of IC1. If it flickers, then the oscillator is running (which it should).
- Transfer this lead to pin 10 of IC2. D7 should flicker when SW2 is pressed, but should be on permanently when it is released. This means that the correct signals are reaching IC2 from IC1.
- If one of the chains of LEDs (i.e. D1 and D2, D3 and D4, D5 and D6) does not light, you may have one *or both* LEDs the wrong way round.

When the die is working, you may care to experiment with the values of R1 and R2, but you should keep their values the same, i.e. R1 = R2. The larger the values of these, the more slowly the die will appear to 'roll'.

Finishing touches

On completion of the project, you will want to mount it in a smart case; any plastic box is suitable for this, with the display board mounted so that the

LEDs protrude through the top and are fixed to it using LED clips. The way in which you mount both boards to the case is entirely up to you.

Parts list

63 The absorption wavemeter

Introduction

The purpose of the absorption wavemeter is to check that a transmitter is radiating within the correct waveband, and to detect any spurious *harmonic* emissions. A harmonic frequency is an integral multiple of the carrier frequency – e.g. if the carrier is at a frequency *f*, the harmonics are at frequencies 2*f*, 3*f*, 4*f* . . . and so on.

It can also be employed as a relative field-strength indicator, being used in experimentation with aerials. What it *cannot* do is to measure the transmitted frequency accurately; all it can do is to place the signal within a particular band, say the 7 MHz or the 18 MHz band (or their harmonics).

How it works

You may recognise the circuit of **Figure 1** as a crystal set with a meter replacing the headphones. It is simply the parallel combination of an inductance with a variable capacitance, which constitutes a resonant circuit with a variable frequency. A dial on the variable capacitor can be roughly calibrated with frequency. The fixed capacitor across the meter helps to improve the meter reading by making it read the peak value of the carrier wave rather than the average value.

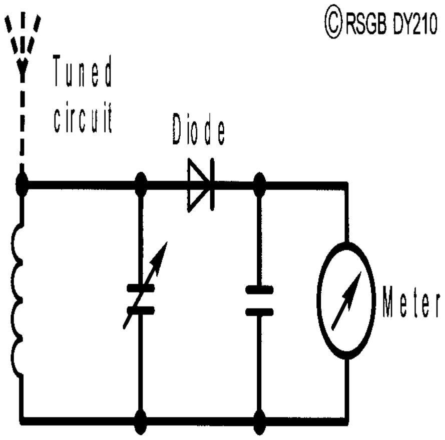

Figure 1 Absorption wavemeter circuit

When the wavemeter is situated in the vicinity of a relatively strong radio-frequency (RF) field, the inductor absorbs a small amount of energy from that field. If the circuit is resonant at the same frequency as that of the transmitter, an RF voltage is produced across the coil and is proportional to the strength of the RF field. The RF voltage is *rectified*, or *detected* (turned from AC into DC) by the diode and the second capacitor, and is displayed by the meter.

The tuned circuit

The formula for calculating the resonant frequency of a coil and capacitor is relatively simple. It is

$$f = \frac{1}{2\pi\sqrt{LC}},$$

where f is the resonant frequency (Hz),
L is the inductance (H), and
C is the capacitance (F).

If this formula puts you off, there is this slightly easier version:

$$f = \frac{159}{\sqrt{LC}},$$

where f is the frequency in **MHz**,
L is the inductance in **microhenries** (**μH**), and
C is the capacitance in **picofarads** (**pF**).

When a variable capacitor is specified, it is usual to quote its maximum capacitance, i.e. the value when the vanes are fully meshed. When the value of the capacitor is small, it is usual to quote its minimum capacitance also, the value when the vanes are fully open. If you use a variable capacitor of 10–100 pF with a 100 μH inductor, you will use the value of 10 pF to calculate the maximum resonant frequency, and the value of 100 pF to calculate the minimum resonant frequency, giving a tuning range of 1.6 MHz to 5 MHz. Check it yourself!

64 An HF absorption wavemeter

Introduction

An absorption wavemeter is basically a simple tunable detector circuit, such as would be used in a crystal set, but with the headphones replaced by a meter, in order to indicate the strength of the received signal.

The circuit

Figure 1 shows the circuit of the wavemeter. It is designed to cover all the HF bands from 1.8 MHz to 28 MHz in four switchable ranges. There is no built-in method of amplification, so a sensitive meter is needed in order to indicate sufficiently using the available absorbed energy. The meter does not need calibrating, it serves to produce only an indication of the absorbed power, *not* its absolute value.

An absorption wavemeter does not have outstanding selectivity, mainly because of the loading effect of the meter. This problem is ameliorated here (but only slightly) by the inclusion of R1 in series with the meter. It gives

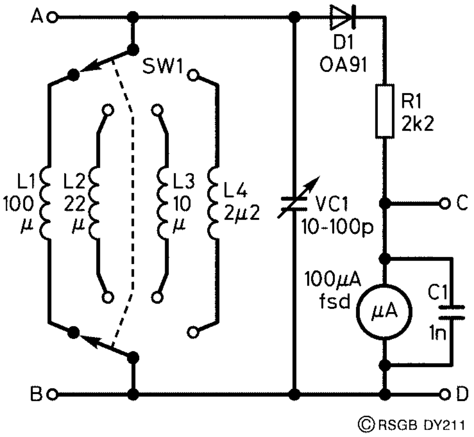

Figure 1 HF absorption wavemeter, circuit diagram

improved selectivity at the expense of a slight loss of sensitivity. The appearance of capacitor C1 across the meter is discussed in *The Absorption Wavemeter*, in the previous section.

Coils

These can be purchased (see the parts list) or hand-wound on short lengths of PVC water pipe or conduit, and the coil-winding details are given in **Table 1**. In theory, the 100 pF tuning capacitor would cover all the HF bands with only three coils, omitting the 22 μH coil. Sample calculations are explained in the previous article. However, its inclusion avoids the common problem of having some bands cramped at the extreme edges of the tuning scales.

100	157	79	26

Construction

Hand-wound coils, using 19–25 mm PVC formers, have single-layer windings, with their ends secured by threading the wires through two small holes drilled in the formers at each end of each winding.

You may have wondered about the use of the two-pole switch SW1, as all the lower ends of the coils are grounded anyway. The answer lies in the ease of construction. Each coil can be mounted on the tags of the switch for support. If you are using the commercial coils, they are small enough to be accommodated on a miniature rotary switch; a larger rotary switch is required for hand-wound coils. The specification of a 6-way switch allows for the addition of extra frequency ranges at little extra cost. Rotary switches such as the 2-pole, 6-way variety have an adjustable end-stop which allows the number of ways to be set anywhere between 2-ways and 6-ways. Remove the nuts from the switch, and a ‘washer’ will fall out. It is not a washer, really, and has a little piece of metal bent over at right angles to the washer. This fits into one of 12 holes in the body of the switch, and prevents the shaft from turning through 360° and selecting the number of ways.

Calibration

This process needs a commercial amateur-bands transceiver, if it is to be done quickly and accurately.

- Connect the transceiver to a dummy load, and connect a piece of flexible wire from point A in Figure 1 and wrap two or three turns around the cable between the transceiver and the dummy load.
- Turn the transceiver power level control to minimum, and set the frequency at 1.81 MHz and the mode to FM or AM. Switch to transmit.
- With the wavemeter set to its lowest frequency range (i.e. 1.8–3.5 MHz), rotate the tuning capacitor until maximum deflection is obtained from the meter needle. Write the frequency on the inner ring of the wavemeter scale at that point.
- Switch off and retune the transmitter to 3.5 MHz. Repeat the above process.
- Repeat, using switch range 2 for 3.5, 7 and 10 MHz, range 3 for 7, 10 and 14 MHz, and range 4 for 14, 18, 21, 24 and 28 MHz.

An alternative source of calibration signal could be an HF signal generator, with a single-turn loop of wire at the remote end of its cable, and the wire from the wavemeter brought close to the loop.

Remember that the marks on the scale represent frequency *bands*, not precise frequencies.

Extending the range

If you would like to experiment with increasing the range to the lower VHF band, then 50 MHz should be achievable with an additional self-supporting coil (no former). Try three turns of 20 SWG enamelled copper wire of 25 mm ID (internal diameter). Wind it on some 25 mm PVC pipe, as before, then slide out the pipe! The same result could be achieved with four turns of 19 or 20 mm ID, or 12 turns of 7.1 mm ID.

Parts list

Resistor	
R1	2200 ohms (Ω) 0.25 watt, 10% tolerance
Capacitors	
C1	1 nanofarad (nF) min. ceramic
VC1	100 picofarad (pF) variable
Inductors	
L1	100 microhenries (μH)
L2	22 microhenries (μH)
L3	10 microhenries (μH)
L4	2.2 microhenries (μH)
Semiconductors	
D1	Germanium OA91 or 1N4148
Additional items	
SW1	Rotary 2-pole, 6-way
	Moving-coil meter, 50 or 100 μA FSD (any meter of this sensitivity will do)
	Plastic box, approx. 150 by 80 by 50 mm
	Connecting wire, coloured

65 A vertical aerial for 70 cm

Introduction

If the range of your hand-held transceiver is very limited, what you need is a vertical aerial mounted outside. This design is a half-wave dipole fed at the end instead of the middle. Because the impedance of the dipole is high at its ends (and low in the centre), a matching circuit is needed so that this high impedance can be matched to that of the low-impedance coaxial cable. All that is needed is a coil, which increases the *electrical length* of the aerial to ⅝-wavelength. (Note that the *electrical* length (i.e. the length as it appears to an RF signal) is not necessarily the same as the *actual* length.)

Construction

The aerial element and the coil are made from a single piece of 1.5 mm welding (brazing) rod, and the dimensions are given in **Figure 1.** Wind the coil around a 4 mm rod or the shank of a twist drill. The lower end is filed to a point and then soldered into the centre conductor of a 4-hole panel-mounting BNC socket. (Try to obtain a good-quality BNC socket with PTFE insulation – the insulation of cheaper sockets is easily damaged.) Trim the element to 427 mm (top of element to top of coil) *after* the wire has been soldered to the socket.

The base coil causes the aerial to be rather ‘whippy’, so a piece of 5 mm plastic knitting needle can be cut to the length of the coil and then forced into it.

The radials are made from four lengths of 3 mm welding rod. These are bent and soldered into the four mounting holes of the socket, and then cut to the lengths shown in Figure 1.

Testing

Using a standing-wave-ratio (SWR) meter connected between your aerial and the transceiver, measure the SWR (or obtain some indication of the reflected power) on transmit. If it is greater than 1.5, switch off the transmitter, trim about 3 mm off the end of the element, and try again. Repeat the process until the measured SWR (or the reflected power) is as low as you can get it.

Figure 1 Construction of the 70 cm antenna

Installation

The aerial is made waterproof by enclosing it in a 22 mm diameter PVC waste water pipe. It is 'weldable', and available at plumbers' merchants, usually by the metre. A coupler is slotted to take the radials (Figure 1). File the BNC socket as required, so that it slides inside the coupler until the radials poke out of the slots. Cut a length of plastic tubing which is 30 mm longer than the aerial, and push it into the coupler. You will then need a plastic bung or screw-top to waterproof the top end.

Plastic welding solution is now applied to the joints, sealing the aerial inside the tube. The coupler has been weakened as a result of making the slots, so it is worthwhile applying PVC tape around this joint until the welding solution sets.

A support for the aerial is made from an off-cut of tube pushed into the lower end of the coupler and held with a self-tapping screw.

Parts list

1	4-hole panel-mounting BNC socket
1 m	3 mm brazing rod (may be available from a small garage)
1 m	1.5 mm brazing rod
1 m	22 mm PVC waste water pipe
1	22 mm straight coupler
	Plastic welding solution

66 A UHF corner reflector aerial

Introduction

The corner reflector is a well-known design and is capable of good performance on the VHF and UHF bands. At UHF, the practical implementation of the corner reflector is an ideal constructional project.

Some details

Expressed quite simply, the aerial consists of a $\frac{\lambda}{2}$ dipole (where λ is the standard symbol for wavelength, making a '$\frac{\lambda}{2}$ dipole' a half-wave dipole).

Nothing new in that, you might say. However, the interesting feature is the reflector, which is not the usual single element, but a 90° metal 'corner', acting rather like a parabolic dish as used for satellite signal reception. The wind resistance of this type of reflector makes it impractical so, to reduce the 'windage' quite significantly, we make the 'corner' from closely spaced rods, as illustrated in **Figure 1**.

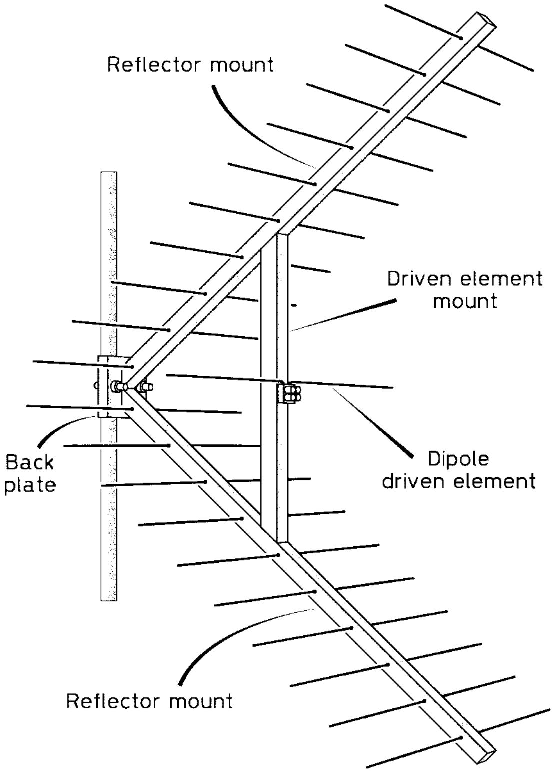

Figure 1 70 cm corner reflector antenna

©RSGB DY215

The reflector consists of a number of 0.6λ rods, spaced from each other by 0.1λ. The aerial frame can be made of metal or wood, but wood is easier to work with, and mounting the elements to the frame is simpler. The prototype was made with wood of 20 mm by 15 mm cross-section, as **Figure 2** shows. The wood was varnished for protection. The elements were made from 1.5 mm diameter copper wire, because a large reel of the wire happened to be available. The wire diameter is not critical; tubing could be used just as successfully. 14 SWG hard-drawn copper aerial wire would be even better than that used in the prototype.

Figure 2 Driven element dimensions, together with boom dimensions for driven element and reflectors

Construction

This project is just as much a woodworking project as a radio project! Follow the instructions carefully, and you should have little trouble.

- Cut the booms for the reflectors, as shown in Figure 2. A mitre block is invaluable here in producing the 45° corners.
- Using the dimensions given on the diagram, mark the hole positions for the reflector elements, and then drill holes of a size which holds the elements firmly.
- Cut the driven element boom according to the diagram, and mark the point midway along the longer side, which will assist you later in positioning the driven element.
- Cut the back plate to size (about 120 mm by 80 mm). You may need to alter this size depending on the size of the U-bolt you will be using to clamp the aerial to the mast.

- If you want to be extra cautious in your construction, use the belt-and-braces approach, commonly known as 'screw-and-glue' to fix the booms to each other and to the back plate.
- Fix the reflector booms to the back plate first, then slide in the driven-element boom until it will go no further, then apply the wood glue and screw the two ends tightly to the reflector booms. Leave for the period prescribed by the glue manufacturers for the glue to harden.
- Varnish the whole structure.
- Cut the driven element to the correct size plus a couple of centimetres (the reason for this will be evident in the *Testing* section), and fix it to the centre of its boom (at the position you marked earlier) with a 'chocolate block' connector to which the coaxial feeder cable will eventually be connected.
- Cut and fix the reflector elements in place. If you find that these are a loose fit in the holes then, *for each element*, drill a pilot hole through the boom to intersect the hole for the element. File off the point of a woodscrew, and screw it gently into the pilot hole until it meets the element and grips it in place. You will now see why the point was filed off! Alternatively, you can glue the elements in place.

Testing

Place the aerial on a mast, clear of obstructions. Connect it to a transceiver with a length of coaxial cable, with a standing-wave-ratio (SWR) meter in circuit. Find a clear frequency, identify your transmission and ask if the frequency *really is* clear. If so, key the transmitter again and note the SWR. **Do not stand in front of any aerial when it is radiating!** The length of the driven element must be adjusted to obtain an SWR of less than 2. If you have to shorten the dipole, bend the ends over rather than cut them off. That way, if you go too far, your can lengthen them again! The dipole was initially cut too long intentionally, to allow for adjustment here! Bending the ends over also reduces the risk of physical damage to clothing, skin and eyes. You may like to consider applying the same technique to the reflector elements for that reason alone.

Moving on . . .

Once you have warmed to the idea of the corner reflector as an aerial, you might like to ring the changes regarding the reflector. How about replacing the 20 reflector elements with a wire mesh, such as garden centres sell as 'chicken wire'? Choose the finest mesh if there is a choice. Some extra support may be needed around the edges of the mesh, but you could go on to make a comparison of aerial gain between the two types, using the *UHF Field Strength Meter* described elsewhere in this book.

Materials

Stiff wire or thin-walled tubing for dipole and reflector
Frame – wood, 15 mm by 20 mm cross-section, lengths given in text
Back plate – stout plywood, dimensions given in text
U-bolt to suit mast
Wood screws
Wood glue
50 W coaxial cable for feeder
2-terminal ‘chocolate block’ for dipole connection to feeder
Varnish

67 A switched dummy load

Introduction

A dummy load is a pure resistor of value 50 ohms which can replace your transmitting aerial and enable you to operate the transmitter for test purposes without radiating a signal. It sounds simple enough, but there are two main problems. Firstly, it is impossible to delve into your junk box and emerge with a resistor that will dissipate 100 W PEP and still retain its marked resistance value. Secondly, a ‘pure resistance’ is very difficult to achieve. A pure resistance is a device which has resistance but no reactance. All common resistors have significant reactance at radio frequencies, particularly the wire-wound varieties, which have a helical (i.e. wound like a coil) construction. This is particularly annoying, because wire-wound construction is normally used for large-wattage resistors.

Although all resistors have *some* reactance, not all are quite as bad as the wire-wound type. Carbon film resistors are made by depositing a thin film of carbon on the surface of a small, hollow ceramic cylinder, the thickness of the film of carbon determining the value of the resistor. Provided the lead lengths are kept short, these resistors have a tolerably small reactance, and will be used in this project.

Bearing the load

A 2 W carbon film resistor is hardly going to withstand our 100 W PEP of SSB, so it is obvious that the design of our dummy load must be a little more complex than a single resistor and a switch, despite what **Figure 1** might suggest! In fact, it uses 20 resistors, each of value 1000 Ω (1 kΩ). How does this solve our problem?

Perhaps a little theory is in order here, but no more than is required by the Radio Amateurs' Examination.

When two *equal* resistors of value r are combined in parallel (i.e. side by side), the total resistance, R_T, is given by:

$$\frac{1}{R_T} = \frac{1}{r} + \frac{1}{r}.$$

Adding $1/r$ to $1/r$ gives $2/r$, therefore:

$$\frac{1}{R_T} = \frac{2}{r}, \quad \text{i.e. } R_T = r/2.$$

So, by connecting *two* equal resistors in parallel, we get a combined resistance which is *half* the individual resistances. If we combine *three* in parallel, we get a *third* of the resistance, and so on.

Here, we are connecting *20* resistors of 1 kΩ in parallel, so we will produce an overall resistance of *one-twentieth* of the individual resistance, i.e. 1000/20 = 50 Ω, which is what we set out to achieve!

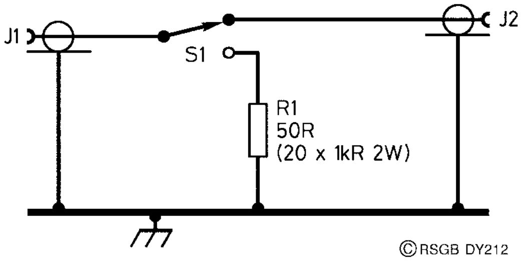

Figure 1 Basic circuit diagram

This is not the only advantage, though. Each resistor is capable of dissipating 2 W, so 20 of them will safely dissipate 40 W, for short periods at least. This power dissipation is approximately the same as 100 W PEP of normal speech, so the design should be capable of use in an 'average' amateur station. The power-handling ability of any dummy load can be improved by providing a 'heat sink' which helps to conduct the heat energy away from the resistors, thus lowering their temperature. One popular heat sink is a can of transformer oil, into which the resistors are immersed. This design uses a rather more mundane heat sink, but which is adequate for the job in hand.

Pouring the heat away

Two basic PCBs are needed, the details being given in **Figure 2**. Both measure 11 × 35 mm. Each has a set of 20 holes of diameter about 1 mm to take the ends of the resistors. Only one of them has two 3 mm holes which are used for mounting the completed load. **Figure 3** shows how the heat sink is assembled. Solder one end of each resistor into the 'earth' PCB, and then mount this to the box using the two bolts as shown in the diagram. Between each rank of resistors is a 'sandwich' consisting of an aluminium strip and two pieces of ceramic wall tile, to act as a heat sink for the resistors. Heat sink compound is used to provide good thermal contact between the resistors and the tiles, and between the tiles and the aluminium strip. This is shown in the lower part of Figure 3. Thread the loose wires of the resistors through the holes in the second PCB, solder into place, and crop the protruding wires.

Switching

A changeover switch must be used so that the transceiver can be switched between the dummy load and the aerial without unscrewing connectors. For most purposes, an ordinary 10 A 230 V changeover switch will suffice, as found in many electrical shops and DIY stores.

Wire this into the circuit as shown in Figure 1 and Figure 3. Check your wiring. Put S1 in the 'dummy load' position. If you have a multimeter which includes an ohmmeter, measure the resistance across the socket, J1, before connecting it to the transceiver. It should be very near 50 Ω. With S1 in the 'aerial' position, there should be an infinite resistance across J1. Move your ohmmeter to read the resistance across J2. It should be infinite for both positions of S1. If all seems correct, close the box and your dummy load is ready for use!

  Nuts and bolts as required

68 A simple Morse oscillator

Introduction

This is an excellent project which uses the 'junk box' as its source of components. If you have trouble in finding the bits for this one, a good source of the components for this and many other similar projects is to be found with the parts list at the end of the project.

The circuit

This is shown in **Figure 1**, and uses an 'unknown' Plessey chip, which makes the overall circuit extremely easy to build. A 0.1 µF capacitor is connected between pins 7 and 8, a speaker (in the popular 8 to 25 Ω impedance range) is connected between pins 8 and 9. If a 9 V battery is connected with its positive terminal to pin 8 and its negative terminal to pin 1, 3 or 5, a tone will be produced in the speaker.

To make this circuit into a good Morse practice oscillator, it is necessary only to insert a Morse key into the supply rail from the battery.

However, there is another refinement which you may care to build into the circuit. The tone from the loudspeaker is different, depending upon which of pins 1, 3 or 5 you use. In the prototype, a single-pole changeover switch was used to select the tones from pin 1 or pin 3, and the Morse key would be connected to the circuit via a small jack socket. There is no need for an on/off switch, as the Morse key performs that function. The switch and the jack socket can be seen in the photograph.

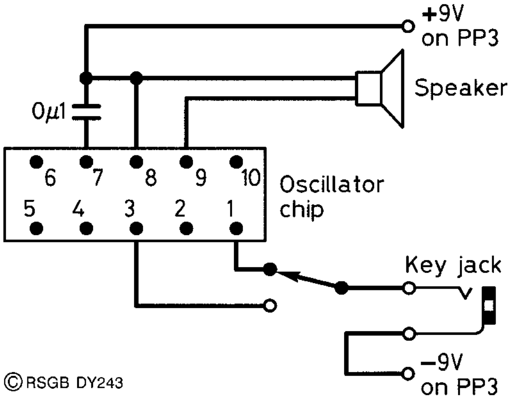

Figure 1 Morse oscillator, circuit diagram

The case

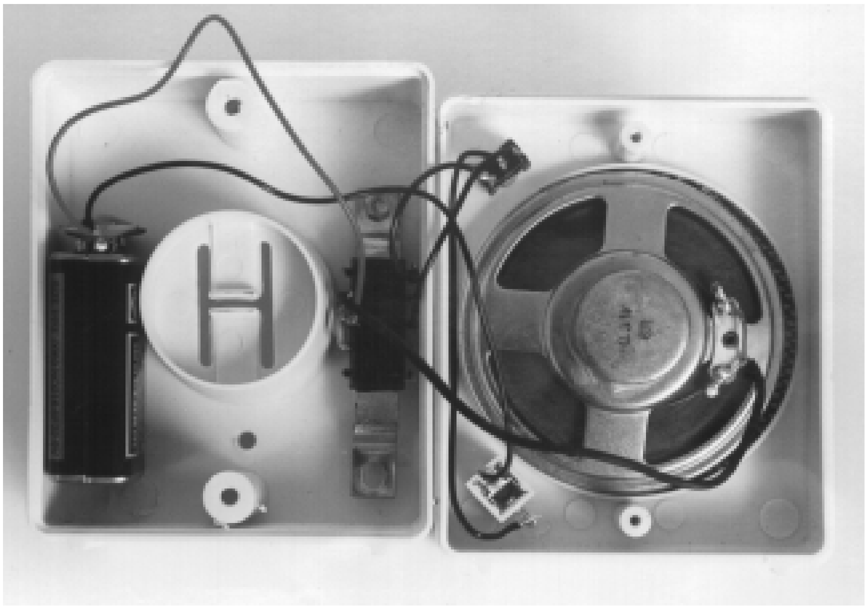
Almost any small loudspeaker will do; the higher the impedance the better. The ‘impedance’ is the figure usually printed on the rear of the speaker magnet. It is a value given in ohms (Ω). For simple circuits like this, you will usually find that the higher the impedance (within reason), the louder the sound it will produce. Speakers from old transistor radios will work, although their impedances can be rather low sometimes.

Any case big enough to house the components and the battery will be suitable. The prototype used a ‘Walkman’-type speaker and case, and is shown in the photograph.

To use the circuit, simply attach a 3.5 mm jack plug to your Morse key, and insert it into the socket. Nothing should happen until you press the key, when a tone should be heard from the loudspeaker.

Another application

Try soldering the two wires of a ‘twisted pair’ to the 3.5 mm jack plug. Touching the wires together produces a tone from the speaker. This simple circuit can then be used as a ‘continuity tester’. Touch the two wires to the ends of a fuse. If there is no sound, then the fuse is blown. There are many other such tests you could perform with this device – to check whether there really *is* a connection between one end of a wire and the other, for example.



Warning

You must **never** make such tests on any equipment which is connected to the mains supply, even if it is switched off. If you want to make any such tests, make sure you are supervised by someone who understands what you are doing and is competent to advise and supervise you.

Parts list

Plessey oscillator chip
0.1 μF capacitor (disc ceramic)
Loudspeaker 8 to 25 Ω
3.5 mm jack socket (and 3.5 mm jack plug if needed)
Single-pole changeover switch

The Plessey oscillator chip is available from J. Birkett, 25 The Strait, Lincoln LN2 1JF, tel: 01522 520 767.

John Birkett may also provide a kit of parts (the chip, capacitor and loudspeaker).

69 A bipolar transistor tester

Introduction

This is a circuit which will test normal transistors, i.e. npn or pnp. It has the advantage of being able to test devices while they are still connected in their original circuits. However, when such tests are made, **the circuit containing the transistor under test must not be switched on**.

The circuit and how it works

The circuit runs from a 9 V battery such as a PP3 or six AA-type 1.5 V cells. Alkaline cells are to be preferred, as their electrolyte leakage properties are better. The circuit shown in **Figure 1** uses a single CMOS integrated circuit type 4001 or 4011. CMOS circuits require special handling precautions which are described in the project *Christmas Tree LEDs*, elsewhere in this book.

Figure 1 Transistor tester, circuit diagram

Inside the IC are four logic gates (see *Digital Logic Circuits*) which are all connected as inverters, which means that the output signal is always the logical 'opposite' of the input. The first two gates are connected as an oscillator; the circuit being the same as that used in *An Electronic Die*.

The output of the oscillator, at pin 11, is connected to the input of a buffer stage, IC1c, which helps to isolate the oscillator from the circuit that follows it. The buffer output appears on pin 3, which we shall label as *test point A* for future use. Another inverter, IC1d, follows this, its output at pin 4 being labelled *test point B*.

There are two LEDs connected back to back at the circuit output. These are D5 and D6, D5 being red and D6 being green. Whatever the output of the oscillator at any instant, one of the LEDs must be lit and the other unlit. With point A positive and point B zero, the red LED is lit, when A is zero and B is positive, the green LED is lit. Because the oscillator output is repeatedly switching from one polarity to the other, the lit LED is alternately red and green. They switch between the two colours much faster than we can see, so what we think we see are both LEDs lit together.

The two 100 ohm resistors, R3 and R4, provide the bias to the base of the transistor under test. When A is positive and B is zero, the base-emitter junction of the transistor will be forward-biased, and the transistor will switch on (if it is a working npn type). When the transistor is on, it effectively short-circuits D5 (the red LED) and it extinguishes. When point A is zero and B is positive, an npn transistor will be switched off and the green LED (D6) will light. Thus, for a working npn transistor, only the green LED is lit.

If the transistor under test is a pnp type, it will switch on when A is zero and B positive, thus short-circuiting the red LED (D6). When A is positive and B zero, the transistor is off and the red LED (D5) is lit. Thus for a working pnp transistor, only the red LED is lit.

To summarise, the states of the LEDs indicate the following conditions:

- Both LEDs apparently lit: no transistor connected, or transistor permanently open circuit.
- Neither LED lit: a collector-emitter short-circuit is almost certain.
- Red LED alone: pnp transistor in working order.
- Green LED alone: npn transistor in working order.

Construction

The prototype tester was built on a piece of Veroboard measuring 15 strips by 18 holes. Cut the tracks using a track-cutting tool or a 3 mm (⅛ inch) twist drill, as shown in **Figure 2**. Notice that, in this diagram, there is no

track ‘I’, so try to avoid miscounting when you translate diagram positions to real positions on the board. Hold the board up to a strong light to ensure that there is no copper swarf shorting adjacent tracks together, and that you have made the cuts in the correct places.

Having done this, insert and solder Veropins for all the connections to be made to components not on the board itself. Then solder in the IC holder and the wire links. Then insert the other components in the order resistors, capacitors and diodes D1–D4. Some resistors are mounted vertically so that their connections are on adjacent tracks. Double check the diode polarities – it is easy to make a mistake when wiring diodes in anti-parallel! Next, connect up the off–board components, again making sure that the LEDs have the correct polarity. The probe leads for the emitter, base and collector should be made from different colours of wire and terminated in probe clips (small insulated crocodile clips).

Check carefully for dry joints and errant blobs of solder. Plug the IC into its holder, ensuring that it is inserted the right way round, as shown in Figure 2.

Testing

Without a transistor in circuit, and the battery connected, both LEDs should be lit. Connect a known good npn transistor and verify that the green LED lights. Now simulate two transistor faults: disconnect the base lead and both LEDs should light; remove the transistor and connect the emitter and collector leads together. Neither LED should light.

Repeat the tests with a known good pnp transistor. The results should be the same, except that the correct indication should now be a lit red LED. On your computer, make a small label of the bulleted list above, to fit on your tester showing the states of the LEDs and what they mean. It will act as a useful *aide mémoire* when you use the tester in future.

Using

The circuit will test transistors in isolation or in an existing circuit, i.e. prior to use. You can check the lead identifications in component catalogues such as the Maplin catalogue. The tester is ideal for going through the large bags of unmarked transistors that you can buy for a song at rallies. You can sort them into three piles – npn, pnp and dud!

Parts list

Resistors: all 0.25 watt, 10% tolerance or better

70 The ‘Yearling’ 20 m receiver

Introduction

Published to celebrate the first anniversary of *D-i-Y Radio,* this excellent receiver design forms a suitable ‘second receiver project’ for those who have successfully completed the MW receivers earlier in this series. The receiver is powered from a PP3 battery or from a mains adaptor, and can be built with the help of an experienced constructor, on a prototype board. The circuit diagram and some of the components used are shown in the separate diagram. Headphones or a loudspeaker can be used and, once the radio is completed, a few simple adjustments will make the *Yearling* spring to life!

Building the receiver

Before starting the constructional process, start by identifying all the parts. One by one, tick them off against the parts list. Are their values correct? The varactor diode is a twin type (see circuit diagram overleaf), and must be cut *carefully* down the middle, producing two devices, D1 and D2, with two wires each.

First, solder the IC sockets, followed by the coils (inductors); L1 is pink inside the top, and L2 is yellow inside. Then, solder in the varactors; the lettering on D1 should be next to coil L1, and the lettering on D2 should face resistor R7. After those, the capacitors, wire links and resistors should be soldered to the board. Take care to wire the voltage regulator, IC3, correctly. Solder in the crystal X1 as quickly and deftly as you can – crystals do *not* take kindly to having their leads bent and being fried with a soldering iron! Make sure that the electrolytic capacitors C2, C12, C15 and C16 are fitted the right way round. Most electrolytic capacitors have only the negative lead marked.

Figure 1 shows the rear of the front panel, illustrating the connections from the board and antenna socket to the controls. All normal connecting wires are 22 SWG or thereabouts, with insulation. Their lengths should be about 15 cm, except for the battery lead to the switch, which is about 8 cm. It is recommended that you use different-coloured wire for each connection to a control. **Figure 2** shows this. The variable resistor section of VR5, the AF gain control, uses single screened cable connected to 0 V (ground) at the

board end. Now fit the ICs into their sockets. Make sure that they are the right way round (see circuit diagram) and that each pin lies directly above its corresponding socket before applying *gentle* pressure with the back of the board firmly supported.

Check that all the connections are correct (don’t *assume* this – check the ends of each wire against the circuit diagram) and that all your soldered joints are shiny. Lastly, drill the five 10.5 mm diameter holes for the main controls. On the side of the case, a 6.3 mm diameter hole is needed for the speaker socket, and 8 mm holes for the antenna and earth sockets. The external power socket requires an 11 mm diameter hole.

Adjusting it

Before you can make adjustments, and in order to hear *anything* on your *Yearling*, you will need to connect an antenna (aerial) to the antenna socket. About 8 metres of wire, preferably outdoors and as high as possible, is all you need to connect to the socket. Connect the 3.5 mm jack socket for the speaker, and a 3.5 mm jack to your speaker leads. Connect a battery and switch on.

1. Using a very small screwdriver or, better still, a non-metallic ‘trimming tool’, *gently* screw in the core of L2 as far as it will go, but *don’t force it*. Then unscrew it by three turns anticlockwise.
2. Set VR1, VR2 and VR4 to mid-position and rotate the core of L1 anticlockwise until the hissing noise you hear reaches a maximum intensity. Then adjust L2 for maximum noise.
3. If you now tune carefully with the main tuning control, VR4, you should hear some amateur Single-Sideband (SSB) speech signals. You may have to adjust the bandspread (fine tuning) control, VR3, to make the speech sound normal.
4. Having verified that everything is working, switch off and mount the controls on the front panel and the sockets on the side. To do this, it is much safer to disconnect all the controls and sockets, mount them in their final positions, and then wire them up again.
5. Fit the front panel knobs, connect your aerial and switch on again, checking that everything is working. Then, locate the cluster of CW (Morse) signals to be found at the bottom of the 20 metre band, set the bandspread control to mid-position and slacken off the main tuning knob. Turn the knob (but *not* the control!) until the pointer lies a little clockwise of 14.0 MHz. The SSB signals should now lie roughly between the dial centre and 14.35 MHz. Tighten up the knob.
6. Finally, fix the board to the rear panel, and secure the battery (if you are using one). Attach the rear panel to the back of the box, and you are finished!

Listening!

Make a habit of keeping the bandspread control in its centre position when searching for stations; then you can adjust it either way to make the signals readable. Unless you have a very big aerial, it is best to have the 'RF Gain' control, VR1, at maximum. Use the 'Antenna Tune' control, VR2, to give the best signal, and control the volume with the 'OFF/AF Gain' control. You will find some excellent DX stations with your *Yearling* receiver, and it will serve you well.

71 Adding the 80 metre band to the Yearling receiver

Background

You will have noticed that your *Yearling* receiver has a dial which shows coverage of the 80-metre amateur band (3.5–3.8 MHz). This band is used for local contacts during the day, and contacts up to about 1600 miles in darkness. Longer distances are possible, particularly in the middle of winter.

The modifications

Only a few extra parts are required, as you may have noticed from the parts list. A low-pass filter, FL1 (one which passes low frequencies and rejects higher frequencies), is switched into the circuit on 80 m. The circuit of the

Figure 2 The underside of the PCB. Wires are connected from the switch and filter as shown

switch and its connections is shown in **Figure 1**. Before making the modifications, dismantle the receiver so that you have easy (and safe) access to the case and the track side of the PCB.

1. The first thing to do is to drill a 6.5 mm diameter hole in the side of the case into which the switch fits.
2. Then, using a sharp Stanley knife or scalpel, carefully cut the track on the PCB as shown in **Figure 2**, making a gap about 1 mm wide.
3. Using 10 cm lengths of different-coloured insulated wire, make the four connections, a, b, c and d, to the PCB, as shown in Figure 2.
4. Solder the two links on the filter, and then make the connections to the switch, capacitors and PCB. You will have to disconnect the existing wire between the RF gain control, VR1, and pin 4 of L1 on the PCB.
5. Lastly, check your new connections carefully, then mount the switch in the new hole and fix the filter to the bottom of the case with a little glue, as shown in **Figure 3**. Reassemble the circuit, and replace the back of the case.

More testing!

Firstly, switch your new switch, S1, into the 20 m position, to check that the original circuit still works! If you find that the 'Antenna Tune' control peaks at a slightly different position, don't worry.

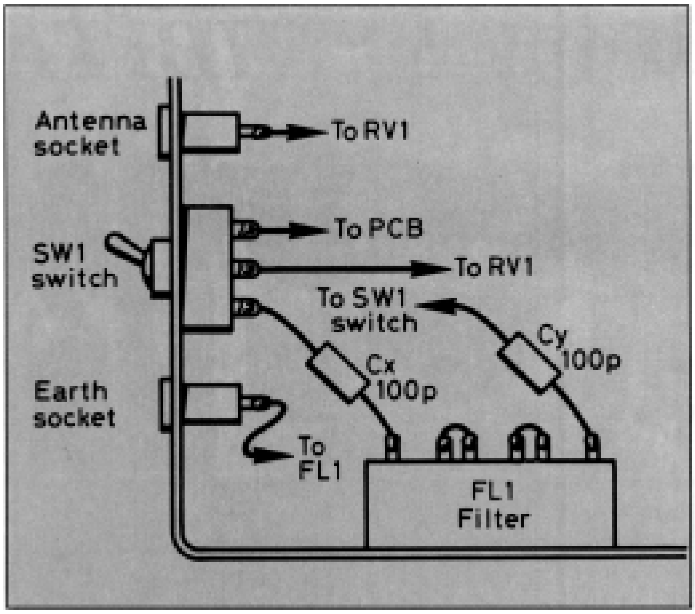

Figure 3 Internal view of the Yearling case. The filter FL1 is attached to the base with glue

Now switch to 80 m, and tune around the anticlockwise end of the dial; you should hear some SSB stations, particularly in the evenings and at weekends, when may people are on the air. At the other end of the travel of the tuning control, you should hear CW (Morse) stations.

The Radio Society of Great Britain broadcasts amateur radio news every Sunday morning on or about 3.65 MHz; the table below has the details. Finally, a good antenna is more important than ever for 80 metre reception – aim for more height and length, and then consider the project concerned with making an Antenna Tuning Unit (ATU)!

Parts list

Capacitors (all rated at 16 V or more, tolerance 10% or better)

Cx, Cy	100 picofarads (pF) polystyrene

Filter

FL1	Toko 237LVS1110 low-pass filter

Additional items

SW1	2-pole 2-way (changeover) toggle switch
7 off	Short lengths of insulated wire of different colours

The RSGB news broadcasts, GB2RS – Sunday mornings

Frequency (MHz)	*Local time*	*Reception area*
3.650	0900	SE England
3.650	0930	Midlands
3.650	1000	SW England
3.650	1100	Yorkshire
3.640	1130	Aberdeen
3.660	1130	Glasgow

The Midlands transmission is repeated at 1800 (6pm) local time on 3.650 MHz. All frequencies are approximate in order to avoid interference, and use lower sideband (LSB). If you also have a 40 metre receiver, there are GB2RS news broadcasts on 7.048 MHz at 0900 local time from Northern Ireland and from 1100 local time from the north midlands.

72 How the Yearling works

Introduction

The *Yearling* was designed to provide an introduction to *Amateur Radio* on the 20 m amateur band. Let's look at how the different sections (or 'stages') of a radio work, and how they fit together to form a complete receiver. **Figure 1** shows a block diagram which you can follow and compare with the circuit diagram of your *Yearling* receiver.

The antenna (or aerial)

Connected to your receiver, it will pick up not only amateur signals, but all other signals as well! This means that the receiver has to select the one signal that interests you, while rejecting all the others. The following stages do just that.

The RF filter

This stage (centred around L1) selects the band of radio frequencies (RF) containing the signal you want, in this case, those having wavelengths around 20 m. Signals from the 40 m band, for example, would not get through.

The crystal oscillator

This is an oscillator circuit designed around a quartz crystal (X1), and has a very stable frequency. It produces a single, very pure frequency to feed into the mixer. A crystal having a frequency between 8.800 MHz and 9.000 MHz is suitable for this circuit. The oscillator and mixer functions are both carried out inside IC1.

The first mixer

Yes, this stage 'mixes' two signals together. In this case, the two signals are (i) from the aerial via the RF Filter, and (ii) from the crystal oscillator. Two

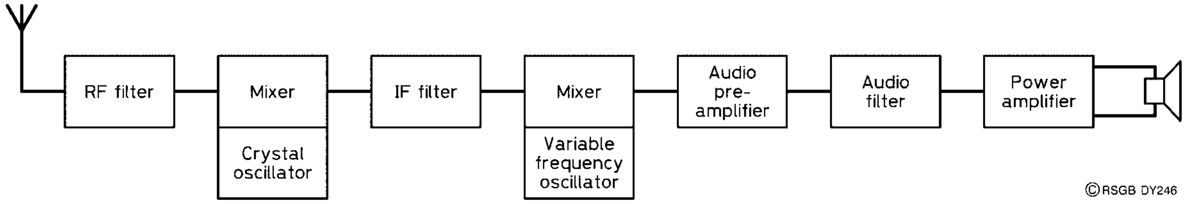

Figure 1 Block diagram of the Yearling, showing how the various stages fit together to make a complete radio receiver

bands of signals emerge from the mixer. The first is centred upon a frequency equal to the incoming signal frequency **added** to the crystal frequency, and the second is centred upon a frequency equal to the incoming signal frequency **subtracted** from the crystal frequency. Look at an example – if the signal is at 14 MHz and the oscillator at 9 MHz, then the mixer outputs will be 14 + 9 = 23 MHz and 14 – 9 = 5 MHz.

Intermediate frequency (IF) filter

It is the purpose of the IF filter (centred around L2) to select only one of these two bands of frequencies emerging from the mixer. In this case, it is the lower band of frequencies (around 5 MHz) which we select. This is because, in general, lower frequencies are easier to handle than higher ones.

Variable-frequency oscillator (VFO)

The VFO (part of IC2) enables us to tune into a particular station, and operates over a band of frequencies between 5 MHz and 5.35 MHz in this receiver. You will notice that IC1 and IC2 are the same type of chip, so that you will be expecting another mixer stage to be associated with the VFO. You are quite right!

The second mixer

This mixer obeys exactly the same rules as those of mixer 1. Sum and difference frequencies are produced, like this. Mixing is between the incoming IF signals (around 5 MHz) and the VFO signals (around 5 MHz), producing output frequency bands centred upon 10 MHz and 0 MHz. The use of the words ‘band of frequencies’ throughout this explanation is intentional. If all the signals were pure, there would be no bands; the bands are produced because of one thing – the modulation imposed on the pure frequencies at the transmitter. So, the ‘bands’ contain the one thing that we want to extract from the signal, and that is the speech or Morse code that the signal contains. The band of frequencies at 0 MHz is just that – the audio frequencies we want in the loudspeaker. Because of this, the audio frequency output of the second mixer is selected and passed on for amplification.

The audio preamplifier

Preliminary amplification of the minute audio signal which emerges from the second mixer is provided by IC4a, which will respond only to audio signals, automatically rejecting the 10 MHz signal.

The audio filter

The bandwidth of normal speech when transmitted by an amateur station is around 3 kHz, so there is no advantage to be gained in amplifying frequencies greater than this. IC4b is known as a low-pass filter, because it passes (lets through) lower frequencies and rejects higher ones.

The power amplifier

IC5 produces the final audio amplification and provides enough power (about 350 milliwatts (mW) to drive a small speaker.

How does it work on 80 m?

If you have fitted the 80 m modification to your receiver, you are probably wondering how the circuit works at this different frequency. Firstly, the filter which you fitted selects the 80 m band instead of the 20 m band. The only other slight difference lies in the way the first mixer stage works. Its job is to produce sum and difference frequencies from the incoming signal and crystal frequencies. On 20 m, it did this by subtracting the crystal frequency (9 MHz) from the incoming frequency (14 MHz) to produce an IF output of 5 MHz. On 80 m, the incoming frequency (3.5 MHz) is subtracted from the crystal frequency (9 MHz) to produce an IF output of 5.5 MHz, which is still within the tuning range of the VFO in the next stage.

73 A field strength meter

Introduction

Having a reliable field strength meter is always useful. There are two basic types – the tuned variety (also known as an absorption wavemeter) and the broad-band variety. A project centred on the tuned variety can be found in this book (*An HF absorption wavemeter*), and the way it works is also presented (*The absorption wavemeter*). This project describes an untuned or broad-band type which is every bit as useful as the tuned type, when it is the level of RF in which you are principally interested.

With the possible exception of the meter, you may have all the parts needed in your junk box. The prototype was distinguished by its meter, found at a rally, and marked 'Safe', 'Dangerous' and 'Explosive' on its scale.

How it works

The basic field strength meter uses the circuit of a crystal set, but with a meter replacing the headphones. A better design, which is used here, is that of a voltage doubler, giving more sensitivity. **Figure 1** illustrates the voltage doubler circuit.

The AC input shown will be our RF input, which will be explained soon. Diode D1 will pass the positive half of the signal and use it to charge up C1 to the peak value of the signal. D2 uses the negative half of the signal to charge up C2 to the same value. Because C1 and C2 are in series, the peak voltage appearing across *both* of them (which is the DC output voltage) is equal to *twice* the peak input voltage, hence the name voltage doubler. If you're wondering why DC is present at the output when AC comes in at the

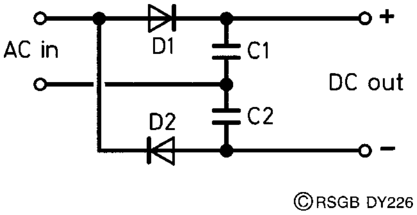

Figure 1 Voltage doubler circuit

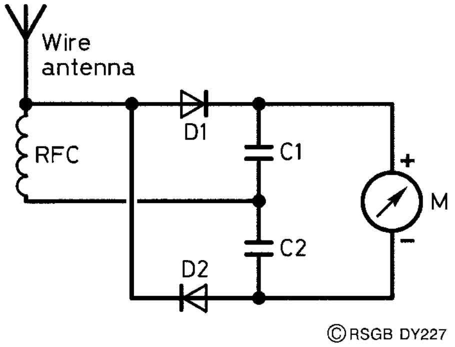
input, remember that capacitors pass AC (RF) but block DC; thus the RF is shorted out through C1 and C2, but the steady voltage (DC) remains across the two capacitors. The voltage is thus proportional to the size of the RF signal applied at the input.

The circuit

The voltage doubler is converted into a field strength meter using the circuit of **Figure 2**. A piece of wire serves as the aerial to provide an RF signal across the radio-frequency choke (RFC). A choke is an inductor which is large enough to prevent the RF passing through it – it 'chokes' the RF. This produces the maximum RF signal at the input to the voltage doubler, and the DC output from it is measured on the meter.



©RSGB DY227

Figure 2 Field strength meter

The parts used are not very critical. The RF choke can have any value between about 1 mH and 2.5 mH. Almost any common diode such as the 1N914 or 1N4148 can be used for D1 and D2. The two capacitors could be any value between 1 nF and 100 nF (0.001 μF and 0.1 μF). The meter should be reasonably sensitive, with a full-scale deflection (FSD) in the range 50 μA to 100 μA. Look for VU meters at rallies – these are ideal.

Construction

The prototype circuit was made on matrix board. If you don't want to use pins with the board, simply push the component leads through the holes and make the connections on the underside of the board, either with the excess component leads themselves, or with ordinary connecting wire.

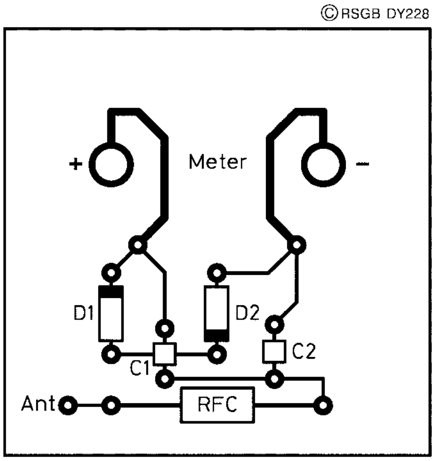


Figure 3 Board layout and interconnections

Component side of board shown.
All connections are under board

Figure 3 shows how the parts are placed and connected. The matrix board can be mounted directly on the meter using its terminal bolts!

In use

Needing no power supply other than an RF signal, just connect it all up and leave it to work! A short length of insulated wire is enough to pick up some RF and display it on the meter. Using a 200 μA meter, about 3 metres of wire gave a good deflection on the meter. To increase deflection, the wire can be wrapped around the aerial lead, provided that the wire is PVC covered and doesn't come into contact with the aerial wire.

This requires a little experimentation. Try a long piece of wire first and adjust its position until the meter needle kicks whenever there is a transmission. It is very reassuring to see the meter moving during a transmission. Although SWR meters also indicate power, they are usually set to read reverse power, and show little or no movement during transmission.

Parts list

D1, D2	1N914, 1N4148 or similar
C1, C2	10 nF disc ceramic
RFC	Miniature axial choke (1 mH)
Meter	Surplus VU meter or similar
Matrix board or similar	

Components are available from Maplin.

74 Preselector for a short-wave receiver

Introduction

A preselector is a simple RF tuned amplifier which is inserted between the aerial and the receiver. It provides some extra gain and may improve the overall performance of the receiver. This project uses a Field-Effect Transistor (FET) amplifier in grounded-gate mode.

The design has a tuned circuit at both the input and output which, with excessive gain and poor construction, would produce only one thing – oscillation! So, to avoid this happening, we will have only a low gain, and use a circuit which provides good isolation between input and output. The grounded-gate FET amplifier fulfils both these criteria. It will also cover a frequency range from about 7 to 30 MHz, which includes most of the HF amateur bands.

The circuit

This is shown in **Figure 1**. The signal from the aerial arrives at an RF transformer, the secondary of which is tuned with capacitor VC1a. The output from the tuned circuit is taken from a tap on the secondary to the source of the FET. The gate is grounded (earthed) and the amplified signal appears at the FET drain, which is then fed to the primary of another RF transformer, which is tuned by VC1b. The output to the receiver comes from the secondary of the RF transformer.

(tap L1 4 turns from ground)
L1a, L2a = 3 turns
©RSGB DY256

Figure 1 HF preselector, circuit diagram

Notice that the two RF transformers are identical, but they are used 'back to back', with the secondary of the first and the primary of the second being tuned. They are tuned with identical capacitors, fitted on the same shaft of a variable capacitor. We say that the two capacitors are 'ganged'. Because L1 and L2 are the same, and VC1a and VC1b are the same, both RF transformers should be resonant at the same frequency, no matter what that frequency is.

Construction

The final layout should look something like that shown in **Figure 2**. The external connectors and controls being two SO-239 sockets for connection to your receiver and aerial, a tuning control and its associated scale, and an on/off switch.

The circuit can be put together on a plain matrix board, using pins to anchor the components, or simply by pushing the component leads through the board and making connections on the underside. The layout of the prototype is shown in **Figure 3**. Mounting the board to the aluminium box is accomplished with bolts, solder tags and stand-off insulators.

Check your construction against the circuit diagram and against the layout diagram. Wire in the PP3 battery clip, put the switch in the 'off' position, and fit the battery. Testing can be carried out without fitting the top of the box.

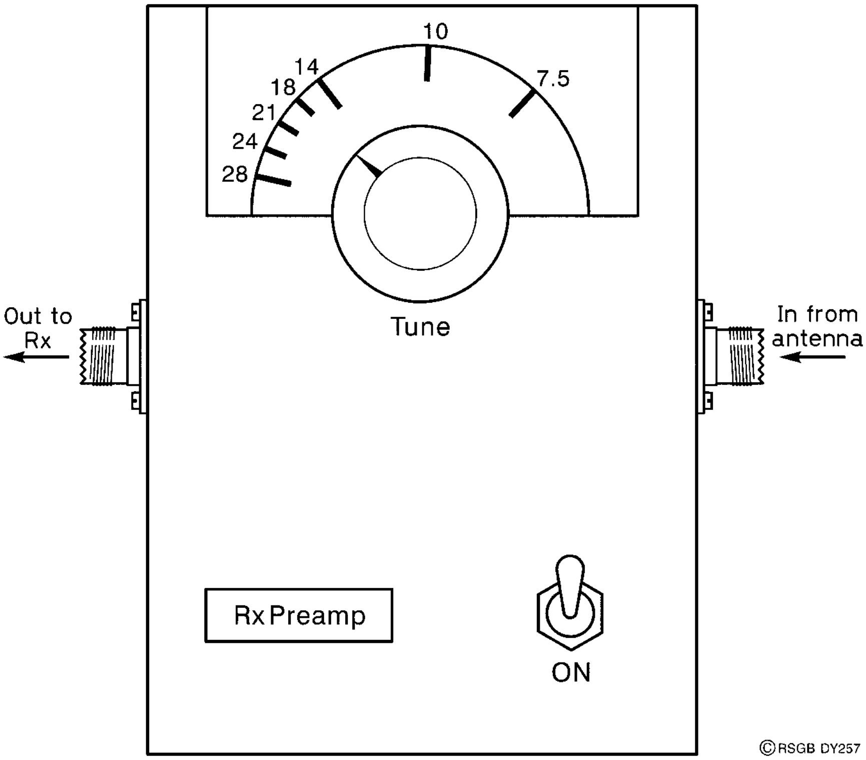

Figure 2 HF preselector, front panel layout

Testing

Don't fit your preselector yet. Tune your radio to a broadcast station, preferably a fairly weak one. Disconnect the aerial and fit your preselector between the aerial and receiver. Switch it on and rotate the tuning knob slowly. You should find a position where your original station is received more clearly than before. If it doesn't work at all, recheck your wiring. Is there a positive voltage on the drain of the FET? If not, work back towards the positive battery terminal. Is there a voltage at the junction of L2 and R2? Is there a voltage at the junction of L2 and R3? Is there a voltage at the junction of R3 and the battery lead? If there isn't a voltage at that point, then you have probably mounted your switch upside down, and it is off, not on! It's a common mistake.

Calibration

This is not obligatory, surprisingly enough. However, if having a frequency scale appeals to you, then using an RF signal generator (or using the services of a friend who has one) is the simplest solution. Feed in a weak modulated

signal from the generator to the preselector, and rotate VC1 until the signal is maximum. Mark this frequency on your dial. Repeat the process for the frequencies shown on the dial in Figure 2.

If you have a commercial transceiver, feed its output into a dummy load (such as the type described in *A Switched Dummy Load*, elsewhere in this book) using a distinctive modulating signal such as an idling RTTY signal. Set the receiver to the same frequency with the preselector out of circuit. Insert it into the aerial lead, and search for the signal with VC1 until it gives the maximum deflection on your S-meter, then mark the frequency on your dial.

75 An audible continuity tester

Introduction

This is not the only continuity tester in this book. This alone attests to their use, so you may well want to experiment with several designs, then come up with one of your own! The very simplest form of continuity tester is probably a battery and a bulb in series, with the circuit being closed by connecting it to a fuse or other object being tested for continuity. The bulb could be replaced by a buzzer to give an audible indication. The current taken by the buzzer could damage some components, however. An ohmmeter can also be used, and is very popular for the purpose, as it indicates whether the circuit is low, medium or high resistance. This project has the advantages of indicating whether there is no continuity, some resistance or good continuity, and making an audible sound, so that you don't have to move your eyes from the circuit while making the test.

The circuit

Using only one integrated circuit, four components and a battery, this is a particularly simple circuit, as **Figure 1** shows. IC1 is usually used to flash an LED from a 1.5 V source, and to have a low current consumption. By changing the component values, IC1 is made to oscillate at audio frequencies, and we can hear these through the loudspeaker, LS1. Low-impedance speakers can be used, but result in an increased current drain, so the higher the impedance, the better.

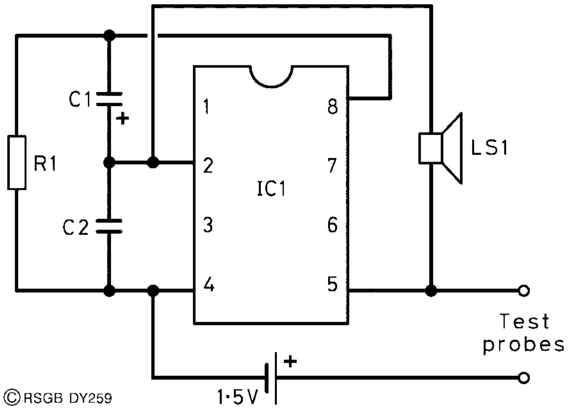

Figure 1 Continuity tester, circuit diagram

Construction

The layout of the circuit on Veroboard measuring 7 strips by 15 holes is shown in **Figure 2**. Start by making the four track cuts which will lie underneath the IC. Use a track cutter or a 3 mm ($\frac{1}{8}$ inch) twist drill rotated between thumb and forefinger for this. Solder the Veropins in place, followed by the wire link. Then solder in the IC holder, the resistor and the capacitors, making sure that the electrolytic capacitor, C1, is connected the correct way round.

Check, with the board against a bright light, that there are no shorted tracks, either by large blobs of solder or by copper swarf from the track-cutting process. Then insert IC1 into its holder the right way round. The probes can be ordinary connecting wire, the free ends being tinned with solder to prevent wire whiskers from touching components other than the one you are testing.

If you are happy that the circuit and the wiring appear to be correct, fit the battery into its clip. Nothing should happen until the probes are touched together, when you should hear a note from the loudspeaker. If nothing happens, all you can do is to recheck your circuit, as there is nothing else to go wrong!

Figure 2 Continuity tester, component layout

Any box can be used; there is no justification for a metal case, unless you want to make use of something, which is to hand, such as a tobacco tin. Alternatively, any suitable plastic box will do.

Use

The tester will give different pitch notes for resistances of different values. The higher the resistance, the higher the pitch from the speaker. Try it with small inductors, and you will learn to recognise the different tones produced by the IC.

Safety notice

Using the continuity tester on components *in situ* is not advisable, as the results could be misleading. It can be dangerous to make measurements *in situ* on equipment, which is operating. If you must make such tests, always disconnect the equipment form its power source first.

Parts list

Resistor

R1	1000 Ω (1 kΩ), 0.25 W carbon, 10% or better

Capacitors

76 An experimental 70 cm rhombic aerial

Introduction

Most commonly used aerials can be classed as *resonant* or *standing-wave* aerials. There is another class known as *non-resonant* or *travelling-wave*. Resonant aerials, such as the dipole, are narrow-band; this occurs because resonance occurs only over a narrow band of frequencies. Travelling-wave aerials, on the other hand, can operate over a wide band of frequencies.

The *rhombic* is an example of a non-resonant or travelling-wave aerial. It is often employed for fixed commercial and military short-wave radio links. Made with wire, it has a diamond shape when looking down on it from above. The four corners are supported on four masts. It is a very effective aerial, and has good gain, a quality which can be judged from the *polar diagram* shown in **Figure 1**. This has been obtained from a computer program, and so is the perfect shape for a rhombic aerial.

Theory (but only a little)

A polar diagram shows graphically the ability of an aerial to radiate (or receive) more effectively in one direction at the expensive of the radiation in other directions. Figure 1 shows the polar diagrams of two aerials, a simple 70 cm dipole and the rhombic described in this project. The dipole has the

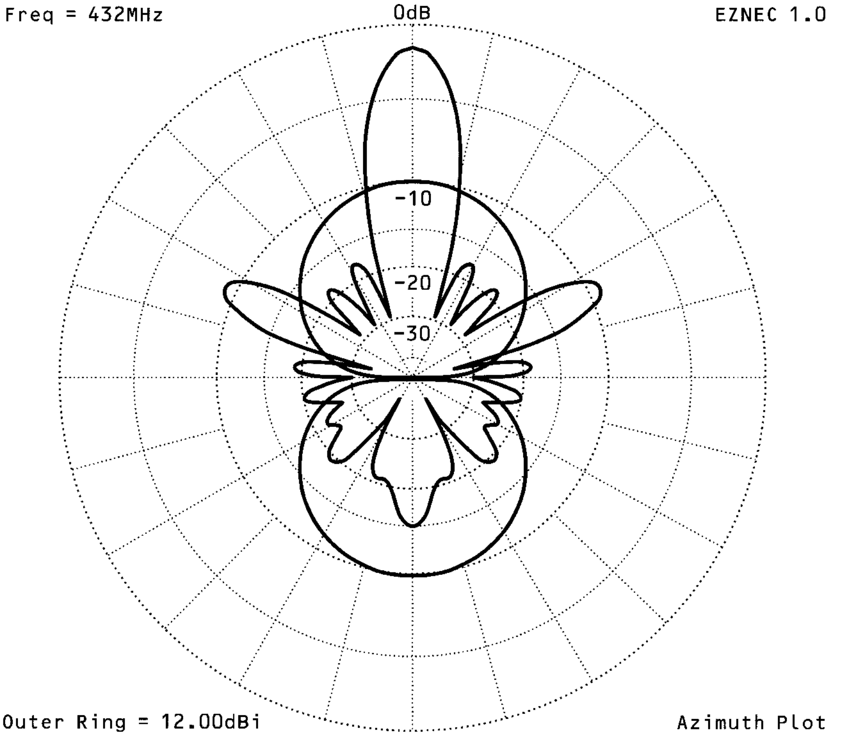

Figure 1 The horizontal polar diagrams of the small rhombic antenna and a dipole compared

©RSGB DY262

well-known figure-of-eight shape, showing a symmetrical angular behaviour about the direction of the aerial and about a direction perpendicular to the aerial. That of the rhombic, on the other hand, is quite irregular by comparison, but is still symmetrical about one axis only, not two. It's this asymmetry that gives the rhombic its gain, by virtue of its *front-to-back ratio*. This is the ratio of the power radiated forwards to that being radiated backwards. Notice the large *lobe* (lump) at the top of the polar diagram; this is the direction in which the aerial transmits best. The lobe in the opposite direction has been reduced significantly, allowing more power to be directed forwards, not backwards

Problems

The rhombic is not found in every amateur's back garden, despite its attractions. To work best each edge of the diamond shape should be about two wavelengths long. Hence, a rhombic for the 20 metre band could be about 80 m from tip to tip! Another disadvantage is that, because of its size, it cannot be rotated.

It will operate well over a range of frequencies. An HF rhombic could work on the 7, 10, 14, 18, 21 and 28 MHz bands. One for the lower VHF frequencies could operate on the 50, 70 and 144 MHz bands.

Its large size is less of a problem at UHF. A portable rhombic can be made for 70 cm which can be used with a hand-held transceiver. The aerial design to be described here will give a gain of up to 9 dB relative to a dipole. This is written as 9 dBd, the second ‘d’ meaning ‘relative to a dipole’. This is equivalent to improving your signal by 1.5 S-points at the receiver or (and you may be surprised by this) by fitting a linear amplifier to your transceiver that would take 5 W input and produce 40 W output to a normal dipole! Consider the relative costs of the two approaches to producing the same received signal. You will also receive everyone else’s signals 1.5 S-points better than before!

Unlike the popular Yagi aerial, this design has no critical dimensions and can be folded up for transport by car or bicycle. It has a fairly high input (or feed) impedance, being fed usually by balanced twin feeder. To feed it with standard 50 Ω coaxial cable, a matching transformer in the form of a *balun* is required. A balun will convert the *bal*anced (symmetrical) aerial impedance to the *un*balanced and lower impedance of the coaxial cable. The details of how to build the balun, which in this case is a half-wave transformer, are included in the constructional details.

Construction

The aerial frame is made up of 1 cm × 2 cm strips of wood fixed to a plywood centre using 30 mm long M4 bolts, as shown in **Figure 2a**. The outer bolts fixing the front and side supports can be removed for folding prior to transportation, as shown in **Figure 2b**.

The wires are fixed to the front and rear supports using screw connectors, sometimes called ‘chocolate block’ connectors. Detail X and Y of Figure 2 show how this is done. The side supports have holes in the ends through which the wire is threaded.

The aerial must be mounted in the horizontal plane using a small shelf bracket attached to the centre plate, using the same bolts that hold the rear support. The other half of the bracket may be mounted to a vertical mast using screws or jubilee clips (hose clips).

The balun

Cut a 23 cm length of coaxial cable; this is to be our half-wave transformer. Cut and remove 2 cm from each end of the sheath. Make the braid into a pigtail at each end. Cut and remove 1 cm of the inner insulator from each

Figure 2 Construction of the UHF rhombic antenna

end, leaving 1 cm of the centre conductor exposed. Fasten this piece of cable to the chocolate block connector together with the coaxial feeder cable as shown in Detail Y of Figure 2. The braids of all three prepared ends are soldered together, but are not connected to anything else. The inner conductor of the feeder from the transceiver is soldered to one end of the centre conductor of the 23 cm piece, and is connected to one end of the rhombic by one side of the chocolate block. The other end of the half-wave transformer also goes to the chocolate block, where it is connected to the other side of the rhombic loop.

The opposite corner of the rhombic, as shown in Detail X of Figure 2, shows that the loop is broken at the chocolate block, and is 'terminated' by two 600 Ω resistors in parallel. This makes the aerial a broad-band travelling-wave device, and gives it its directivity and gain. There is a rule of thumb, which includes a safety factor, which says that the terminating resistor must be able to absorb one-half of the maximum transmitter output power. So, if you use two 2 W 600 Ω carbon resistors (*not* wire-wound resistors) in parallel, you can use a transmitter with an output of 8 W, which is more than adequate for 70 cm hand-helds.

Using the rhombic

Fit the aerial to a pole or mast in the horizontal plane, if you intend to use CW or SSB, but in the vertical plane if you want to concentrate on FM work. In the latter case, a wood or fibreglass pole is mandatory. Tune to a local repeater, whose signal strength you know. Rotate the aerial to face the repeater, and you should see that the signal strength is greatly improved! Verify the directional properties of the aerial by rotating it and observing the changes in signal strength on your S-meter.

77 Water level alarm

Introduction

This is a simple device which, when you have built it, you begin to wonder how you ever managed without it! It will sound a buzzer when the level of water reaches a particular point, which you can set and vary at will.

Detecting water

Water is not too difficult to detect electrically, because it is a conductor of electricity. Not a good one, but sufficiently so to carry enough current to control a warning circuit.

The circuit is shown in **Figure 1**. If you imagine a resistor placed between the ends marked 'water detector', the circuit is then recognisable as a transistor used as an electronic switch. Whether the switch is off or on depends on the value of this resistor. If the resistance is low, the transistor switches on and the buzzer sounds. If the resistance is high, the transistor switches off and the buzzer stops.

Figure 1 Circuit diagram of the water level detector

Construction

The unit is made in two separate sections – the detector board (**Figure 2**) and the main board (**Figure 3**). The main board is plain perforated board (without copper strips). The components are pushed through holes in the main board and connected together on the underside. The battery is held on with sticky tape. No on/off switch is used, as the circuit consumes virtually no current when it is not sounding the buzzer.

Unlike some buzzers, this type is polarised, and the red lead must go to the supply as shown in Figs 1 and 3.

The detector board is a piece of standard matrix board – the type with copper strips along one side. It measures 9 strips by 15 holes, and is wired in such a way that alternate strips are connected together, as Figure 2 shows. This gives a greater surface area for the water to touch, thus increasing the sensitivity of detection.

Figure 3 Water detector constructed from stripboard

The two boards are connected by ordinary twisted pair, enabling the detector to hang over the edge of the water container, with the buzzer circuit safely out of the way. When positioning the detector board, the left-hand edge (as shown in Figure 2) should face downwards, with the connecting-wire edge facing upwards. When the water level rises, the water causes current to flow between adjacent strips, and the higher the water, the lower the resistance between them. Eventually, the resistance will be low enough to turn on the transistor and sound the alarm.

78 A delta loop for 20 metres

Introduction

HF aerials take up a lot of room when they are straight. Space can be saved by bending them and, at the same time, giving them properties which are quite different from their original linear forms. The delta loops shown in the accompanying diagrams have the shape of the Greek upper-case letter delta (Δ) upside down. It can be upright, except that it is more practical to have the feed point at the bottom than at the top.

Putting the loop together

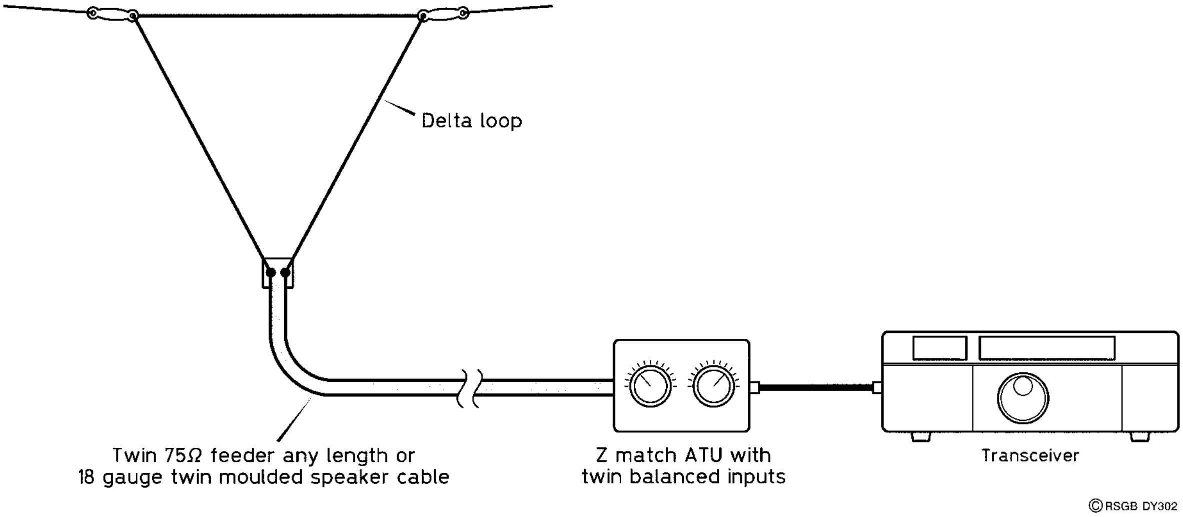
This is the design for a loop to be used on the 20 metre band. It is a very popular band and carries most of the amateur radio DX traffic. The aerial is light in weight and operates best if the top section is at least 30 ft above the ground, with the feeder point being about 6 ft above ground. All you need is some good wire, some polypropylene rope, some insulators and a method of matching the output of this 75 Ω balanced aerial to the 50 Ω unbalanced coaxial input of your transceiver or receiver.

Each of the three sides must be 7.2 m long. Using tent pegs or six-inch nails, mark out the three corners on the lawn, making sure that each pair of pegs or nails is exactly 7.2 m apart. Put the wire around the nails, together with two insulators on the wire for the two top corners. These insulators can be of the ‘dog bone’ variety, or of the home-made type, using a piece of flat plastic with holes in each end. The use of these is shown in **Figure 1**. Located at the positions of two of the tent pegs or nails, they must be secured at those points by any convenient means.

Now attach a support rope to the free end of each of the insulators, ready for suspension, as shown in the diagrams, from any convenient supports (house, tower, tree, etc.). The top section of the loop could be taped to a continuous piece of rope between the two supports. You might like to try this if you think it is easier. Then, when you find some dog-bone insulators, you can change the design and see if there is any noticeable change of performance.

Connecting to the radio

If you are the proud possessor of an aerial tuning unit (ATU) with a balanced output, all you will need is a length of twin cable soldered to the



Delta loop
Twin 75Ω feeder any length or
18 gauge twin moulded speaker cable
Z match ATU with

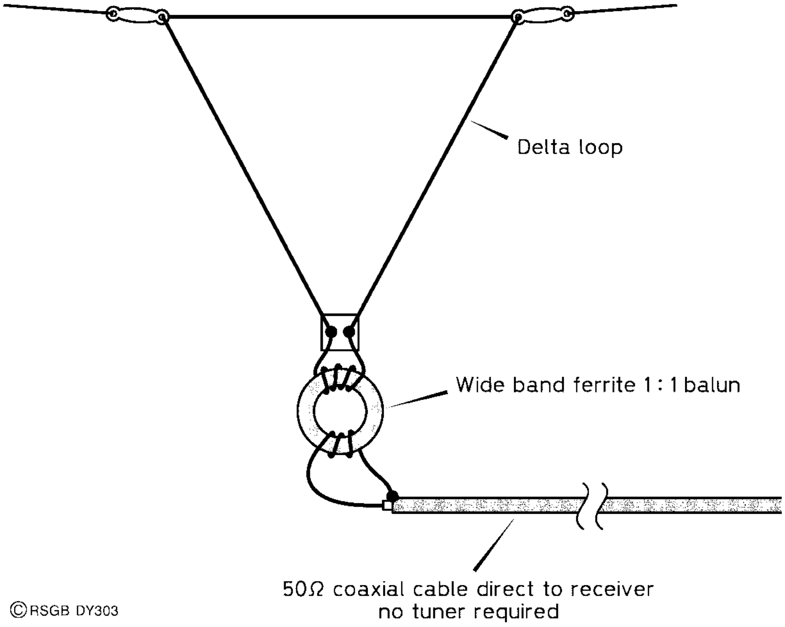
Transceiver
©RSGB DY302

Figure 1 Multiband version of the delta loop connected to the ASTU using 75 Ω twin feeder

ends of your delta loop and connected to the balanced output terminals on the ATU, as Figure 1 shows.

Another way is to buy a ferrite-cored 1:1 balun, and use it as indicated in **Figure 2**. This produces an aerial which will operate over the whole range of amateur and commercial short-wave frequencies, when used with an ATU.



Delta loop
Wide band ferrite 1 : 1 balun

Figure 2 Multiband version of the delta loop using 75 Ω coaxial cable. This arrangement requires an ASTU if used with a multiband antenna

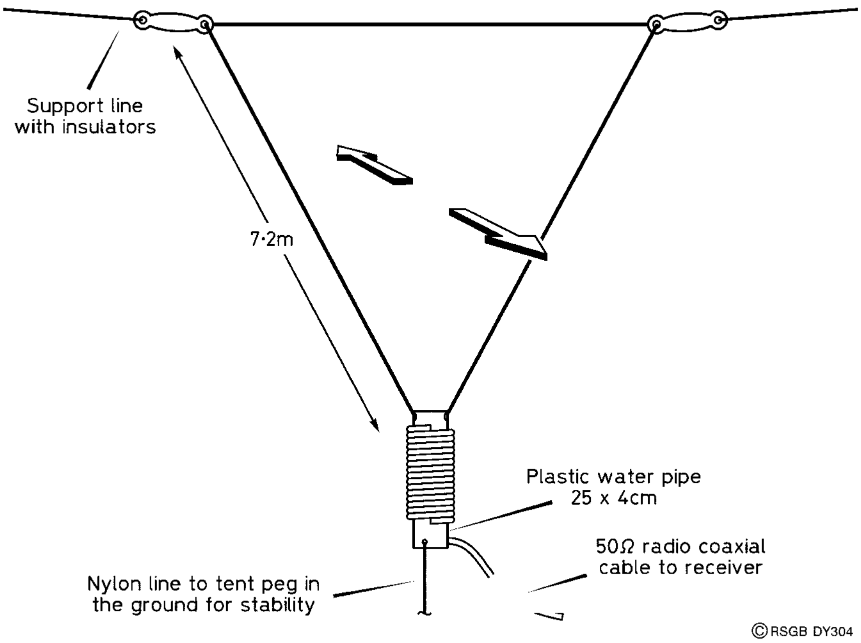

Figure 3 Single band version of the loop antenna using a coaxial balun. The direction of maximum signal strength is indicated by the arrows

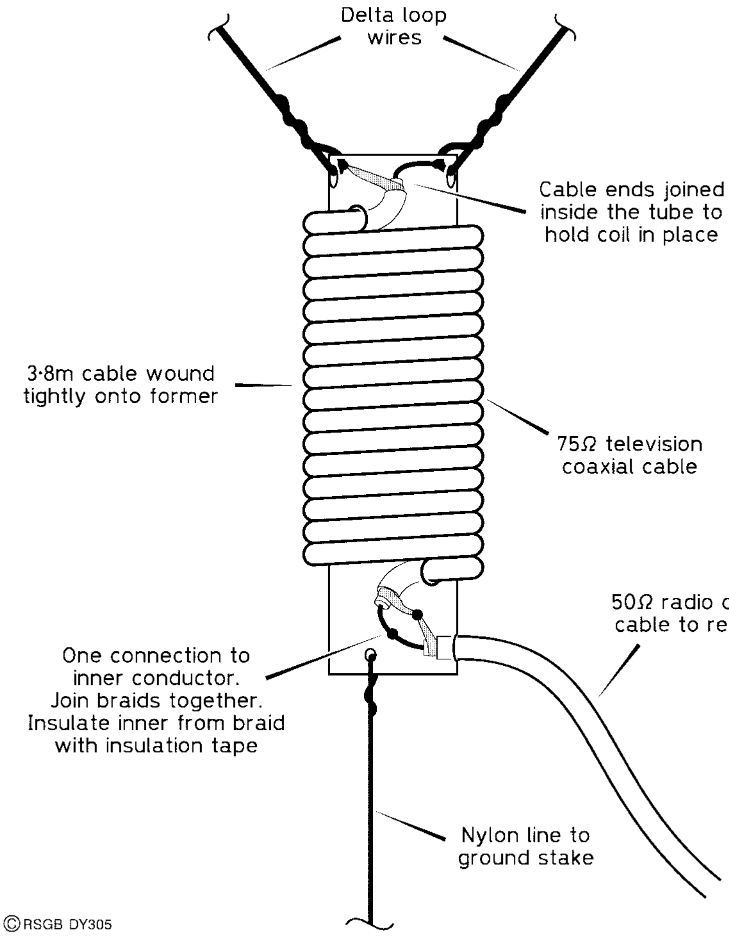
However, since this aerial is designed to be a single-band type, there is a simpler answer to the problem of matching the aerial to your 50 Ω coaxial cable – **Figure 3** shows this. Make a tuned balun with a length of plastic water pipe, 25 cm long and 4 cm diameter and a piece of good-quality TV aerial cable. TV aerial cable has a characteristic impedance of 75 Ω, compared with the 50 Ω of the coaxial feeder that we usually use with amateur radio equipment. Use the type with a brown sheath and a closely knit earth braid, not the type having an earth foil inside the sheath.

The length we need for the balun is 3.8 m, but always allow between 3 and 4 cm extra for preparing the ends. Drill two small holes diametrically opposed in the top of the tube; these will be used to anchor the two ends of the delta loop, as shown in Figure 3. Drill another single hole in the bottom end of the tube, which will be used to anchor a nylon line going to the ground to add stability to the loop. Then, after drilling a pilot hole, drill a 5 or 6 mm hole near the top end of the tube, as shown in **Figure 4**. Prepare both ends of the coaxial cable, then feed one end into the tube, far enough for its ends to be soldered to the ends of the loop when the assembly reaches that stage.

Now, close-wrap the cable around the tube until only about 3 cm remain. Holding the cable tightly, drill another 6 mm hole beside the free end of the cable and feed it into this hole. At this point, feed the two ends of the loop into the top two holes and twist it back on itself. Figure 4 shows how this is done. Then, solder the ends of the coaxial balun to the ends of the loop.



Delta loop wires

75Ω television coaxial cable
50Ω radio coaxial cable to receiver
One connection to inner conductor. Join braids together. Insulate inner from braid with insulation tape
Nylon line to ground stake
©RSGB DY305

Figure 4 Construction of the balun

The bottom ends of the balun are then soldered to the 50 Ω coax which goes to your shack and to the transceiver.

Hoist the aerial into position carefully, being careful not to pull too hard on the support lines. Then, take the nylon line from the bottom of the balun to a peg in the ground. This adds stability to the aerial.

Using the delta loop

It is a directional aerial, as Figure 3 shows. It produces maximum power (and has maximum receive sensitivity) along a direction perpendicular to its own plane. Don't be too concerned with which direction it is pointing at first. Give it a try 'on the air' and see how it performs. Then you can contemplate how to point it in your favourite direction, to the USA, or Australia, for example.

Experimenting

You may want to enclose the balun in some sort of weatherproof container. Plastic ice cream containers are favourites for this sort of job. Seal all the holes where wires enter it with silicone sealant or self-amalgamating tape.

If you have used ordinary single-strand or multi-strand wire for your aerial, it will stretch over time under its own weight and that of the balun. Its operating frequency will fall slightly as a result. If you notice a significant difference, then dismantle it, remeasure and fix the sides and erect it again, perhaps facing a different direction. You can buy pre-stretched or hard-drawn wire for such purposes, if you feel that periodic tweaking of your aerial is a chore.

You can make a delta loop for different frequencies simply by scaling the lengths of wire for the loop and for the balun according to the design frequency. If your maths isn't quite up to this, enlist the help of someone well versed either in maths or aerial design!

79 A simple desk microphone

Introduction

A hand-held transceiver is usually the first type used by most novices. It is ideal when used out of doors, in the shack or mobile. However, using one in the shack with an outside aerial is not the best of solutions.

This article describes the design of a desk microphone which can be used either for transceivers using a common microphone and push-to-talk (PTT) line, or for those using a separate PTT line.

It is a simple design, using the barrels of two plastic pens, the lid of an old coffee jar, and the plastic sheath of a DIN plug.

Construction

The end caps and the ink tubes should be removed from two ball-point pens, leaving only the two plastic shells. One of them is used for the vertical microphone support, while the other is used to hold the microphone element.

The vertical support should have the pointed end shaped so that it holds the microphone support at a convenient angle, as **Figure 1** shows.

The base should be prepared next – see **Figure 2**. Four holes are required. Two, A and B, are small holes for the cable to be fed through. A third, C, is slightly larger and is used to take one of the plastic end caps. The fourth hole, D, is determined by the type of switch that you want to use for the PTT function.

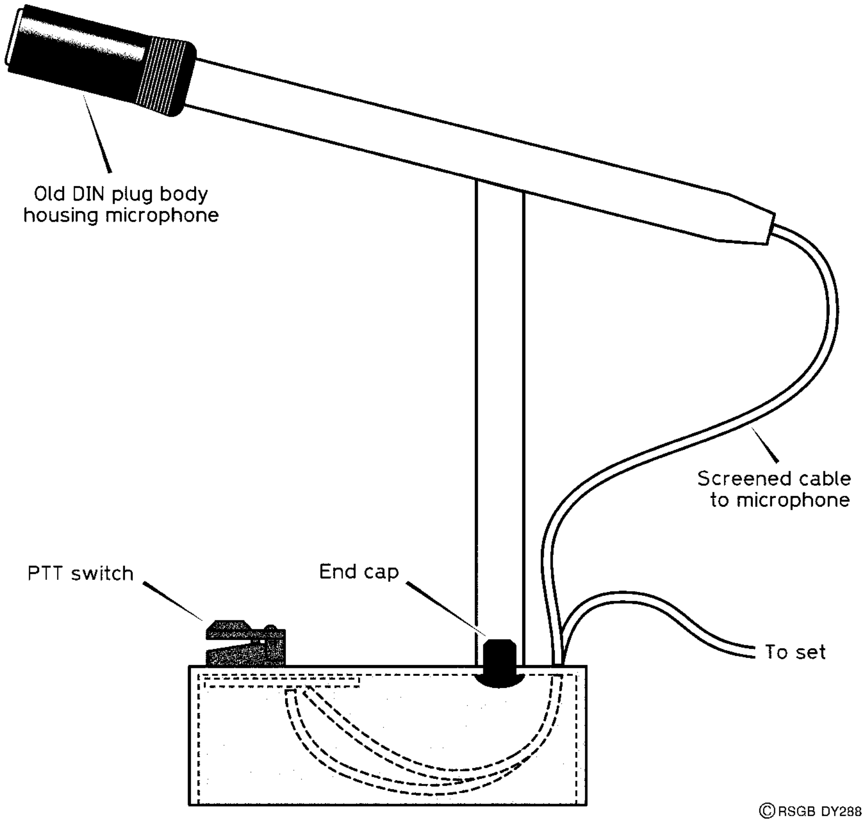
Figure 2 The microphone stand base

Some epoxy resin such as Araldite Rapid is used to mount the separate parts. Mix only a small amount at a time, and glue each part of the base assembly and allow to harden before moving on. Be sure to read and follow the instructions for the use of the glue to prevent accidents.

Firstly, glue the end cap to the base, feeding it underneath and pushing it up through hole C. Then, the vertical pen body is placed over the protruding end cap and glued into place, making sure that the top (shaped) end is pointing in the right direction to hold the other plastic tube carrying the microphone. While the glue hardens, place the DIN plug sheath on the second pen body. Place and glue this pen body on the shaped top of the vertical support, making sure that the whole assembly is supported while the glue sets. What you should have now ought to resemble **Figure 3**, but without the microphone and wiring. Leave everything to set for 24 hours.

Any switch of the press-to-make variety can be used for your PTT switch, but choose one which does not apply too much force to operate! If you find the whole assembly is too light and slides over your table, some plasticine can be pushed into the base when all the wiring has been completed.



Old DIN plug body housing microphone
Screened cable to microphone
PTT switch
End cap
To set
©RSGB DY288

Figure 3 Complete microphone stand assembly

The circuit

A small electret condenser microphone is used, powered by a DC supply. Most hand-held radios use a single screened lead for both the PTT line and the microphone audio lead. In such cases, the circuit of **Figure 4** will operate the PTT function. Note that the PTT switch is in series with the audio lead from the microphone. If you find that the PTT switch does not switch your radio into transmit, reduce R1 from its normal value of 33 kΩ to 27 kΩ. You should find that the original value works with most hand-helds.

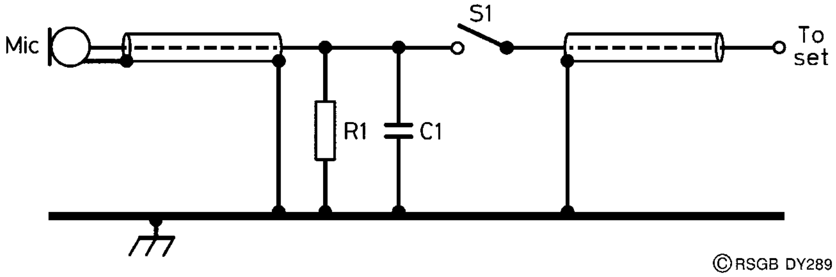


Figure 4 Wiring diagram for hand-held radios

For radios with a separate PTT lead, the circuit of **Figure 5** is used. However, a power supply is needed for the electret microphone. This can be a PP3 battery, or can (in most cases) be derived from the microphone socket on the transceiver. You will need to consult the makers' handbook for this information. Figure 5 shows the PTT switch wired in a 'ground-to-transmit' configuration, which is correct for most base-station transceivers. If you're in any doubt about what your radio needs, consult an experienced friend.

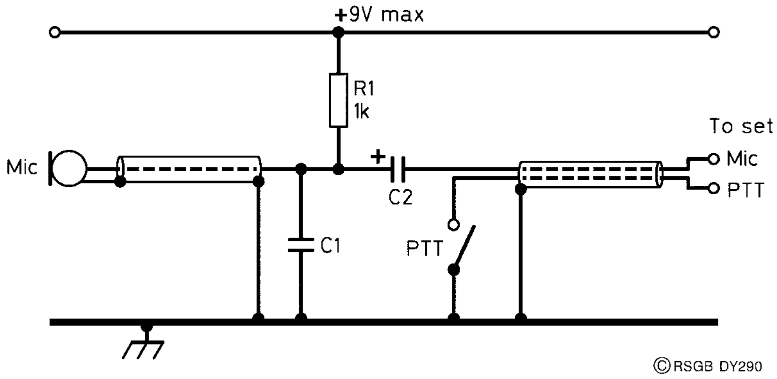

Figure 5 Wiring diagram for radios which use separate PTT lines

The last connections

The microphone element should be connected with screened cable. Tape (masking or insulating) should be wound around the electret insert until it is a snug fit inside the DIN plug sheath. Feed the screened cable through the barrel of the pen until it emerges from the far end. Poke it through hole B and make the connections under the coffee jar lid. The components can all be mounted on the PTT switch or on a small piece of Veroboard mounted under the top surface. The output lead emerges through hole A and is of sufficient length to reach your transceiver. A suitable plug needs to be fitted to it.

80 Morse oscillator

Introduction

This is not the simplest Morse oscillator to build, but it differs from the simple circuits in that it produces a pure note, not a coarse, rasping sound. People who have practised Morse using a non-sinusoidal oscillator sometimes find that they have trouble copying Morse code with a pure tone. As the pure tone is the correct way to receive Morse code, it is important that you should learn to listen to the code from a pure oscillator – so here's one!

The twin-T

There are many oscillator circuits, and there are many variations of the twin-T oscillator that we are going to use. **Figure 1** shows one version of a very useful circuit. All oscillators must have positive feedback in order to work. The feedback determines the frequency of the note produced by the oscillator.

Figure 1 Circuit diagram of the sinewave oscillator and amplifier

Here, the feedback circuit looks like two letter Ts. If you look at Figure 1, one T is formed by R1, R2 and C3, the other by C1, C2 and R3 – hence the name 'Twin-T'. Notice that the two Ts are connected in parallel between the collector and base of TR1, so any signal appearing at the collector is fed into both Ts. What emerges is then fed back into the base, producing in turn a signal at the collector. And so it goes on, producing a sine wave output.

The oscillator output is fed into an integrated circuit amplifier for output via a small loudspeaker.

Putting it together

The prototype was constructed on plain matrix board (the type *without* the copper strips), as shown in **Figure 2**. The components have their leads pushed through the holes in the board, and connections are made underneath.

Build the amplifier circuit first, using a socket for IC1. Connect the 9 V supply and touch pin 3 with an ordinary piece of wire. If a buzz is heard from the speaker, all should be well. If not, check your circuit and make changes until it does.

Build the oscillator circuit, and connect its output to the volume control VR1 via C4. Set VR1 half-way along its travel and switch on. A note should be heard from the speaker when the Morse key is depressed. The component values making up the twin-T determine the frequency of the note. Try varying them if you think your note is too high or too low. Whatever changes you make, either to the resistors or the capacitors, always ensure that R1 = R2 and that C1 = C2.

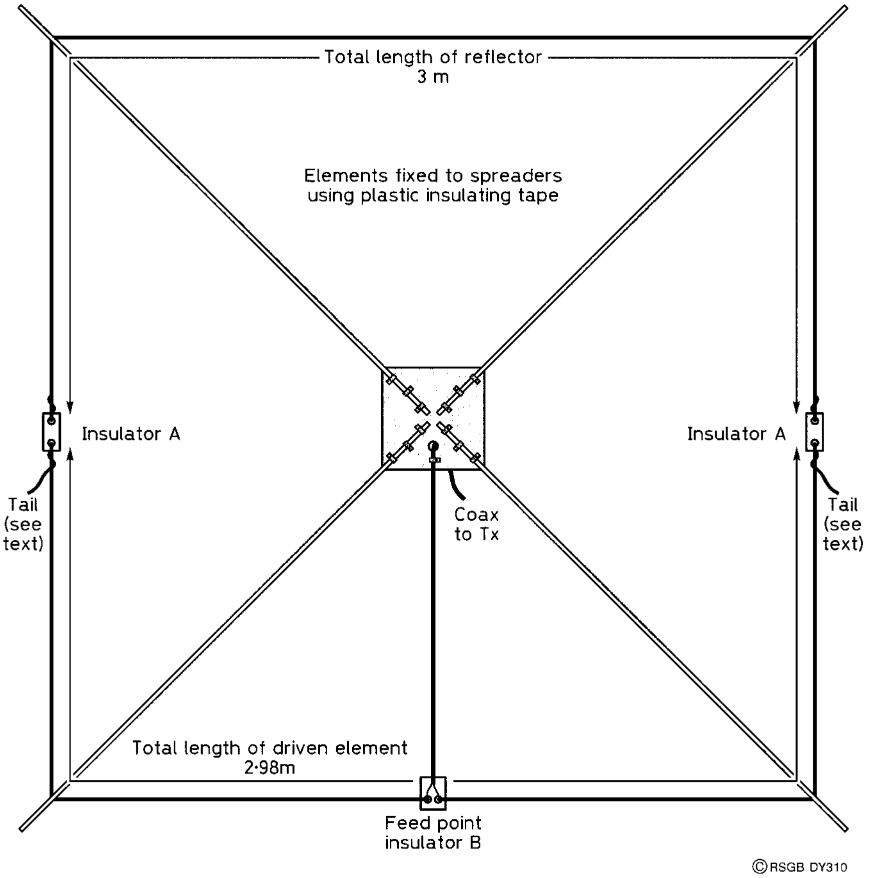
81 A simple 6 m beam

Introduction

The attraction of building your own aerials is an abiding feature of our hobby. You can *buy* almost any shape or size of aerial, but one you have made yourself can often work every bit as well as a commercial device costing ten times as much.

The design

This aerial, designed for use on the 6 m band, is essentially a two-element Yagi, with the elements bent in order to reduce the physical size. It is known



Total length of reflector
3 m

Figure 1 Plan view of the complete 50 MHz VK2ABQ antenna

as the VK2ABQ beam, and was designed originally for the 20, 15 and 10 m bands, principally because of its space-saving qualities. It is made using a wooden frame and wire elements, and is ideal for portable operation.

Tools ready?

The beam is shown in **Figure 1**. The driven element is the one whose centre is fed by the coaxial cable, and lies between the two insulators marked A and the feedpoint at B. The reflector is also anchored at the points A, and lies over the upper half of the frame.

The wooden centrepiece is used to support the cross-pieces and to mount the aerial on the mast, using a common shelf bracket. The cross-pieces, known as *spreaders*, can be wooden canes or dowelling, and are mounted to the centrepiece using cable clips and adhesive. **Figure 2** shows how this is done.

If the aerial is to be a permanent installation, the spreaders should be weatherproofed using a good-quality exterior varnish. The wire elements are PVC covered and fed through holes in the spreaders.

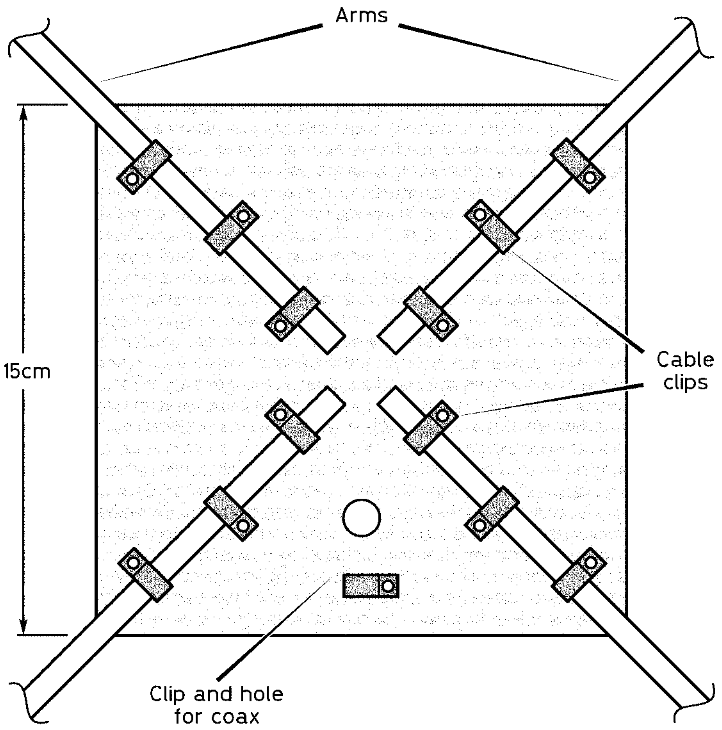

Figure 2 Centre support piece

©RSGB DY309

The end insulators are made of drilled perspex, and the wire passed through the two holes and twisted, as shown in **Figure 3**.

Note: if you have not drilled holes in perspex before, take care! The drill bit must be well-lubricated because it generates a lot of heat (enough to melt the perspex and jam the drill). Never turn the drill for more than a few seconds at a time, and moisten the bit in between. Start with a pilot hole and use bits of increasing size until the hole is the size you want.

Another perspex insulator is used to secure the feeder to the aerial, as shown in Figure 3. The feeder then passes directly to the centrepiece, where it is fastened with a cable clip and then passes down the mast.

Figure 3 Details of insulators

Adjustment

The driven element (A–B–A) in Figure 1 is fixed to the end insulators in such a way as to have 'pigtails' which are about 10 cm long. Using an SWR meter between the aerial and the transmitter, trim the pigtails equally at each end for minimum SWR in that portion of the 6 m band in which you plan to work. Make sure that the transmitter is off when you trim the ends, as high voltages can be present there. Always listen on the frequency before you transmit and, when you do, ask if the frequency is in use and identify yourself. Use as little power as possible.

The prototype had an SWR of 1.2 at 50.2 MHz and performed well. If you look at Figure 1, which is a view of the aerial from above, you will immediately see that when the aerial is horizontal, it radiates with horizontal polarisation in a direction from the top of the page to the bottom. A metal pole or mast can be used for horizontal polarisation, but if you intend to use the aerial for vertical polarisation, it is much better to use a wooden or fibreglass pole.

Portable use

If you plan to operate portable with this aerial, the only real modifications you need are to the centrepiece and how it supports the spreaders. Instead of using glue and cable clips, nuts and bolts through the spreaders and centrepiece would allow the spreaders to be 'hinged' closed for transport.

Materials

Centrepiece	Hardwood, 15 × 15 × 25 mm
4 spreaders	110 cm long (cane or 6 mm dowel)
Wire	1.5 mm PVC-covered copper
50 Ω coaxial cable	RG58 or similar
Cable clips	6 mm (12 off)
Varnish	Polyurethane for waterproofing
Tape	Self-amalgamating, to waterproof all soldered joints
Insulators	See text

82 An integrated-circuit amplifier

Introduction

A simple audio-frequency amplifier is a very useful building-block in many more advanced electronic circuits. It is also a very useful piece of test equipment. To have one spare in the shack can be a life-saver at times.

Planning

Get into the habit of planning your project. How do you want it to look when it is finished. Do you want it in a box? Do you want it 'open-plan', with all the components on view?

The 'minimalist' approach to any project is simply a front panel and a baseboard, on to which all the components are fitted. In this case, the front panel would accommodate the loudspeaker, the volume control and the input and output jack sockets, and the baseboard would support the circuit board. Once you have decided these things, and know the size of the board, speaker and volume control, you can decided how big the panel and baseboard should be.

The amplifier

Instead of building the amplifier from discrete components (i.e. transistors), as was done in the project *An audio-frequency amplifier* (which you will find elsewhere in this book), we are going to use an integrated-circuit (IC) amplifier. External resistors and capacitors are still needed but, compared with the number of components *inside* the chip, these are very few indeed!

The IC we are going to use is the TBA820M. The circuit may look complicated, but with the use of a matrix circuit board it becomes quite simple. **Figure 1** shows the circuit diagram and **Figure 2** the layout on the board. The external connections to the PCB are shown in **Figure 3**.

To avoid having a separate switch to switch off the power supply when the amplifier is not being used, a volume control which incorporates a switch is used.

What power supply?

If the amplifier is to be used only for short periods, as a test instrument, for example, then it can be run from a PP3 battery, which can be mounted on the baseboard. If you intend to use it often, then a connection to an external power supply is preferable. For this option, you may want to consider fixing two terminals to the baseboard for this connection.

83 A novice ATU

Introduction

Having an aerial tuning unit (ATU) is always useful. It is used for adjusting the aerial impedance, as 'seen' by the transceiver, to be the same as that of the transceiver itself, usually 50 Ω. This process is called *matching*, and ensures that the receiver and the power amplifier (PA) stage of the transmitter work efficiently.

This design is due to the late Doug DeMaw, W1FB, and uses readily available components. It will handle up to about 5 W, and operates over the frequency range 1.8 to 30 MHz.

Circuit evolution

The basic circuit of one type of ATU is shown in **Figure 1**. On transmit, the input signal at L1 is coupled into L2, which forms a resonant circuit with C1. The signal across the resonant circuit is fed to the aerial by C2. The combination of L2 and C1 helps to remove signal harmonics, because they are not at the resonant frequency and are shunted to earth. On receive, only those signals which are within the pass-band of L2 and C1 will pass into the receiver. This improves receiver performance by rejecting many out-of-band signals which the simpler receiver doesn't like.

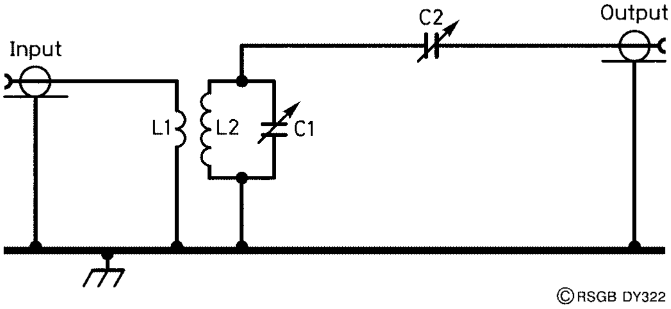

Figure 1 Basic circuit of the ATU

For this design, the all-important resonant frequency is chosen to be in the 80 metre band. If we want to make the circuit operate on other bands, we need to change either L2 or C1. It is easy to change L2 by using a set of switched inductors (L3–L5) as shown attached to S1 in **Figure 2**. Forget about S2 and L6 for the moment.

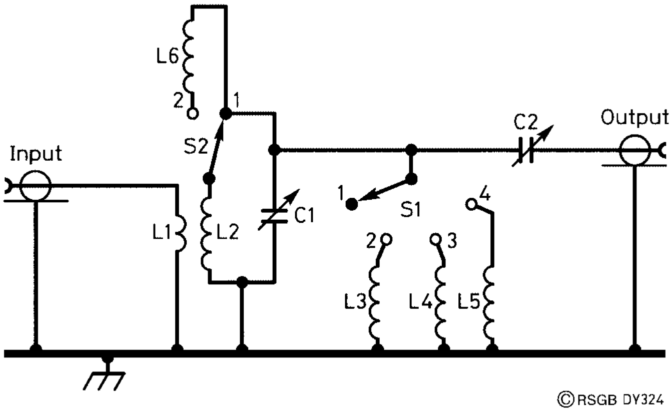

Figure 2 L6 added for 160 m

When S1 is in position 1, the circuit reverts to that of Figure 1. S2 should be brought into circuit only when S1 is in position 1. Looking at the way the circuit is drawn, you can see that when S2 is in position 2, we have two coils in series, which is equivalent to adding more turns to L2. More turns means more inductance, which lowers the resonant frequency still more, and gives coverage of the 160 m band.

Rather than having to remember to flick S2 to the correct position *and* move S1 to position 1 when we want to operate on 160 m, both functions can be combined into one rotary switch with two wafers. This circuit is shown in **Figure 3**.

Figure 3 Two-pole switch for all bands

In all positions of S1a *except* position 1, the extra coil, L6, is shorted out. The two halves of the switch, S1a and S1b, move together, as the shaft is turned, so both halves are in position 1 at the same time, position 2 at the same time, and so on. The two switches, S1 and S2, are said to be *ganged*.

Construction

L1 is formed by winding four turns of 22 SWG enamelled copper wire over L2, as in **Figure 4**. L2 already exists on the purchased former. After scraping the enamel off the ends of the wire (with a sharp knife or sandpaper), one end of L1 must be soldered to one end of L2, as shown in Figure 4. The free end of L1 goes to the transceiver aerial socket.

All components except the capacitors are assembled on the switch. Note that the rotor of C1 is earthed, but neither side of C2 is earthed. This means that the metal shaft of C2 is not earthed, and touching it will detune the ATU. Using a plastic knob for C2 will minimise this effect. If you decide to use a metal box, take precautions to ensure that no part of C2 is in electrical contact with the box.

Figure 4 L1 is wound over L2 as shown

The capacitors are mounted using M2.5 screws. Make sure that the screws do not foul the vanes of the capacitor. If your screws are too long, a few washers between the box and the capacitor will solve the problem!

In use

The best indication of a good match is obtained with a standing-wave meter between the ATU and the transceiver. The controls are adjusted alternately to ‘feel’ your way to a better and better match.

For receive-only use, the same alternate adjustments are used, watching for the maximum signal strength on the S-meter or, for a very weak signal, making the signal from the loudspeaker as large as possible.

84 CW QRP transmitter for 80 metres

Introduction

This is a relatively simple transmitter design having an output of 1 W. The design is not new, having been described before in other amateur radio publications. The components are all available new and the total cost should not exceed £15.

The circuit

Like other simple transmitters (see *An 80 Metre Crystal-Controlled CW Transmitter* and *A Breadboard 80 m CW Transmitter* elsewhere in this book) this one is crystal controlled. This assures frequency stability, but limits the usefulness of the transmitter. The key to increased frequency coverage without a conventional Variable Frequency Oscillator (VFO) is the use of a low-cost 3.58 MHz *ceramic resonator*. The 'pulling' range of a 3.58 MHz ceramic resonator covers the UK novice 80 m sub-band and some of the CW segment below 3.525 MHz.

A ceramic resonator is like a crystal, but not quite as stable in frequency. Its main advantage is its large pulling range.

The block diagram is shown in **Figure 1**. It is very similar to a crystal-controlled transmitter, and includes an oscillator, buffer and final amplifier.

Figure 1 Block diagram of the ceramic resonator controlled 80 m CW transmitter

This amplifier is keyed, the oscillator remaining running all the time. This improves frequency stability because the oscillator is not being continuously stopped and started by the key. It is switched off while receiving, though, to avoid interference with the received signal. Transmit/receive switching is accomplished by a panel-mounted switch controlling both the aerial, oscillator and buffer switching.

Figure 2 shows the transmitter circuit diagram. An unusual aspect of this transmitter is the use of a digital CMOS integrated circuit (IC) type 4069 for the buffer and oscillator stages. The IC houses six inverters, four of which are used in the circuit. One is used as the oscillator, two are used for the buffer stage, and the fourth provides an output for a direct-conversion receiver, should one be added at a later date.

The frequency of the oscillator is changed by varying the capacitance in the ceramic resonator circuit. This is provided by VC1.

The power amplifier (PA) is a small MOSFET (metal oxide semiconductor field-effect transistor), TR1. This is capable of providing an output power of 2 W but, in this circuit, it is run conservatively to give 1.5 W. The output can be varied by changing the resistance (R5 + R6) in the gate circuit. to raise the output power by decreasing the values of these resistors may result in immediate MOSFET failure.

A pi-network (C8, RFC, C9) provides impedance matching to 50 Ω, together with harmonic suppression. Like all inductors in this transmitter, the pi-network inductor is a pre-wound RF choke. A pi-network is so called because the components are arranged in the shape of the Greek letter pi (π).

Keying is carried out by a pnp transistor switch, TR2. Closing the key earths the base and supplies 12 V to the collector of TR2 and to the drain of the MOSFET, TR1, allowing the PA to operate.

Construction

You must house your transmitter in a metal box, to avoid hand-capacity effects and the radiation of spurious frequencies. Size is not important, provided it is large enough to accommodate the transmitter without cramping the components. You may want to allow space for future additions such as a direct-conversion receiver, break-in keying, sidetone or a small power amplifier. A good size is 5 × 15 × 15 cm. You can make your own box, buy it, or even use a biscuit tin!

Front and rear panel connectors can be fitted first. The choice of these is a personal matter, but a good working choice would be:

(a) Power socket – 2.1 mm panel socket – centre pin positive.
(b) Key socket – ¼ inch jack socket.
(c) Aerial and receiver connectors – panel-mounting SO239 type.

Particular attention must be paid to the mounting of the variable capacitor, VC1. Make sure the hole for the shaft is amply big enough, and if you use screws to mount the capacitor on the front panel, then make sure they are not too long, otherwise they will touch the vanes of the capacitor! Mounting can be by means of glue, sparingly applied and kept well away from the shaft.

A board size of about 6 × 10 cm is adequate. Component layout on the board is suggested in **Figure 3**. The prototype used ordinary matrix board, which is preferable to stripboard for a design like this; stripboard has undue capacitance between adjacent strips. Component leads are fed through holes in the board and are connected underneath. Make sure that leads and connections are rigid because, if they can move, there is always the danger of short-circuiting, and capacitance changes.

To facilitate construction, servicing and testing, it is advisable to use Veropins for connections to the variable capacitor, transmit/receive switch,

aerial and power sockets. Use screws and spacers to mount the circuit board to the box. Mounting the board horizontally assists troubleshooting.

Use a socket for the IC, and observe the CMOS handling precautions given in *An Electronic Die*, elsewhere in this book. When soldering the leads to the ceramic resonator, do it quickly – excessive heat damages the device. The earth lead running acoss the bottom of the board must be connected to the metal case by a short length of stout wire.

Testing

After carefully checking your wiring, both against the circuit diagram and the layout diagram, it is time to test your circuit. You will need a multimeter, an 80 m SSB receiver and a 50 Ω dummy load. A good design of dummy load can be found in the project *A Switched Dummy Load*, also in this book. An RF power meter and frequency counter will also be useful, although if your receiver has a digital frequency readout and S-meter, the latter two items are not really necessary. You will also need a 12 V 1 A power supply unit (PSU) to power the transmitter.

Switch the transmitter to receive and switch on the transmitter. No current should be consumed. Switch to transmit and check that pin 14 of IC1 is 6.8 V positive. With the dummy load connected to the aerial socket, press the key. The voltage on TR2 collector should now be 12 V, dropping to zero when the key is released.

Now check the operation of the oscillator. In transmit mode, you ought to be able to find a strong carrier signal with the receiver, even though the dummy load is connected. Adjusting the variable capacitor should change the frequency. At the lower end of the frequency range, you may find that the oscillator is unreliable in starting, because the circuit is attempting to pull the resonator too low in frequency. If this is the case, set the trimmer at the back of VC1 to minimum capacitance. If your version of VC1 has two trimmers, and you don't know which one to set, set them *both* to minimum capacitance. If there is still a problem, reduce the value of RFC1 to 6.8 or 4.7 μH.

In all probability, the unmodified circuit of Figure 2 will not require any of the changes outlined here. A coverage of 3.518 to 3.558 MHz should be possible, while preserving good frequency stability and reliable oscillation.

A signal probe (see *An RF Signal Probe*, elsewhere in this book) is useful for checking the operation of the oscillator and PA. Alternatively, an RF power meter or the receiver's S-meter can be used. With the PA running, the unit should draw between 200 and 300 mA. If TR1 becomes too hot to touch after a few seconds of transmitting, increase R5 or R6 to limit the transistor's heat dissipation. A small 6.3 V bulb connected across the aerial output is a simple way to check that the PA is working. An orange/white glow when the key is pressed is indicative of correct operation.

The final test is to monitor keying 'quality'. With your dummy load connected, press the key and listen to the note on the receiver's loudspeaker. Then operate the key, sending a string of dits, for example. What you hear should be free of chirps and clicks, as well as being stable in frequency. This test is sometimes better performed with no aerial connected to the receiver, thus preventing receiver overload and its associated plops. No problems should be encountered here.

Frequency tuning

A peculiarity of ceramic resonators is that, every now and again, their frequency changes abruptly by 100 Hz or so, then remains stable for some time. This is certainly noticeable in the received signal, but does not detract from the QSO and no characters are lost as a result. Try to keep the area around the ceramic resonator cool, to avoid temperature variations.

85 An audio booster for your hand-held

Introduction

The audio output from many hand-held transceivers and receivers usually leaves much to be desired, so this little amplifier was designed to increase the output at minimal expense.

All that is needed is a separate amplifier and bigger loudspeaker. This is accomplished using a single integrated circuit (IC), a few components, and a loudspeaker from the junk box. This circuit will enable the output from your hand-held to be heard easily in a car.

The circuit

This is shown in **Figure 1**. It uses only those components necessary to operate the IC amplifier. VR1 is the preset volume control, and varies the signal coming from the 'External speaker' jack on the hand-held before feeding it into the IC for amplification. C1 blocks any constant voltage present on the input.

Figure 1 Circuit diagram of the audio amplifier. The power is derived from the cigarette lighter socket and the fuse is in-line with the lead

The IC output comes from pin 4 and is fed via the electrolytic capacitor, C4, to the loudspeaker. The circuit is provided with an on/off switch, fuse and LED to indicate when the circuit is switched on.

Construction

The box is made of aluminium. This is necessary to help to dissipate some of the heat generated by the IC. Do not build the circuit inside a plastic box unless you take special precautions! The IC has a metal mounting tab with a hole, specifically designed to be mounted to a metal box or other metal heat sink. Apply plenty of heat sink compound between the tab and the box, tighten the nut and bolt, and then wipe off any excess compound. The box will get slightly warm in operation.

The size of the box is not specified. You may want to decide on this when you find a loudspeaker. Choose one which will be able to handle 6 W

output. Drill all the holes in the box first. Holes for the speaker, input phono socket and the LED. The amplifier can be constructed on ordinary matrix board, which can be mounted inside the box with screws and spacers.

The layout is shown, for your guidance, in **Figure 2**. The components are mounted by pushing their leads through the holes in the board and making connections on the underside. The preset volume control, VR1, is set such that the hand-held's volume control is sufficient to control the final output over a good volume range. Use a screened lead from the 'External speaker' jack socket to the phono plug.

An external power supply is needed for this circuit. The normal dry battery which we usually use for small projects in this book will *not* work here, so you will need a proper mains power supply producing a stabilised 12 V. If you are going to use the unit principally in a car, then the cigar lighter socket can supply this voltage easily. Do make sure that the polarity is correct before you switch on!

When you plug the jack plug from your booster into the 'External speaker' socket on your hand-held, its internal speaker will be muted, so don't think that something dire has gone wrong! Adjust VR1 for a good volume range on your booster, when the volume control is turned on the hand-held.

86 A grid dip oscillator

Introduction

When an inductor and a capacitor are connected, whether in series or parallel, they form a circuit with a natural (or *resonant*) frequency. The circuit stores energy, and this energy is being constantly shifted from the inductor to the capacitor and back again.

The dip oscillator is a simple instrument used to measure the resonant frequency of a tuned circuit without having to make any direct connection to the circuit. The circuit is more commonly known as the *grid dip oscillator* (GDO), from the days when the active device in the circuit was a valve. The FET or Field-Effect Transistor operates in a way which is very similar to that of the valve, so it is not quite a misnomer to call this instrument a grid dip oscillator, too.

The circuit

The GDO uses a calibrated, tunable FET oscillator in the circuit of **Figure 1**. It has a frequency range of 1.6 to 35.2 MHz in four ranges using a set of plug-in coils, shown in **Figure 2**. When the oscillator coil, L1, is placed near an external resonant circuit, some of its RF energy is coupled into the external circuit. A gain in energy of the external circuit must mean a loss of energy in the GDO circuit, resulting in a change of current through TR1, which is measured by the meter, M1.

The current through TR1 is of the order of 5 to 8 mA, but the change of current may be only a few microamps. To measure a very small

change superimposed on a much larger standing current, the method of *offset* can be used.

One connection to the meter goes to the source of the FET, while the other goes to a variable offset voltage set by VR1. M1 has a full-scale deflection (FSD) of 100 μA. If the current through TR1 changes, the voltage across R3 changes. When there is no resonance, the voltage at the wiper of VR1 is set to be very slightly greater than that across R3, and there is a 75% FSD meter deflection. When the voltage across R3 decreases very slightly, due to external circuit resonance, a significant 'dip' in the meter deflection is produced, hence the name of the instrument.

The circuit is not difficult to make on standard matrix board. Provided you can follow a circuit and translate it into a good component layout, then this project is probably only an evening's work.

The most important part of the GDO is the tuning capacitor and its associated frequency-calibrated dial. New, air-spaced tuning capacitors can cost you up to £20, so it is worth delving around in junk boxes, or scouring the tables at a local boot sale or rally. The tuning capacitor from an old transistor radio should be perfect. It may even have a slow-motion drive and a dial which can be remarked for the project.

Choose a coil plug and socket arrangement that is practical. Think about crystal holders or phono plugs and sockets. The prototype shown in Figure 1 and Figure 2 used 2-pin DIN plugs, with the coil wound on the outside of the plastic plug cover. Figure 2 shows the coil construction and the winding details.

If you use a variable capacitor, VC1, with a value different from that shown in the parts list, then the frequency ranges will be different. This does not matter, as it will be taken into account during calibration.

Position VC1 so that the dial will be easy to see and to operate, while locating the coil socket as close to it as possible. **Figure 3** shows the traditional layout of the GDO.

Calibration

Because the GDO also radiates a very small amount of energy, a general coverage receiver can be used to calibrate the dial. Don't try to aim for great accuracy and clutter the dial with marks and figures! If you include C10, R7 and R8 in your circuit, you can connect a frequency counter directly to the GDO and leave it in circuit all the time.

The GDO in use

Always try to place the external tuned circuit with its coil coaxial with the plug-in coil, as shown in Figs 1 and 3. If the coils are at right angles, the GDO may not produce any resonance. Set the offset control to give about 75% FSD and slowly tune L1 through its whole range. If no dip occurs, you may have the wrong coil plugged in. When you eventually find a dip, move the external coil further away until only a minute dip is seen. You may have to retune the dip meter as you do this, but it gives a much more accurate reading of frequency.

Remember that you cannot 'dip' a coil by itself – there must always be a capacitor present.

Aerial resonance

Figure 4 shows how to check the resonance of a dipole aerial. Disconnect the coax feed at the aerial and place a short piece of wire, terminated with crocodile clips, across the centre insulator to short together the two ends of the aerial. By placing the GDO close to the shorting link, a dip should be seen on the meter while VC1 is turned. Alternatively, a loop in the element can be made around the coil, as in Figure 4, or the shorting link can be made long enough to loop over the coil. The latter method does not require tampering with the mounting and tensioning of the dipole wires.

87 A CW transmitter for 160 to 20 metres

Introduction

This very small transmitter is designed to work on any band from top band (160 m) to 20 m, with an RF output of 1 W. It will work on higher frequencies but with a reduced output.

The circuit

The three-transistor circuit is shown in **Figure 1**. It comprises a crystal oscillator using a BC182 transistor which drives a 2N3866 power amplifier (PA) keyed by a ZTX750 PNP transistor. The oscillator and PA are coupled by a capacitor and resistor; this provides a very small amount of positive bias to the PA.

The oscillator can be used as a basic crystal oscillator but, by including a variable series capacitor as shown in Figure 1, the crystal frequency can be 'pulled' slightly, making the oscillator a *variable crystal oscillator* (VXO).

Construction

The PCB layout is shown in **Figure 2** and in the photograph. Although the prototype was built around a PCB, this circuit is equally amenable to

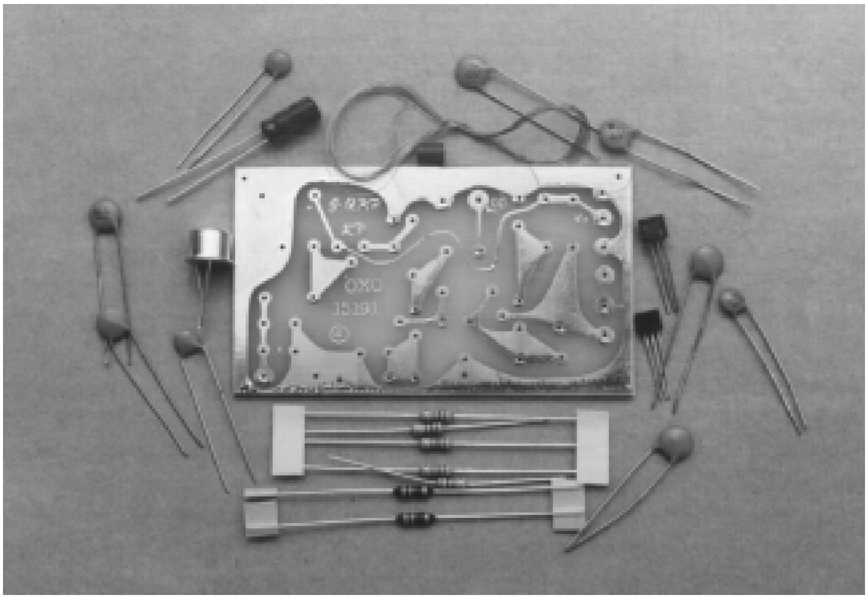
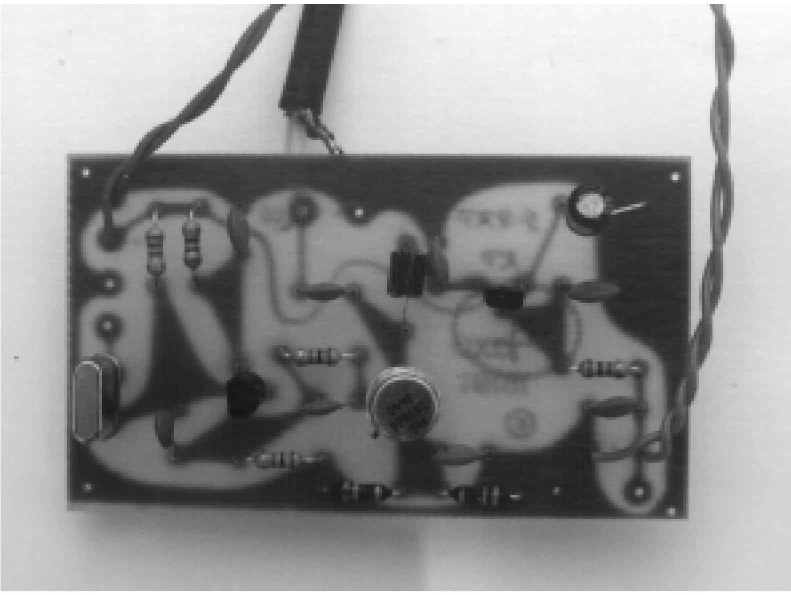
construction on a matrix board. Populating the PCB is very simple, and you can expect to be able to do this in about one hour. The radio-frequency choke (RFC) is made by winding 10 turns of 33 SWG wire on a ferrite bead. The enamel coating of the wire is intended to vaporise when soldered into the board, thus obviating the need to remove the enamel manually with a knife or sandpaper. However, if you do have problems with the PA either not working or keying intermittently, it is suggested that you investigate the RFC connections immediately!

If you decide to make the VXO version, you will have to cut the track between the crystal and earth, and connect the variable capacitor (250 pF) across the break.

In use

After performing the usual checks on the accuracy of your circuit building and the wiring of the external components, it is time to connect a 12 V battery between the points shown in Figure 2. Do not switch on yet. An aerial needs to be connected to the output via an ATU and a crystal, of frequency matching that of the aerial, fitted. The variable capacitor should give you a tuning range from about 14.058 to 14.064 MHz. ‘Netting’ (the process of tuning your transmitter to the same frequency as that of a received station) is achieved simply, because the oscillator is always running, and the leakage of the signal (despite the fact that the PA is not powered) is sufficient to bring the two frequencies to zero beat.





Warning

Note that the transmitter has no filtering; harmonics are not suppressed. It is strongly recommended that you use this transmitter in conjunction with the excellent low-pass filter described in the project *A 7-element low-pass filter for transmitters*, described elsewhere in this book.

88 Matching the end-fed random-wire aerial

Introduction

Many amateurs who do not have the space (or money) for a multi-band beam aerial, make use of the simplest possible alternative – the longest piece of wire that they can erect, with its end connected to the transceiver or receiver by an aerial tuning unit (ATU).

The length of the wire is not of major importance. Any length between 10 m and 80 m, with bends if necessary, will suffice. A good earth connection to the radio is just as important. Bends in the aerial wire can have some interesting effects on the directional properties of the aerial; V- or L-bends, or even a square shape are permitted. The only thing *not* permitted is to fold the wire back on itself in a tight hairpin bend!

Longish wire aerials

The term ‘long wire’ is usually used (incorrectly) to describe an end-fed aerial. How long is a piece of string? It depends what you mean by ‘long’. In aerial parlance, it means ‘long with respect to one wavelength’. Again, this depends on the band you are using. A long wire at 20 m is somewhat different from a long wire at 160 m. However, if you have sufficient real estate for a long wire on the 160 m band it must, by definition, be a long wire on all the other bands, too!

This should put you on your guard when analysing published data about feed-point impedance and the directional properties of a long wire aerial. Such theoretical data relate to a *real*, *ideal* long wire which is straight, horizontal, very high above perfect (conducting) ground, and not obstructed in any way. So your aerial doesn't quite match these criteria? Join the club!

Don't let this dampen your ardour when it comes to evaluating what the longish wire can do for you. The following should explain why.

Feed-point impedance

The impedance at the end of a longish-wire aerial can vary from a few tens of ohms to several thousand ohms, depending on the frequency in use and the wire length. It is also affected by factors such as bends, height above ground, proximity to buildings and wire diameter.

The actual value doesn't matter, provided we can make the aerial *appear* to have a 50 Ω impedance at the aerial socket of the transmitter. This process is what we call *impedance matching*, or simply *matching*. It maximises the power transfer from the transmitter to the aerial, and from the aerial to the receiver.

That is why an aerial tuning unit, or ATU, is almost (but not necessarily) obligatory.

The ATU

Many commercially produced HF receivers and transceivers have single 50 Ω coaxial sockets as their one and only means for connecting an external aerial. This means that an external aerial should have a 50 Ω feed impedance if it is to work efficiently, and it rules out most of the aerials being used by amateurs on the HF bands. Some means is necessary to change the aerial feed impedance to 'match' that of the transceiver. Such impedance-matching, or Z-matching (because Z is the symbol for impedance, just as L is the symbol for inductance) is the rôle of the ATU.

These can be bought and will accommodate either an end-fed or a coax-fed aerial. They can be bought ready for use or in kit form. Whether you want one for receiving only, or for use with a low-power (QRP) or high-power (QRO) transmitter, will determine what you need and how much you pay.

A simple single-band ATU

The simplest form of ATU is shown in **Figure 1**. It is simply a parallel LC (coil and capacitor) circuit, resonant at the chosen frequency, with taps on the coil for the aerial and the coaxial feed to the transceiver. If we assume the circuit is resonant, a high impedance exists at the top of the coil, and a low impedance at the bottom.

We said earlier that the end-fed longish wire presented an impedance which was high (or at least higher than 50 Ω). This explains why the aerial is tapped to the coil near the top, where the impedance is high, and the 50 Ω coax is tapped near the bottom, where the impedance is low.

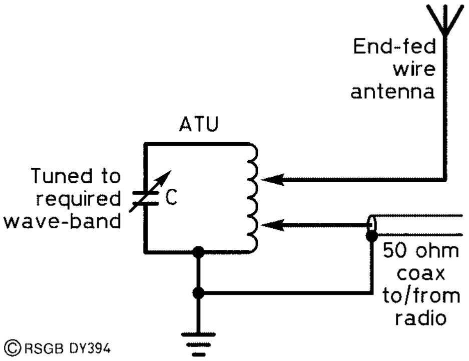


Figure 1 Parallel tuned circuit as single-band ATU for end-fed longish-wire antenna

Because the feed-point impedance of the aerial changes with frequency, so must the point at which the aerial is tapped to the coil to achieve impedance matching. The value of C must be changed also, to ensure that the circuit is resonant, and the 50 Ω tap will require tweaking also.

Setting up an ATU is quite simple. Make up an LC parallel-tuned circuit consisting of 50 turns of enamelled copper wire on an empty 35 mm film plastic container (or similar), tuned with a 500 pF variable capacitor. Make sure the enamel is removed from the ends of the wire before soldering.

Solder the inner wire of the coaxial cable from the radio to the first or second turn of the coil from its grounded end. Then solder the braid to the grounded end. Connect the aerial about one-third of the way down the coil from the top, removing the enamel at the connection point.

Adjust the variable capacitor for maximum noise or signal strength in the receiver. Then, try different tapping points from the aerial, to maximise the signal again. This matches the aerial impedance to that of the tuned circuit. Repeat the process with the coax tap, thus matching the impedance of the radio and the cable to that of the tuned circuit.

You will no doubt find that the tapping process on the coil was not easily accomplished, especially when the enamel must be removed at each tapping point without shorting adjacent turns together. It is therefore logical to produce a design where the taps have been prepared during the winding of the coil, and are selected with a rotary switch. To this end, the following multi-band design is described.

A multi-band ATU

The same type of coil design around a 35 mm film container is used (see **Figure 2**). The tapping points can be prepared in advance by a little judicious planning. Dismantle your original coil and measure the length of wire on it. It will be a little more than a calculation of $50 \times \pi D$ would suggest (where D is the diameter of the film container), due to the lack of tension in the coil and the wire diameter itself. You will need aerial tapping points at turns 1, 2, 3, 5, 10, 15, 20, 25, 30, 35, 40 and 45, corresponding to all the bands from 28 MHz to 1.8 MHz. The coaxial cable tap is fixed at turn 2 (an acceptable compromise). All the turns are counted from the earthy end.

Cut another piece of enamelled copper the same length as you used originally. Then, with the aid of an ordinary calculator, work out the positions of the points where the enamel must be removed for the taps. For example, turn 15 will have to be made $\frac{15}{50}$ of the way along the wire, turn 20 tap made at $\frac{20}{50}$ of the way along. So, if the length of wire is, say 4.7 metres, the two taps in question will be made at $\frac{15}{50} \times 4.7 = 1.41$ m and $\frac{20}{50} \times 4.7 = 1.88$ m from one end. This must be repeated for each of the tap positions, and the enamel removed ready for the wire to be soldered to it. With a

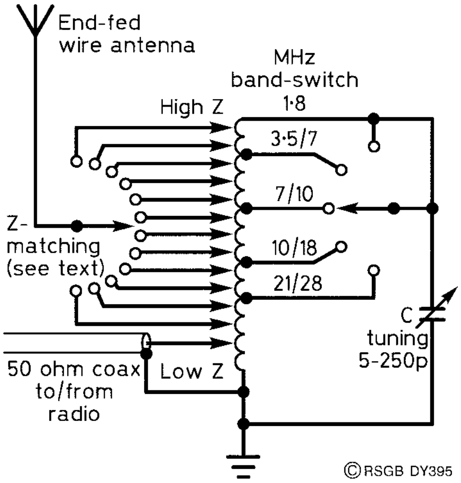

Figure 2 Simple multi-band ATU for end-fed longish-wire antennas

soldering iron, tin each tap point while the copper is shiny, thus ensuring a good, low-resistance connection. Do not solder on the taps yet.

The coil can now be wound as before. The taps can be soldered on, taking the lead from each one to the wafer of a single-pole 12-way rotary switch, the pole being connected to the aerial.

The tuning of the ATU is carried out by the same 250 pF capacitor, with a single-pole 5-way rotary switch used to select the band. Its tapping points will need to be chosen manually, using the method described earlier. Don't attempt to make new tapping points on the coil for this – use the taps available on the wafer of the other rotary switch, and find which is optimum for each band.

Notes

- For the aerial, use PVC-covered stranded tinned copper, of size 16/0.2 mm or 24/0.2 mm.
- Make the wire as long as possible, but anything over 10 m should be OK.
- Keep the wire as high as you can, in the clear and away from obstructions.
- Don't worry about bends, but don't use hairpin bends.
- Use a good insulator to attach your aerial – anything plastic will do.
- Anchor the wire near the point of entry to the building, but use a U-bend to prevent ingress of water.
- The wire can be brought in through the corner of a window, the PVC acting as an insulator. If you must drill a hole in the brickwork, make sure it slopes upwards from outside, so that water is deterred from entering.
- Use a good RF earth (as opposed to an electrical earth) such as half a dozen bare copper wires buried under the lawn in a fan shape. They should be joined together at the point of the fan and strapped to the earth connector of your ATU.

Preface

This book began life as a selection of tables for electronics engineers. Dealing with such common requirements as setting op-amp gains, forming non-standard resistor values from standard pairs and setting CR time constants, it was my hope that such a book would find common favour.

In writing explanatory notes to accompany these tables, I found myself constantly wondering how much knowledge to assume on the part of the reader. After all, the book should be as useful to a beginner as to a professional with 20 years of experience.

The time came to make a decision, and Part One was born. In it I have attempted to go from first principles to the point where the reader can hope to understand the workings of the circuits discussed in Parts Two and Three with little prior knowledge. My intention has been to be non-mathematical, logical and concise. I have drawn a line at explaining the workings of electronic devices as there is not time or space, and this book only deals with them in the final chapter. An overview of the op-amp is given there. I hope that Part One provides a useful foundation for the beginner and a point of reference for the more experienced.

How well all this works as a whole will not be seen until the book is subjected to the final test by its readership. It is my hope that it will prove a valuable aid to you, whatever your level of experience. I will be happy to receive comments, criticism or suggestions for future improvement (and also to hear about any places where my spellchecker replaced 'squarewave' with 'scurvy' without my asking it to).

This Page Intentionally Left Blank

Part One

Basic Concepts

Introduction to Part One

In this part of the book we take a look at the founding principles of electronics, from voltage, current and Ohm's Law to some basic ways to analyse circuits mathematically. If you know all of this then skip it, using it for reference as required. If not then read on.

I have tried to arrange ideas so that you are introduced to them sequentially, but this is a bit impractical in places. So if you are a real newcomer to electronics I'd like to suggest two readings; the first to get an overview of each topic, the second to cross-refer between them and to begin to see how they relate to each other.

This Page Intentionally Left Blank

1 Fundamentals

To the beginner

Before getting into the technical stuff, we might wish to ask ourselves what electricity is. My first recollection of thinking about it (though I did not know that I was) is of being a child and dismantling a prized radio to find out that no one was inside; just a mind-boggling collection of small coloured objects which evidently were not sweets, though some looked like them. My first direct experience of electricity was more sudden; an electric shock from a bar fire while trying to melt some plastic on it. I knew it was hot, but hadn't expected that! Later I came across the manual for a record player and amplifier in the house, which was old-fashioned enough to come with a circuit diagram. I was fascinated by it. It meant something to someone, but these hieroglyphics were like no language that I could figure out.

Later I took a technician's course, and a confusing set of concepts was presented to me as explanation for this unseen and magical force. Electricity, I had now realised, is used in a huge range of ways; recording sound, reproducing pictures, lighting our darkness and a lot else besides. All this was, they told me, due to unseen little balls which whiz around in some materials, creating equally unseen lines which can cause little balls in other places to whiz around as well. And this the mental territory of staid, rational looking people who would probably claim that they don't believe in magic.

I have to confess that, some years later, I have still not seen the little balls or the lines which they fling about, and I'm not very sure that I really understand them. But I have managed a reasonable career as a technician and an engineer, and I believe that I would have a fair chance of fixing my cassette machine, TV or house wiring should they misfunction. On the whole, I have not thought about the antics of little balls very much (though I suppose that it helps to know that they are there). Electricity looks, in my mind, more like water, wires like pipes, resistors like very thin pipes, capacitors like pairs of half-filled balloons which squash against each other, and inductors like – well something else. (I never said that the analogy was complete or accurate.)

I say all this as, I hope, a source of comfort to the new student of the subject who may be suffering the same pangs of insecurity about atoms, electrons and so on that I went through. Unless you feel strongly to do otherwise, let them live their own strange lives. You can be a very competent and effective user of the principles of electricity and electronics without needing to know much about them (though the same might not be said of completing your college course). Leave it to the physicists. What helps a great deal is having a good and clear grasp of the laws of electricity, and being able, as much as is possible, to prove them to yourself.

What is electricity?

We are never concerned with the behaviour of an individual atom in electronics; but with their movement in vast numbers, as they fling themselves, lemming-like, around the wires of your circuit. And yet we hardly think of them at all. We think a great deal about 'voltage', 'current' and about the golden rule of electronics, Ohm's Law. You will meet these soon.

Actually it is not atoms that move, but mostly bits of them, even tinier particles called electrons which separate themselves somehow from the larger atom which is their usual home. These electrons are now called 'free electrons'. Though unimaginably small, they are pretty powerful. They carry something which is called a 'negative charge' which is another way of saying that if, having been separated from the parent atom, they should ever encounter another with a vacancy then they will be in there like a shot and pretty difficult to move. And the feeling is mutual; once it has lost an electron the atom feels the loss and will try to bring close to it any waifs that it senses nearby. Being much bigger, it moves much less easily, or not at all. All of which physicists understate quite magnificently when they describe atoms which are an electron short as being 'holes'. Where a material has very few free electrons but many holes it is said to be 'positively charged'. The movement of charge is called 'electric current'.

If we can't see electricity, how do we measure it?

The answer is that we don't, directly. We measure voltage and current, we read the values written on the sides of components, and we work the rest out from there. But that's jumping the gun. Who built the meters that we use for measurement? What did they use?

Electricity is unseen. It is only through its ability to affect things physically that we know anything about it, be that people a hundred and more years ago, watching thunderstorms and making the legs of dead frogs jump, or us with our loudspeakers and computer screens. There are two ways of converting electrical energy to mechanical energy that we are concerned with.

MMF and current

MMF is most familiar to us as magnetism. The physical force that you feel between magnets is called MMF, or 'magnetomotive force'. A less familiar manifestation occurs when two wires with electric current passing through them are placed near to each other. A physical force exists between them. (It's usually too small to feel but the effect is exploited in electric motors.) An MMF is a result of a magnetic field, and the study of magnetic fields is called electromagnetics, which we won't get involved in here.

If we were to make the wires a given length and separate them by a given distance we could increase the current until we had some given measurable force. Then we would have a unit value of electrical current, the ampere or amp. The amp is abbreviated to A. The symbol which we use for electrical current in equations is I.

This in turn gives rise to a unit of measurement for electric charge, the coulomb. The coulomb is defined as the amount of charge passing a point in a wire that carries one amp of current in one second. This gives us our first equation:

$$I = \frac{\Delta Q}{\Delta t} \tag{1.1}$$

where I is current in amps, Q is charge in coulombs and t is time in seconds. (The symbol Δ means 'change in', so the term $\frac{\Delta Q}{\Delta t}$ means 'change in charge divided by change in time'–or the amount of charge which passed the point divided by the time period that charge was measured for.)

This tells us that a charge of one coulomb passing a point in one second equates to a current of one amp; two coulombs in a second, or half a coulomb in one second would be two amps; and so on. A coulomb is a lot of charge. Typically we deal in charges of thousandths of coulomb per second (mC/s), or mA. (The prefix 'm' denotes a thousandth. We will use these prefixes increasingly as we progress. They are described fully in Appendix 1.)

'Electron current' and 'conventional current' There is something of a mix-up which has taken place over history with regard to the direction of current flow, and no one has ever bothered to sort it out. You would think from what we've said above that, as the electrons do most or all of the running around in circuits, the current flow would be from the negative end of a battery to the positive end. It is, but we have a convention of always arrowing diagrams with the direction of current flow reversed. When people were discovering the laws of electricity they had some idea about things moving in wires but no way of seeing in which direction, so they had to guess. They guessed wrongly. Later this was discovered, but by this time people had been labelling currents on circuit diagrams for ages, quite happily and without any problem. The numbers all work out the same; its like deciding to rewrite your bank statement with the signs reversed. A minus sign means you are in credit or have deposited cash, and a plus that you took money out or are in debt. So long as you know what the symbols mean there is no problem. So it was with current flow, and they left it at that. It was too much hassle to change the labels on everything. If you hear talk about 'electron current' (which goes from negative to positive) and 'conventional current'

(positive to negative) this is what it means. Most people, and this book, use conventional current.

EMF and voltage

Electric charges of the same polarity repel and of opposite polarity attract. The attraction is the second physical force, called the 'electromotive force' or EMF. This is how electrons and holes know about each others' presence and are caused to move towards each other. EMF's are caused by electric fields. The study of electric fields is electrostatics and, like electromagnetics, we won't get into it here.

EMF is often called 'potential difference' or 'voltage'. It is measured in volts, abbreviated to V. When we need a symbol for voltage in equations we will also use V.

Voltage is a comparison between two places that are charged. We say that one place on a circuit is '10 V positive with respect to' another or that a potential difference of 10 V exists. The important thing to remember is that the number is always a difference between two places, or it means nothing. Generally we take one point, the metal chassis of equipment, mains earth or perhaps a piece of wire connected to the power supply, and we call it '0 V' or 'earth'. This becomes our reference for other measurements, unless we state otherwise.

The volt is defined by its ability to make charge do work (by pushing it more or less quickly through something and generating another form of energy, like heat or light). The amount of potential required to make one coulomb of charge do one joule of work is one volt:

$$V = \frac{J}{Q} \tag{1.2}$$

where V is voltage in volts, J is work in joules and Q is charge in coulombs. A joule is a measurement of energy or of work done which is derived from physical quantities. We will not actually use this but we will develop it into something more useful in Chapter 2. For now it is enough to know that a volt is a definite measurable quantity.

How fast does electricity move? When a current flows through a wire, the same electron doesn't go in one end and come out of the other; one bounces a little way along, until it is able to find a home, which it often does by dislodging another and sending it on its way down the wire. (In doing so it generates heat.) The average speed of electron movement in a wire is extremely low, fractions of millimetres per second, even for currents which are, by our standards, large.

However, what we generally mean by this question is something very different; when we apply a voltage to one end of a wire, how long is it before the voltage is felt at the other end of the wire? The answer is that the impulse travels at the speed of light – instantly for all our purposes.

An analogy is a string of marbles in a narrow tube. If you shove the end marble very hard, the impulse (the voltage) travels along the tube like a wave and reaches the other end quickly, say one metre in a second. In that time, any one marble may have only moved 1 cm. So the average marble speed (the current) is 1 cm/s while the impulse speed is 1 m/s, 100 times greater. The average marble speed changes at the other end of the tube just as quickly – they start falling out of the tube at a rate of 1 cm/s, a second later. With electrons the effect is the same, but unimaginably more exaggerated.

If that seems a bit confusing, please don't worry – it is to most people. The important thing is that changes in voltage or current travel instantly but electrons have different physical speeds. (The second fact is only relevant if you want to understand how power is dissipated in components. Even if you don't, you can get by quite well just knowing that it is. We look at this in Chapter 3.)

2 Circuits and components

Conductors and insulators

Why do some materials conduct electricity, while others don't? Some materials are populated by good and careful atoms which don't lose their electrons easily (and probably feel ashamed if they do). Hence the itinerant population is low. The few free electrons that exist tend to sit miserably in one place, having given up hope of ever finding a home. These are insulators, typically air, rubber or the fibreglass backing of a circuit board. In other materials atoms are positively feckless. There are many free electrons and should some charged material come near they move accordingly. How do they know? They feel the voltage. These are conductors. Most metals are conductors. We use copper a great deal, gold where corrosion could be a problem, and sometimes aluminium or other metals for housing equipment.

Resistance

Some materials fall into a kind of grey area between being conductors and insulators. We can use these to make resistors. It's as if the material was a kind of mud; if we make the mud thicker electrons move less easily. The resistance of a given piece of a material depends on 'how thick the mud is' (the 'resistivity' of the material) and its geometry. Making it thinner increases, and doubling or tripling length doubles or triples, its resistance.

Ohm's Law

The unit for resistance is the ohm, or , and the symbol in equations is R. Now we come to the most important equation in electronics:

$$V = IR \tag{2.1a}$$

with V in volts, I in amps, R in ohms. This is Ohm's Law. We will use it so much that it bears being rewritten in its two other forms:

$$I = \frac{V}{R} \tag{2.1b}$$

and:

$$R = \frac{V}{I} \tag{2.1c}$$

These are used so frequently that you need to know them by heart.

Ohm's Law tells us that placing a steady voltage across a material causes a proportional steady current to flow.

Even insulators and conductors have resistance. Insulators have very high resistance; tens or hundreds of MΩ or more, so that for the normal voltages that we use an unmeasurably small current flows. If the voltage is raised to sufficiently high levels, usually at least a kV, a condition called 'breakdown' occurs; electrons are blasted free from atoms within the structure of the material, and its essential nature is changed. You will know if this happens; there is a nasty burning smell, and things stop working. It is a condition which we try to avoid.

Conductors are the opposite; their resistance is very low, small fractions of an ohm typically. The commonest conductor that we use is copper. We cannot normally measure the voltage across a piece of copper wire, unless it is long. We can find out, from catalogues and so on, the resistance per metre of any given type of wire; this depends on the wire, but figures of around 0.1 Ω/m are typical. Occasionally we need to find this out and calculate the total resistance of a length of cable when our wires are very long, in a large system. The wire will also have a maximum current rating, which is what we can pass through it before the amount of heat generated in it becomes dangerous to its structure. The insulating material around it may melt, causing it to short to things that it shouldn't, or the conductor itself. We only need know that we should stay comfortably within the maximum rated current for a conductor. In essence, anything can be destroyed with too much voltage/current.

To summarize, we have three distinct classes of material; conductors, insulators and resistors. Conductors connect our circuit up and have very low resistance. We assume that the voltage is the same at both ends of them unless they are very long or current is very high. They are just vessels to carry current. Insulators are the separating material between different points in a circuit that need to be kept apart and have very high resistance. Resistors are electrical components having a known resistance. We can predict the current through them for any given voltage, or vice versa, using the all-powerful Ohm's Law, $V = IR$.

Circuits, diagrams and common expressions

A circuit is exactly what its name suggests; a loop around which electric current can flow. The loop is generally made up of conductors (bits of wire or otherwise), circuit elements or components (which we start to meet soon) and one or more sources of electrical energy – current or voltage.

Circuit diagrams, sometimes called schematic diagrams, are symbolic representations of the way that the components of a circuit are interconnected. They are the starting point for most designs, and invaluable aid in servicing or fault-finding equipment that already exists. Each element of the circuit, from a battery or a tiny resistor to a complex microprocessor chip, is represented by a symbol, with each connection to it represented by a line joining to it. Interconnections between elements are shown by lines drawn between components. In reality, these could be any form of conductor; a wire soldered directly to a leg of the component (not recommended for a microprocessor!), a copper track on a PCB, or a test lead with a crocodile clip at either end of it.

Sometimes a circuit diagram doesn't show all of the circuit, and you can't see all of the loop around which the current will flow. (For example, see Figure 2.2 later.) The inference here is that things start to happen when something else is connected to it, completing the circuit – in this case a DC voltage (as you will see).

'Block diagrams' are a special type of circuit diagram worthy of explanation. You generally find them with fairly complex electronic circuits which are either too large to see on one drawing, or more understandable by being broken into smaller parts. Each 'circuit block' is drawn as a box or some commonly understood symbol, with lines connecting the blocks. The lines represent 'signals' (in reality any means by which the individual circuits can communicate), generally one or more conductors carrying voltage or current. It is the job of the person drawing the block diagram to make it less vague than this definition!

Two more very common terms – 'short circuit' and 'open circuit'. A short circuit is what happens when you connect two points with a conductor. An open circuit between two points means that they are not connected at all (an insulator is between them).

Resistors

Figure 2.1 A resistor

We buy resistors as discrete electrical components. They come in values ranging from fractions of an ohm to tens of megohms, and are found everywhere in electronic circuits. We will see values between about 10 Ω and 1 M Ω most commonly in our circuits; values outside that do occur, but less commonly. They are identified by a series of coloured bands, each band signifying a number, or sometimes they just have the value written on. The colour code system is described in Appendix 2. The circuit symbol for a resistor is shown in Figure 2.1.

When we combine more than one resistor together in a circuit we can calculate an equivalent resistance for them, and treat them as a single component. There are two ways of doing this.

Resistors in series

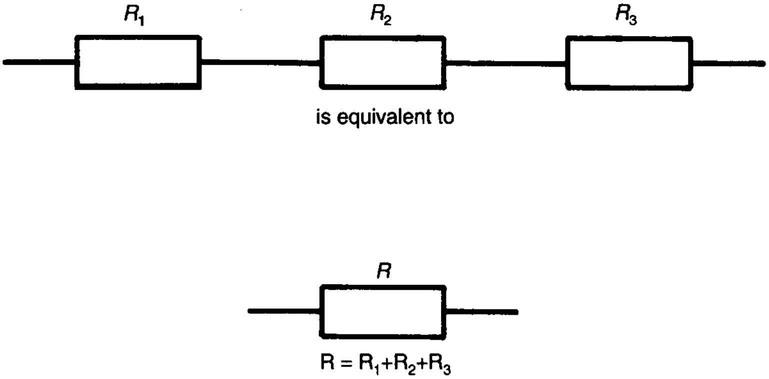

Figure 2.2 Resistors in series

Three resistors in series are shown in Figure 2.2. When we have this situation, we just add the values of the resistors to get their equivalent. We can do this for any number of resistors:

$$R = R_1 + R_2 + R_3 + \cdots + R_N \tag{2.2}$$

Example 2.1: Three resistors of 1k, 4k7 and 680 Ω in series have an equivalent resistance of 6380 Ω

Resistors in parallel

Three resistors in parallel are shown in Figure 2.3. Here we must add the reciprocal of each to get the reciprocal of the equivalent resistance. Again this applies for any number of them:

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \ldots + \frac{1}{R_N} \tag{2.3a}$$

A special case of this worth remembering is when we have just two. Then we can calculate the equivalent in one step by dividing the product by the sum:

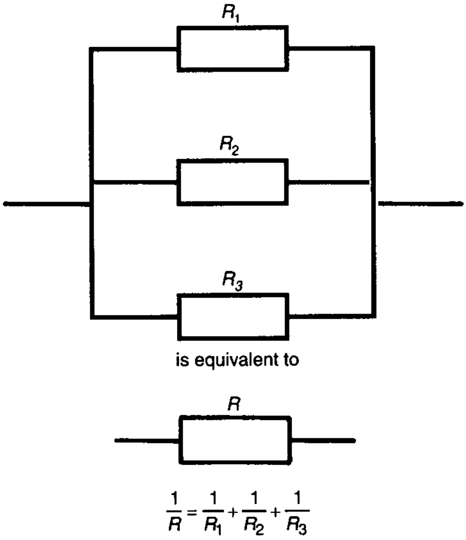

Figure 2.3 Resistors in parallel

Example 2.2: What is the equivalent parallel resistance of the three resistors from Example 2.1?

$$\frac{1}{R}=\frac{1}{1000}+\frac{1}{4700}+\frac{1}{680}=2.68\text{m}$$

$$R=\frac{1}{2.68\text{m}}=373\,\Omega$$

$$R=\frac{R_1.R_2}{R_1+R_2} \tag{2.3b}$$

We can always get some idea of equivalent resistance without calculating. Here are some rules of thumb:

1. For resistors in series the equivalent is always, obviously, larger than the largest resistor.
2. For resistors in parallel the equivalent is always smaller than the smallest.
3. Two same value resistors in parallel have a resistance which is half their value; three a third, and so on.

Are electrons psychic?

There are two ways in which electrons seem to know about what others are doing and be caused to move. One effect is due to EMF and the other to MMF. A full analysis requires excursions into the subjects of electrostatics and magnetics, but luckily we can get a good picture of these effects without all that. Both forces exist and have an application in electronics whether the charges are in the same conductor or two separate ones.

1. An EMF causes opposite charges to be attracted to each other, like ones to be repelled. If the two charges are in the same conductor this causes electrical current. If they are in two conductors separated by an insulator this gives rise to an effect known as capacitance. Capacitance is a property of a pair of isolated conductors which resists a change in the voltage between them.
2. Any electrical current creates a magnetic field, and any change in magnetic field creates a voltage in a conductor in the field. These two effects combine to create an effect known as inductance. There are two types of inductance. Self-inductance is a property of a conductor which opposes change in current flow. Mutual inductance is a property of isolated conductors by which a current flowing in one causes voltage in the other.

Capacitance and capacitors

When two conductors are separated by an insulator there is voltage between them if they have different amounts of charge. Changing that voltage requires charge to be moved, which requires energy. We can buy components specially made to have an appreciable amount of capacitance and use the effect in our circuits. Capacitors ('caps') consist of a pair of conductive plates separated by a special insulator called a 'dielectric', which magnifies the effect. When caps have no voltage across them we say that they are 'discharged' or, conversely, when they do that they are 'charged'.

The capacitance between the plates gets greater when:

1. they are moved closer together
2. they have greater surface area
3. the dielectric has a higher 'dielectric constant' – which, in English, means it is better at magnifying.

The unit of capacitance is the farad, or F, and the symbol used in equations is C. A farad is a lot of capacitance. A capacitor of one farad would have a potential of one volt across it when it had a charge of one volt on it:

$$Q = CV \quad \text{or} \quad C = \frac{Q}{V} \tag{2.4}$$

where Q is charge in coulombs, C is capacitance in farads and V is voltage in volts. This is more useful if we write it in terms of current, using Eqn(1.1):

$$I = \frac{\Delta Q}{\Delta t} = C\,\frac{\Delta V}{\Delta t} \tag{2.5}$$

This tells us that the rate of change of voltage across a capacitor is proportional to the current through it.

Capacitance exists everywhere, but is so small normally, say between two wires running side by side for a few feet, that we wouldn't bother much about it. (For cables containing more one conductor, separated by an insulator ('multicore cables') we can find out a value of 'typical capacitance between cores per metre', which we might take into account, if running signals through long cables, in the same way that we talked about for 'resistance/metre' earlier.)

Capacitors range in value from a few pF to 100 000 μF and more, with physical sizes getting larger with value. Figure 2.4 shows the circuit symbol for a capacitor.

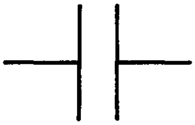

Figure 2.4 A capacitor

Capacitors come in a variety of types, with different characteristics. The most important of these are listed below:

1. Working voltage. If we put too much voltage across a capacitor, its dielectric, an insulator, will break down and current will flow from plate to plate, which it's not supposed to. The device will be destroyed. (They often, but not always, go short circuit.) The maximum working voltage tells us our safe limit. We try to design so that we never get too close to this.
2. Polarization. Large capacitors tend to be 'polarized' types – that is they use a special type of dielectric to squeeze more capacitance into a small volume, but the trade off is that you should only put voltage across them one way around. The most common type of polarized capacitor is the 'electrolytic'. They are marked with positive and negative terminals. If you disobey this by accident they go bang and bits of fluffy stuff come out of the top. Then you change them.
3. Tolerance. This varies greatly from type to type. Electrolytics have tolerances of something like −10%, +20%, because they are designed to be used in situations where you try to get as much capacitance into as small space as possible, and accuracy is not the prime consideration. At the other extreme, silvered mica types can be 1%, and give excellent stability. They are used in situations where the capacitor is used perhaps to set a time constant or a frequency (see Part Two) that must be accurately maintained.
4. Leakage current. Capacitors should be open circuit to a DC voltage. In practice you get a small current flowing, particularly for electrolytics.

There are other specifications which can come into play, but these are the most important. The value of a capacitor is usually written in numbers, in pF or in μF if no unit is specified. Unfortunately it is not always clear which, but it is usually possible to guess from the physical size, once you become familiar with them.

Capacitors in series and parallel

We can combine capacitors in series or parallel as we did with resistors. The law for caps in series is like that for resistors in parallel, and vice versa. Hence putting them in parallel creates a larger capacitor, and in series a smaller one. Here are the formulae:
In parallel:

$$C = C_1 + C_2 + C_3 + \ldots + C_N \tag{2.6}$$

In series:

$$\frac{1}{C} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \ldots + \frac{1}{C_N} \tag{2.7}$$

Self-inductance and inductors

Magnetic fields, when they move through a conductor, cause a voltage which can make electrons move. And electric current (or movement of electrons) causes a magnetic field. This adds up to an interaction of magnetic field, voltage and current, the net effect of which is this: if current flows in a wire there is a certain tendency for it to want to continue to do so, and not to change. (Sometimes we say this another way; when the current through an inductor changes, the inductor sets up a 'back EMF' which opposes the change in current.)

This effect is known as self-inductance (or just inductance). Like capacitance, it is not noticeable under normal circumstances. It can be made much stronger, however, if the wire is wound into a coil shape; the more turns the better. Inductance is also much increased by winding the coil on a core of some special material said to have a high 'permeability'; that is, it has the effect of concentrating the magnetic field. Such a device is called an inductor. Figure 2.5 is the circuit symbol.

The voltage across and current through an inductor are related as follows:

$$V = L\frac{\Delta I}{\Delta t} \tag{2.8}$$

where L is the inductance in its standard unit, the henry (H).

This says that the voltage across an inductor is proportional to the rate of change of current through it. We can see that this is not unlike Eqn (2.5), for a capacitor. And, indeed, capacitors and inductors are in many ways the converse of each other. One resists change in voltage, the other change in current. As we look at these components again in the following chapters, we will see that in each circumstance they do opposite things to each other.

Figure 2.5 An inductor

Inductors are available with values from about 0.01 μH to 100 mH and more. Like capacitors, they get physically larger with value. As large value inductors consist of very many turns of wire on a heavy iron former, they also tend to get very heavy, one reason why they are not as popular as capacitors. They also tend to have a significant amount of resistance, which can be a disadvantage. The main specifications for an inductor are:

1. Internal resistance. This is caused by the large number of turns of wire, which can also be quite thin, to minimize the volume.
2. Maximum DC current. If too much DC current is passed through the wire of which the coil is made, it can overheat and melt, damaging or destroying the component. Even if the amount of DC is not so much as that, the core can 'saturate' – meaning that it doesn't work as well.

Despite their problems, they are quite common in some applications, and sometimes nothing else will do.

Inductors in series and parallel

Again, we can combine the inductance of series or parallel inductors and treat them as a single component. The laws are the same as those for resistors, and the inverse of those for capacitors.

In series:

$$L = L_1 + L_2 + L_3 + \ldots + L_N \tag{2.9}$$

In parallel:

$$\frac{1}{L} = \frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \ldots + \frac{1}{L_N} \tag{2.10}$$

Mutual-inductance and transformers

Magnetic fields also cause electrons in unconnected conductors to influence each other. This effect is called mutual inductance. To make the effect strong, coils of wire are wound together on a core (which again has the effect of concentrating the magnetic field). This is a transformer. The symbol is shown in Figure 2.6.

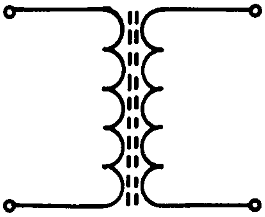

Figure 2.6 A transformer

The coil of a transformer into which you put current is called the 'primary'. The coil(s) from which you take current are the 'secondary(s)'. The 'turns ratio' of a transformer is the ratio of the number of turns on the primary to those on the secondary. When we apply AC voltage to the primary, we get AC from the secondary. And, conveniently:

$$\frac{T_p}{T_s} = \frac{V_p}{V_s} \tag{2.11}$$

where T_p and T_s are the number of turns on primary and secondary, respectively, and V_p and V_s the voltages.

Transformers are very useful in certain situations, the most common being the passing of a signal from one part of a circuit to another while keeping the two electrically isolated. Virtually all equipment connected to the AC mains supply is done so via a transformer. For safety reasons this is a special type, designed to have good electrical isolation. We *never* use anything but a proper mains transformer for this! Transformers are also very useful in many other circuits, and many other special types exist.

3 Direct current

AC and DC signals

We often hear electrical signals classified as 'AC' or 'DC'. These abbreviations stand for the terms 'alternating current' and 'direct current', but they are applied as much to voltages as to currents. In this chapter we will talk about DC. Given that we understand Ohm's Law, stated in Chapter 2, we have actually covered most of what ground there is. We will also introduce the term 'power' and consider its implications, which are important.

Direct current

A DC current is one which flows in one direction only. If we were to connect a resistor between the two terminals of a battery a DC current would result. For conventional current, it would flow from the positive terminal to the negative and have a magnitude, determined by Ohm's Law, of $I = V/R$. Similarly, we would refer to the voltage across that battery as a 'DC voltage'.

One application of DC is supplying power to an electronic circuit. The output from a power supply is often called the 'power rail' or just 'the rail'. The supply could be a separate circuit, operating from AC mains, or batteries. Virtually all circuits require one or more DC voltages to operate. A very common arrangement is to supply two rails with equal and opposite voltages, perhaps one of +15 V and one of −15 V. Then there will be three power rails; 0 V, used as a reference point for the whole circuit, and +/−15 V, used to supply power. Computer circuits often use a single rail of +5 V, perhaps with one or more other voltages used by the circuits which interface the computer to the outside world.

Circuit symbols for DC voltages and currents come in many flavours. Figure 3.1 shows some. You may just get lines, as in (a), with an indication of what the voltage or current is. (In a block diagram, like this example, the arrow may not follow the direction of current flow; it can just show that the supply is an 'input' to the circuit.) The symbol for a battery is shown at (b). The two general symbols for a voltage and current source are shown in (c). These would both indicate an unspecified device or circuit block; the intent is to indicate that a source exists at that point in the circuit, to help you see what is going on without actually telling you what physical devices to expect.

Calculations on DC quantities

Addition, subtraction, multiplication and division can be performed on DC voltages and currents simply by performing the relevant operation on the numbers, paying due regard to their signs.

Resistors in DC circuits

There is hardly anything to say about this; they obey Ohm's Law, as already described. Also you should make sure that the rated power dissipation is not exceeded, as we discuss later.

Capacitors in DC circuits

If we put a DC voltage across a capacitor an instantaneous ('transient') current flows while it charges to the voltage. Thereafter no current flows as long as the voltage remains steady, with the exception of the leakage current that was discussed in Chapter 2. Capacitors are often used to isolate one part of a circuit from another to DC, while allowing AC signals to pass (as a 'DC block').

If we make a steady DC current flow into a capacitor (from a current source) the result is a ramp voltage across it. From Eqn (2.5), the ramp has a slope of:

$$\frac{\Delta V}{\Delta t} = \frac{I}{C} \tag{3.1}$$

$\frac{\Delta V}{\Delta t}$ is the slope of the ramp in volts per second, I is the current in amps and C the capacitance in farads. This is a common method of making ramp generator circuits.

Example 3.1: A steady DC current of 1 mA is fed into a 680 pF capacitor; what is the slope of the voltage across its terminals? How long does it take to change by 10 V?

$\text{slope} = \frac{I}{C} = \frac{1\text{m}}{680\,\text{p}} = 1.47\,\text{V}/\mu\text{s}$

Time taken to change 10 V is $\frac{10}{1.47} = 6.8\,\mu\text{s}$

Inductors in DC circuits

An ideal inductor would be a short to DC. A real one appears to be a resistor with the value of the internal resistance of the inductor (hopefully very low). When DC current is passed through the inductor we get a transient voltage (the back EMF mentioned in Chapter 2). Thereafter the voltage will be small. Because of this, inductors are sometimes used to block AC but pass DC (as a 'choke').

Placing a steady DC voltage across an inductor causes the current waveform to be a ramp (in the same way that a DC current in a capacitor causes a ramp voltage). The slope of the current waveform is, from Eqn (2.8):

$$\frac{\Delta I}{\Delta t} = \frac{V}{L} \tag{3.2}$$

(Did you notice how capacitors and inductors tend to do similar but opposite things to AC and DC voltages and currents?)

Power in DC circuits

Why do we worry about power dissipation?

As we saw in Chapter 2, connecting a voltage across a resistor causes a current to flow. The amount of the current depends on the value of the resistor; the lower the more current. In physical terms, this means that the average electron speed through the resistor is higher. Thus an electron making its way through strikes atoms in its path harder, and creates more heat. (We never have to worry about the electron speed, just the value of current; this is just a reminder of the physical process taking place.) The heat will be lost to the air, hopefully. How quickly the heat can dissipate depends mostly on physical structure of the resistor. If it cannot get away more quickly than it is generated, then the temperature will rise until it reaches a point where it destroys the component. Resistors go brown at this point, start to smell, and eventually go open circuit (sometimes catching fire in the process). Then you change them. Watching miniature resistors (1/8 W or 1/4 W types) catch fire isn't too bad, may even be mildly entertaining. (I have known heavy smoking engineers to use the trick to get a light in the middle of the night when the garage is shut, though I don't recommend the chemical content for your health.) Anything larger than that should definitely be avoided.

So that we can avoid this situation, resistors always have a 'maximum power rating'. Power is measured in watts (W). The power rating of a resistor might be anything from less than 0.1 W, for very small surface-mounted devices, to 100 W or more, for large, heavy devices intended to be bolted to 'heatsinks' (pieces of metal designed to radiate and make heat dissipate more quickly). On opening up pieces of electronic equipment we may sometimes see resistors which have obviously been overheating; the painted exterior may be brown and cracked. This may be the cause of the fault that we are investigating or an indication that some other fault is causing excessive current to flow. Sometimes it is an indication that the designer of the equipment wasn't as meticulous as he might have been. A resistor run continually at its maximum power may show signs of burning without misfunctioning, but the long-term reliability is likely to be reduced.

I have tried to follow a 'rule-of-thumb' which I learnt from an experienced engineer early in my career; to try not to run components continually at more than about one-third to one-half of their rated power. Running them at maximum for a short duration is generally OK; the device has time to cool off. If in doubt, prototype and use common sense. If it goes brown, you are being a bit ambitious.

Power calculation in DC circuits

How do we calculate the power dissipation in a resistor? Power is defined as the rate of energy dissipation, or:

$$P = \frac{J}{t} \tag{3.3a}$$

where P is the power in watts, J is the energy in joules and t is the time in seconds. From Eqn (1.2):

$$V = \frac{J}{Q} \quad \text{or} \quad J = VQ$$

Substituting into Eqn (3.3), we get:

$$P = V\frac{Q}{t} \tag{3.3b}$$

From Eqn (1.1):

$$I = \frac{Q}{t}$$

So:

$$P = VI \tag{3.4a}$$

Like Ohm's Law, this gets used a lot, and you need to know it. (The derivation is just for interest's sake.) The result is important enough to be restated, and learnt, in its two other forms:

$$I = \frac{P}{V} \tag{3.4b}$$

and:

$$V = \frac{P}{I}$$

Example 3.1: A resistor of 10 Ω has a voltage of 3 V across it. How much power does it consume?

Using Ohm's Law

$$I = \frac{V}{R} = 0.3 \text{ A}$$

and using Eqn (3.4a):

$$P = VI = 3 \times 0.3 = 0.9 \text{ W}$$

Often we use two equations which we can get from Ohm's Law and Eqn (3.4a) by a little algebraic substitution:

$$P = \frac{V^2}{R} \qquad (3.4d)$$

and

$$P = I^2 R \qquad (3.4e)$$

These enable us to answer questions like that posed in Example 3.1 in one step. Using Eqn (3.4d):

$$P = \frac{3^2}{10} = 0.9\,\text{W}$$

The business of using components within their maximum power rating quickly becomes fairly intuitive. For a circuit working from low voltages, say +/– 15 V DC, the maximum available voltage is 30 V. Our workshop resistor kit may contain miniature resistors all rated at 1/8 W. This enables us to calculate a value of resistor above which we cannot, no matter how we try, exceed the rated power.

Example 3.2: For the circumstances which we just described, what is the 'minimum' value, following the 'half-rated-power' rule-of-thumb?

$$P = \frac{V^2}{R} \quad \text{so} \quad R = \frac{V^2}{P}$$

P is half of 1/8:

$$\frac{0.125}{2} = 0.0625\,\text{W}$$

$V = 30$ V

Our threshold value of resistance is:

$$\frac{30^2}{0.0625} = 14400\,\Omega$$

– or say 15 kΩ.

This does not mean, of course, that we won't use any components of less than this value; but that above this value we can dot them around without worrying about power rating. At values around 15 kΩ, we only need worry if they spend a lot of time strapped across the power rails, which very few will. Even for low values, we will tend only to get the calculator out when we know that the resistor has a large voltage across it.

4 Alternating current

An AC voltage or current is any which is changing. It will very often be one which changes at a known rate. Where a DC voltage or current is easily described by its magnitude and sign ('3 V DC' or '–16.2 V DC' says it all, as long as we know where 0 V is), AC signals are a bit more complicated. We are going to start by considering the simplest type of AC signal. Then we will look at more complex ones.

The most ubiquitous AC signal is the sine wave. We will understand so much electronics in terms of how circuits respond to sine waves that it is worth our while spending some time describing and thinking about them.

The sine wave

If you haven't known about sine waves before, the word 'sine' probably brings back dimly remembered memories of school maths lessons, trigonometry, and all that goes with it. The sine is a mathematical function which describes the ratio of two sides of a right angled triangle in relation to one of the other angles, and a sine wave is a graph of the ratio against the angle. That's putting it mathematically. To many technicians and engineers, who try to do as much practical work as possible with the minimum use of mathematics, a sine wave is a very useful 'wiggle' which appears on the screens of an oscilloscope (a device which cleverly shows a graph of voltage against time) when they are working on equipment. We describe a great number of the essential properties of circuits in terms of what comes out when the input is a sine wave. The reasons for this are discussed later.

Figure 4.1 shows a sine wave. It is 2 V peak to peak (pk–pk or p–p) with a frequency of 1 Hz. (We'll define these terms soon.) The voltage begins at a level of 0 V, rises smoothly up to a level of 1 V, back down through 0 V to –1 V, and up to 0 V again. Each transition, 0 V to 1 V, 1 V to 0 V, 0 V to –1 V and –1 V to 0 V, takes the same amount of time, 0.25 s. The whole process is referred to as 'one cycle'.

We don't often come across sine waves which exist for one cycle only and then stop, however; usually the voltage oscillates continually while the circuit generating it is on. This may be for many hours. We call this a 'continuous signal'.

There are two things that we need to describe a sine wave unambiguously; how big it is, and how long it takes to complete one cycle. These two quantities we normally call 'amplitude' and either 'period' or 'frequency'.

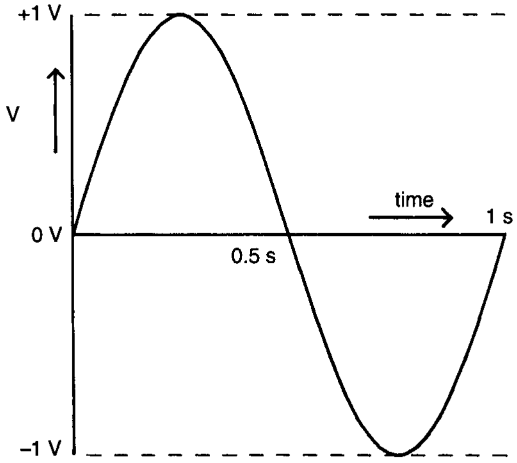

Figure 4.1 A sine wave

Amplitude

There are three ways of defining the amplitude of a sine wave:

1. Peak to peak amplitude is the difference between the positive and the negative peaks. Figure 4.1 is a sine wave of 2 V pk–pk. Pk–pk amplitude can be used to describe signals which are not sine waves as well.
2. Peak amplitude is the difference between the mid-point of the signal and the positive peak. Figure 4.1 is a sine wave of (1–0) = 1 V pk. We can say that:

$$\text{pk amplitude} = \frac{\text{pk} - \text{pk amplitude}}{2} \tag{4.1}$$

3. Root mean square (RMS) amplitude is the level of a DC signal which has the same energy content as the AC signal. This odd way of specifying amplitude exists because it is needed for power calculations (on which more later in this chapter). For a sine wave:

$$\text{RMS amplitude} = \frac{\text{pk amplitude}}{\sqrt{2}}$$

or:

$$\text{RMS amplitude} = \text{pk amplitude} \times 0.707 \tag{4.2a}$$

or again:

$$\text{pk amplitude} = \text{RMS amplitude} \times 1.414 \tag{4.2b}$$

Which of these three we use depends on the situation, and we often need to convert between them. For instance, we might see a sine wave displayed on the screen of our oscilloscope, and wish to calculate the power which it causes to be dissipated in a certain component. Here we might read the pk–pk amplitude from the display, divide by two to get pk amplitude and then multiply by 0.707 to get the RMS amplitude. Then we can make a power calculation. Conversely, we might measure the amplitude of a sine wave using an RMS multimeter. If we needed for some reason to have a rough idea of the pk–pk value of the voltage, we could divide by 0.7 (multiply by 1.4) and then multiply by 2 in our heads – multiply by 2.8.

Period and frequency

The period of a sine wave is the time which it takes to complete one cycle. Its symbol in equations is T, and its unit is that of time, the second (s). For Figure 4.1, T is one second.

It is more usual to refer to the 'frequency' of a sine wave. The symbol for frequency in equations is f, and its unit is the hertz, abbreviated to Hz, meaning cycles per second. The frequency is the number of cycles completed in one second. Converting from frequency to period is very easy:

$$f = \frac{1}{T} \quad \text{or} \quad T = \frac{1}{f} \tag{4.3}$$

with f in Hz and T in s.

So our signal of Figure 4.1 has a frequency of 1 Hz.

Amplitude and frequency are independent of each other; a sine wave of 3 kHz will oscillate 3000 times per second whether it has a level of 1 μV or 10 V. One of 10 V RMS will still be at 10 V RMS, and have the same heating effect through a given resistor whether it is at 10 Hz or 1 MHz.

(An interesting aside to this second case; if the frequency were 0.01 Hz, a period of 100 s, would this still be true? No; remember, from Chapter 3, the mechanism of heating and cooling of resistive components. In this case, the frequency is so low that we would do better to consider it as a slowly varying DC voltage. For a quarter of the period, 25 s, the resistor will have a voltage across it of 20 V or greater! This time is obviously long enough to destroy the resistor if it is not adequately rated. In our power calculations, we should budget for the pk amplitude of about 14 V. This is a very extreme example, and such slow moving signals are not often encountered. The statement in the above paragraph holds true for frequencies of a few Hz and above.)

Phase

We can describe a single sine wave completely by specifying its amplitude and frequency. When we are talking about two such signals the important question of phase arises.

Figure 4.2 shows the sine wave of Figure 4.1 again, labelled V_1, and a second nearly identical sine wave which starts its cycle at a later time t, labelled V_2. We say that there is a phase difference between V_1 and V_2.

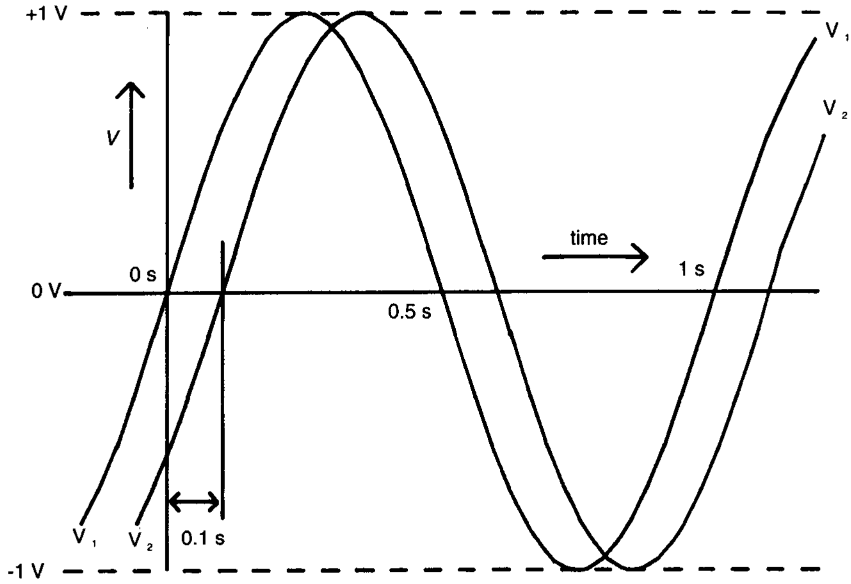

Figure 4.2 Illustration of phase

Phase is an angular quantity, and its units are degrees or radians. We use degrees in this book. There are two important points to bear in mind when talking about phase:

1. We only generally make phase comparisons between waveforms of the same frequency.
2. Phase, like voltage, is a relative quantity. It is meaningless to say that, for instance, 'the voltage has a phase angle of 30°' unless we specify that that 30° refers to some other waveform. A reference must be specified.

To calculate the phase difference between two waveforms, we use the following expression:

$$\phi = \frac{360t}{T} \tag{4.4a}$$

We can, of course, calculate t from ϕ and T:

$$t = \frac{T\phi}{360} \tag{4.4b}$$

where ϕ is the phase in degrees, t is the time difference in seconds and T is the period in seconds. For example, if t in Figure 3.2 is 100 ms, then $\phi = 36°$. V_2 starts 100 ms after V_1, so we can either say that V_2 lags V_1 by 36° or that V_1 leads V_2 by 36°. The two statements mean the same thing. We might, if we were being awkward, say that V_2 leads V_1 by (360–36)° or 324°. This statement means that V_2 starts its cycle 324°, or 900 ms, before V_1 – just as true if they are continuous, but not the easiest way to say it. Normally we specify phase using the smallest possible angle, which is always less than 180°. Sometimes calculations give us numbers larger than this, and we convert them to a more sensible form.

Waveforms which are 90° out of phase are said to be in quadrature, while ones which are 180° out of phase are said to be in antiphase. Putting a waveform in antiphase is 'inverting' it. Waveforms which have no phase difference are simply 'in phase'.

Calculations on AC quantities

We can do calculations on AC quantities of the same frequency to analyse the behaviour of a circuit at that frequency. Every quantity that we use will have two components; magnitude (amplitude) and phase.

Mathematical operations on waveforms of any phase are slightly tricky and require the use of something called 'phasor mathematics'. Ideally, a mathematical technique called 'complex algebra' is used which makes use of a notional quantity called j, equal to $\sqrt{(-1)}$ to denote a phase shift of 90°. This technique allows not only voltages and currents but also combinations of reactances, resistances and even amplification to be treated under one umbrella. The behaviour of circuits can then be predicted at a fixed frequency.
